Collected Algorithms from ACM

IN THREE VOLUMES

A collation of all ACM Algorithms, including Certifications, Remarks, and Translations from the Algorithms Department of *Communications of the ACM, 1960–1975*, from *ACM Transactions on Mathematical Software*, 1975 ff, and from *ACM Transactions on Programming Languages and Systems*, 1981 ff.

Introductory Information
Volume III. Algorithms 493ff.

1981

A Service of the Association for Computing Machinery, Inc.
1133 Avenue of the Americas
New York, New York 10036

Quarterly Updating Service Available by Annual Subscription

ACM Algorithms 493ff. are available by purchase in the form of listing, or card deck, or magnetic tape (9 track EBCDIC, 9 track ASCII, 7 track BCD), from ACM Algorithms Distribution Service, c/o International Mathematical & Statistical Libraries, Inc., Sixth Floor, GNB Building, 7500 Bellaire Boulevard, Houston, TX 77036.

RE: Supplement No. 80

Attached is the quarterly set of sheets for your loose-leaf volume, "Collected Algorithms from ACM." The sheets in this Supplement provide the material that appeared in the algorithms section of the December 1981 issue of TRANSACTIONS ON MATHEMATICAL SOFTWARE.

The sheets for the new algorithms 578, 579, and 580 should be added to the back of the volume in the following order:

578-P1-0(backed by 578-P2-0)	to	578-P3-0(backed by 578-P4-0)
579-P1-0(backed by 579-P2-0)	to	579-P5-0(backed by blank)
580-P1-0(backed by 580-P2-0)		

The sheets containing the CALGO 20-year Index should be inserted with front matter in the loose-leaf binder immediately following page xiv.

RE: Supplement No. 81

Attached is the quarterly set of sheets for your loose-leaf volume, "Collected Algorithms from ACM." The sheets in this Supplement provide the material that appeared in the Algorithms Section of the March 1982 issue of TRANSACTIONS ON MATHEMATICAL SOFTWARE.

The sheets for the new algorithm 581 should be added to the back of the volume in the following order:

581-P1-0(backed by 581-P2-0) to 581-P3-0(backed by 581-P4-0)

The sheets to update algorithms previously provided should be incorporated as follows:

DELETE	INSERT
334-P1-R1(backed by blank)	334-P1-R1(backed by 334-P2-0)

The updated version of the "ACM Algorithms Policy" should replace the one now in the frontmatter, pages ix-xi.

The 1981 Index by Subject to Algorithms should precede the Index by Subject to Algorithms, 1960-1980(pages xv-xxvi).

RE: Supplement No. 82

Attached is the quarterly set of sheets for your looseleaf volume, "Collected Algorithms from ACM." The sheets in this Supplement provide the material that appeared in the algorithms section of the June 1982 issue of TRANSACTIONS ON MATHEMATICAL SOFTWARE.

The sheets for the new algorithms 582, 583, and 584 should be added to the back of the volume in the following order:

582-P1-0(backed by 582-P2-0)	to	582-P3-0(backed by 582-P4-0)
583-P1-0(backed by 583-P2-0)	to	583-P11-0(backed by 583-P12-0)
584-P1-0(backed by 584-P2-0)	to	584-P7-0(backed by 584-P8-0)

The sheets to update algorithms previously provided should be incorporated in the looseleaf binders as follows:

DELETE	INSERT
506-P11-0(backed by blank)	506-P11-0(backed by 506-P12-0)
508-P9-0(backed by 508-P10-0)	508-P9-0(backed by 508-P10-R1)
509-P9-0(backed by 509-P10-0)	509-P9-0(backed by 509-P10-R1)

For those with casebound volumes, the editor suggests that you insert the algorithm updates in the volume where the algorithm appears.

RE: Supplement No. 84

Attached is the quarterly set of sheets for your looseleaf volume, "Collected Algorithms from ACM." The sheets in this Supplement provide the material that appeared in the Algorithms section of the December 1982 issue of TRANSACTIONS ON MATHEMATICAL SOFTWARE.

The sheets for the algorithms 588, 589, 590, and 591 should be added to the back of the volume in the following manner:

588-P1-0(backed by 588-P2-0)		
589-P1-0(backed by 589-P2-0)	to	589-P3-0(backed by 589-P4-0)
590-P1-0(backed by 590-P2-0)	to	590-P5-0(backed by 590-P6-0)
591-P1-0(backed by 591-P2-0)	to	591-P15-0(backed by 591-P16-0)

The sheets to update algorithms previously provided should be incorporated in the looseleaf binders as follows:

DELETE	INSERT
535-P17-0(backed by 535-P18-0)	535-P17-0(backed by 535-P18-R1)
539-31-0(backed by blank)	539-P31-R1(backed by 539-P32-0)
	539-P33-0(backed by blank)
580-P1-0(580-P2-0)	580-P1-0(backed by 580-P2-R1)

The "1982 Index by Subject to Algorithms" should be inserted in front of looseleaf binder with other indexes.

For those with casebound volumes, the editor suggests that you insert the algorithm updates in the volume where the algorithm appears.

Introductory Information

Introductory Information

Preface

The Algorithms department of *Communications of the ACM* (CACM) was established in February 1960, with J. H. Wegstein as editor, for the purpose of publishing algorithms, consisting of procedures and programs, in the Algol language. In 1975 the publication of ACM algorithms material was transferred to *ACM Transactions on Mathematical Software* (TOMS) and in 1981 *ACM Transactions on Programming Languages and Systems* (TOPLAS) published its first algorithm. A wide variety of algorithms have been published and many of them have been used heavily—either in original form or as translated into other languages. Recognizing the general acceptance of the algorithm material published in CACM, TOMS, and TOPLAS the Association for Computing Machinery (ACM) has collected and reprinted the algorithms to make them more readily accessible and more serviceable to a larger group of users.

The collection contains all algorithms published in the Algorithms departments of CACM, TOMS, and TOPLAS. Covering a great variety of subjects, these algorithms include many for standard computational tasks, such as evaluation of special functions, solution of systems of linear equations, estimation of definite integrals, and sorting of data. Most of them are written in Algol or ANS Fortran.

Both to conserve space and because of changing language usage, reference material on ALGOL and Fortran, [6], [7], [10]–[13], is no longer included as it was in earlier editions. Other expositions of ALGOL are given in [2], [3], [8], and [9]. A new Fortran standard was adopted by ANSI in 1978. The official ANSI document for the new Fortran standard [14] is not yet published, but a summary is given in [4].

A cumulative index to algorithms published since 1960 is provided. In addition to algorithms published in CACM, TOMS, and TOPLAS the index lists many which appeared elsewhere. The classification scheme is a modified form of the SHARE classification. The early indexes were prepared by G. E. Forsythe (Algorithms department editor in 1964) and J. M. Varah, and succeeding editors have annually issued updated versions.

Algorithms 1–220 were originally published as received—without any refereeing whatever. Many of these have since been certified and/or corrected by their authors or by other contributors. Beginning with Algorithm 221, in March 1964, all algorithms have been refereed independently. For many, Certifications have appeared, and modifications to some have been proposed in Remarks. In this volume, Certifications and Remarks for a given algorithm are collected with the algorithm.

Since 1964 an effort has been made to choose for publication those of the refereed algorithms that are interesting and of good quality and, at the same time, likely to be useful to others. Probably few of these algorithms would satisfy all the criteria for excellence proposed by G. E. Forsythe [5]. However, it is hoped that many will be useful and will help to disseminate good methods of solution for many problems. Some of the earlier algorithms which were not refereed are very good too, but those having Certifications and/or corrections (included in Remarks) are more likely to be valuable. It is hoped that users of those without Certifications or Remarks will contribute their experiences to TOMS or TOPLAS so that all may benefit from them. Algorithms 1–50 have been reprinted with revisions and corrections by Ageev, Alik, and Galis in the Soviet Union [1].

For general information, the present Algorithms Policy Statement of TOMS and TOPLAS is provided. The Dissemination Agreement is of particular importance: Submittal of an algorithm for publication in TOMS or TOPLAS implies that unrestricted use of the algorithm within a computer is permissible. General permission to copy the algorithm in fair use, but not for profit, is granted provided ACM's copyright notice is given and reference is made to this publication, its date of issue, and to the fact that copying is by permission of the Association for Computing Machinery.

As new Algorithms, Certifications, Remarks, and Translations appear in TOMS or TOPLAS, they are reissued quarterly to Collected Algorithms subscribers, in loose-leaf form, so that their collections may be kept up to date.

Beginning with Algorithm 493, algorithms are available in machine-readable form—tapes or cards—from ACM Algorithms Distribution Service, c/o IMSL, Sixth Floor, GNB Building, 7500 Bellaire Boulevard, Houston, TX 77063.

To facilitate the updating and to make this volume convenient to use, an understanding of the page numbering scheme for the algorithms is helpful. The page designation is in a three-part format: the left part is the

algorithm number; the middle part is the page number within the algorithm (the first page of each algorithm is P1); and the right part is the number of the revision of that page. All sheets in the original, or first, insertion of an algorithm have "0" for the right part. The first revision of a page will have a page number having the left and middle parts identical with those on the page to be replaced, but the right part will be "R1" instead of "0." The second revision of the same page would read R2, and so on. For example, 123-P2-R1 would mean the first revision of page 2 of Algorithm 123. Revised pages for an algorithm, or additional pages if required, are provided when Certifications or Remarks are added.

The Introduction that appeared in Collected Algorithms at its inception was written by John G. Herriot, department editor at that time. It was then revised by Fred T. Krogh, Algorithms Editor from 1976 to 1978. As present Algorithms Editor, I have prepared this revision to include current information.

ACM Algorithms Policy

BY FRED T. KROGH[1]

Matters of Content

A contribution should be in the form of an algorithm, comparison, certification, remark, or translation.

Algorithms

ACM Algorithms are published to make the fruits of software research readily available to as wide an audience as possible. An algorithm must either provide a capability not readily available or perform a task better in some way than has been done before. "Better" can mean anything from improved reliability or efficiency to more attractive packaging. In all cases, an algorithm must be of lasting value and must represent a substantial contribution in terms of the amount of work or the originality required for its creation.

In most cases the communication of new algorithmic ideas should be done either in a companion paper published in one of the ACM Transactions or in previously published work. The textual part of an algorithm submission should give a brief description of what the algorithm does and pertinent information on usage and maintenance. It should not duplicate information in another paper or in the algorithm listing. It is recognized that certain algorithms will be useful to readers of one of the ACM Transactions but deal with subjects not in the usual research domain of that journal. When appropriate, the Algorithms Editor will guide authors to other ACM journals for possible publication of such algorithms.

An ACM algorithm must be complete, portable, well documented, and well structured. The meaning of these terms is clarified below.

1. *Completeness:* With the exception of code used from a previously published ACM algorithm, a submission must include all of the code and test data necessary for the effective use and testing of the algorithm by a large segment of its intended audience. To assist those who use the algorithm, a small test driver should be provided that illustrates the use of the algorithm for a simple test problem. For testing purposes, one should provide in a single driver a sufficient variety of test cases to exercise all the main features of the code. All submitted code, including test drivers and preprocessors, is subject to the refereeing process. Code subject to more restricted use than specified in this policy may be used in a supporting role for an algorithm provided it is available from an established source for a nominal fee, and there is no nearly equivalent code available in the public domain.
2. *Portability:* It must be possible to move the code in machine readable form from one machine to another with only minor, well-documented changes. Programs written in a language having several popular dialects should use only language features common to those dialects. As initial evidence of portability, the author can either include evidence of successful execution on three different computers, i.e., computers with different basic instruction sets, or better, when available, can give the result of running the software through a verifier that checks the code for portability or conformance to a standard. All FORTRAN programs must satisfy one of the following criteria:

   (a) Conformance with the ANSI X3.9-1978 FORTRAN 77 [1].

[1] Policy revised March 1979, by Webb Miller; January 1982, by R. J. Hanson.

(b) Pass the set of tests performed by the PFORT verifier [4].[2]

The Algorithms Editor will attempt to help authors who have trouble meeting either of these requirements. The PFORT verifier can be obtained at no cost from the Editor.

Machine-dependent modules, including assembly language, may be used provided:

(a) They are clearly specified, limited in function, small, and either necessary or a substantial improvement over equivalent portable procedures.
(b) Where possible, portable versions are also submitted to facilitate installation and testing, and to confirm the reader's understanding of the specifications. If portable versions are not provided, then tested versions for at least three different computers must be provided.
(c) A portable test program is provided which exhaustively tests each machine-dependent module of the package.

3. *Documentation:* Each module of the code, including test drivers, must be adequately commented. Comments should include the purpose of the module, definitions of all arguments passed through the calling sequence, through global variable declarations, or obtained via input, and comments setting off and explaining major parts of the code. Comments defining machine dependencies should be gathered together and clearly flagged. Standard names and definitions for machine constants are normally to be used [2]. If these constants are used widely in the submitted algorithms, then they may be accessed through a procedure [3]. Other constants clearly identified in comments (e.g., BIG=SQRT (SOVFLO)) and machine dependencies not in the standard [3], may be introduced. A comment can simply point to the place where full comments are given in cases where large comment blocks would otherwise be repeated. An alphabetical list of internal variables together with how they are used is highly recommended. (Identify temporary variables as temporary.) At present, it is not possible to edit comments to provide a reference to the place in the journal where the algorithm appears. Machine-readable documentation giving more detailed information about the package than can be published is encouraged.
4. *Structure:* Code should be organized so that it is easy to use and modify, yet flexible enough to be useful for most problems in the problem area covered. Indentation should be used to identify loops, compound statements and blocks, and continuation of a statement onto another line. If integers are used for statement labels, they must be strictly increasing and should be far enough apart to allow for future modifications. If the space required by an array is highly problem dependent, then that array should have a variable dimension. (NOTE: FORTRAN requires common blocks with the same name to have the same length.)

Algorithmic ideas may be published as integral parts of regular papers without meeting these criteria. This provision may not, however, be used as a subterfuge to circumvent meeting the criteria for ACM algorithms.

Except for extremely long algorithms, all contributions will appear in their entirety in ACM's looseleaf algorithms periodical *Collected Algorithms from ACM* (CALGO). Algorithms are available in machine-readable form through the ACM Algorithms Distribution Service.

---

[2] The PFORT verifier checks a FORTRAN program for conformance with a portable subset of the former ANSI X3.9-1966 FORTRAN standard.

Comparisons

A comparison is a report on the relative merits and features of highly similar software packages for a specific subject area. This study normally includes reporting and interpreting various cogent observed facts about the packages. These facts are typically based on solving a common set of test problems. The drivers, test problems, and data used in the study are to be sent to the Algorithms Editor, at the time of submission, as an algorithm. This body of information will be used in the refereeing process and will be available as an ACM Algorithm.

Certifications

A certification is a report on a previously published algorithm. It can be a careful study of performance characteristics, a verification of correctness, or a report on extensive testing.

Remarks

A remark is a brief report on a previously published algorithm. It is usually concerned with corrections or modifications.

Translations

A translation may either provide machine-dependent modules for a machine or operating system not covered by an ACM algorithm, or a translation of the algorithm into a different high-level language. A translation will only be considered if it is a translation of an algorithm that still represents the current state of the art and it satisfies all of the criteria of a regular algorithm submission.

Submission Formalities

1. Five copies of all textual material should be sent to the Algorithms Editor. This material must be typewritten and double spaced. Companion papers to algorithms submitted to one of the ACM Transactions should be sent with the algorithm to the Algorithms Editor, as they will be refereed along with the algorithm. The purpose of those parts of the code submission that are included for testing purposes or serve only a supporting role should be clearly identified.
2. Processing of an algorithm will not proceed until it is verified that machine-readable copy of the algorithm has arrived in good form. Before sending machine-readable copy, contact the Algorithms Editor and explain the computer(s) available to you, the size of your submission, and in what form you would like to send the material. If an algorithm requires the use of code subject to restricted use, the use of this code should be cleared first with the Algorithms Editor.
3. Evidence of portability must be included with an algorithm submission.

Dissemination Agreement

Submittal of an algorithm for publication in one of the *ACM Transactions* implies that unrestricted use of the algorithm within a computer is permissible. General permission to copy and distribute the algorithm without fee is granted provided that the copies are not made or distributed for direct commercial advantage. The ACM copyright notice and the title of the publication and its date appear, and notice is given that copying is by permission of the Association for Computing Machinery. To copy otherwise, or to republish, requires a fee and/or specific permission.

Copyright Agreement

Authors of copyrightable algorithms (or their employers) are required to transfer the copyright to ACM upon acceptance of the algorithm for publication, in accordance with ACM policy to own copyright on ACM published material. The Association grants to authors the right to reuse their material and seeks the permission of authors before approving republication.

Software Package Policy

The ACM Algorithm Distribution Service makes it possible to remove the length limitation on algorithms published in TOMS and TOPLAS and allows them to publish and disseminate large programs.

Technically, a collection of algorithms is just another algorithm, but practically ACM editors will distinguish between "ordinary" algorithms and larger entities called polyalgorithms, software packages, systemized collections, etc. This policy statement is an extension of the algorithms policy of TOMS and TOPLAS which describes those software packages that these Transactions are interested in publishing and gives the specific requirements expected for such packages.

General Criteria and Procedures

Usefulness is an important criterion for the acceptance of any ACM algorithm; it is an essential criterion for ACM software packages. An acceptable ACM package must address itself to a standard and widely occurring problem set. Furthermore, it must be designed to ease the user's task as much as possible consistent with the nature of the problem set. The human engineering aspects of the package will be weighted heavily in its evaluation by the editors.

All ACM algorithms, but especially packages, are expected to be of high quality in all respects. ACM packages must use good algorithms in their components, they must use good programming (including style, structure, and adherence to standards), they must be well documented (both for use and modification), and they must be thoroughly tested and evaluated.

Transportability will also be weighted heavily in that it directly affects usefulness. A wonderful package will not be accepted if it requires a specific environment of machine, operating system and I/O devices that is available only at a very few locations. However, complete transportability will not be insisted upon, and in each case a judgment will be made by the editors on whether a reasonable and useful level of transportability has been achieved. It is widely realized that, in general, high level language algorithms cannot yet be constructed to give top performance in a variety of environments.

ACM publication normally consists of two parts: a description of the package and a critical review of it. Authors of a package will submit material for the first part and the editors will seek referee/reviewers for the second part. We note that a multitude of widely distributed software packages already exist, some of excellent quality. We consider such packages to have already been published. Other packages may become widely distributed in the future. Authors independent of the developers of these packages are invited to submit critical reviews of them. An author of a new package is expected to demonstrate the superiority of the new package over any existing packages.

Specific Requirements

The following guidelines for authors give information about the expected contents of papers to be printed in TOMS or TOPLAS, the nature of the packages to be distributed, and the material to be submitted for consideration by the editors.

(1) *The Descriptive Paper.* The paper should contain a clear statement of goals, intended users, expected environment, and the problem domain of the package. Then there should be a discussion of the main components and steps in the development of the package. This includes mathematical descriptions, general algorithm structure, testing and evaluation, documentation, programming, and portability. Interesting design questions should be discussed here. It is not expected that a complete mathematical derivation be given; rather one should give pertinent references. Descriptions of new techniques belong in an independent paper. The aim here is to give the reader a general and reasonably complete description without burdening him with the full details of documentation and techniques. Full details are available from the references and the ACM Algorithm Distribution Service. The paper should give some basic statistics about the package, e.g. length, examples of performance (memory usage, execution times), I/O requirements.

This policy was originally written for TOMS in 1975 by Editor-in-Chief John R. Rice, with Richard M. Heiberger and Charles L. Lawson, who made substantial contributions to the formulation of the policy, and with Edward Battiste, David C. Hoaglin, and Paul Velleman, who made valuable suggestions. This policy now applies also to TOPLAS, in which the first algorithm was published in 1981.

(2) *The Package.* The ACM Algorithm Distribution Service makes three items available: the programs, user documentation, and internal documentation. All documentation is incorporated into the program as machine-readable comments. A package must be of acceptable quality in all of the following aspects: user documentation; internal documentation; ease of use; programming style; consistency of style, structure, and notation; basic algorithmic and mathematical techniques; adherence to language standards; ease of modification and transportation; performance characteristics; overall structure and organization.

(3) *Material To Be Submitted.* The material for an ACM software package should be submitted to the Algorithms Editor or to the Editor-in-Chief of TOMS or of TOPLAS and should consist of the following items:

—machine readable form of package
—descriptive paper (three copies)
—documentation (user and internal—probably part of first item)
—drivers for examples and testing
—test and evaluation results (listings from actual runs, summaries, etc.).

The drivers submitted should exercise all the modules in the package. The test and evaluation results must support the claim of superiority over existing packages; a separate discussion of this aspect will probably be required.

It must be emphasized that finding referees for software packages is likely to be difficult, and that if competent referees cannot be found it will be necessary to reject the manuscript. Authors will improve their chances of finding willing referees if they submit their material in a neat and well organized form. All computer tests submitted should be carefully annotated so that the referee can easily determine the nature of the test, the test data used, the expected results, and the results produced by the package.

(4) *The Critical Review.* This paper will analyze the strengths and weaknesses of the package in an objective manner. It may include extensive discussions of only a few aspects of the package if they are of sufficient interest (particularly for already existing packages). Critical reviews of widely disseminated packages not published in either TOMS or TOPLAS must contain basic information about their distribution, listings, and maintenance support.

Editorial Comment

It is clear that the preparation of a publishable software package is a task well beyond the usual technical publication. The critical review part of publication is a way in which referees can obtain suitable recognition for the substantial effort involved in a thorough evaluation of a package.

1982 Index by Subject to Algorithms

Algorithms published elsewhere are included here. A cumulative index to algorithms published in *Communications*, the *ACM Transactions on Mathematical Software*, and the *ACM Transactions on Programming Languages and Systems* from 1960 through 1980 may be consulted in "Collected Algorithms from ACM," which is a looseleaf collection of all algorithms, each with certifications and remarks, if any, appended. The 1981 index appears in the December 1981 issue of *Communications*.

Laurie, D.P. Algorithm 584: CUBTRI—Automatic cubature over a triangle. (Fortran) *ACM Trans. Math. Softw. 8*, 2 (June 1982), 210–218.

Robinson, I., and deDoncker, E. Algorithm 45: Automatic computation of improper integrals over a bounded or unbounded planar region. (Fortran) *Computing 27*, 3 (1981), 253–284.

INTEGRAL EQUATIONS [D5]

Piessens, R. Algorithm 113: Inversion of the Laplace transform (ALGOL) *Computer Journal 25*, 2 (May 1982), 278–282.

INTERPOLATION [E1]

Brezinski, C. Algorithm 585: A subroutine for the general interpolation and extrapolation problems. (Fortran) *ACM Trans. Math. Softw. 8*, 3 (Sept. 1982), 290–301.

Hanson, R.J. Remark on Algorithm 507: Procedures for quintic natural spline interpolation. *ACM Trans. Math. Softw. 8*, 3 (Sept. 1982), 334.

MATRIX OPERATIONS [F1]

Chan, T.F. Algorithm 581: An improved algorithm for computing the singular value decomposition. (Fortran) *ACM Trans. Math. Softw. 8*, 1 (March 1982), 84–88.

Lewis, J.G. Algorithm 582: The Gibbs-Poole-Stockmeyer and Gibbs-King algorithms for reordering sparse matrices. (Fortran) *ACM Trans. Math. Softw. 8*, 2 (June 1982), 190–194.

Mönch, W. Algorithm 46: Iterative refinement of approximations to a generalized inverse of a matrix. (ALGOL) *Computer 28*, 1 (1982), 79–87.

Dodson, D.S., and Grimes, R.G. Remark on Algorithm 539: Basic linear algebra subprograms for Fortran Usage. *ACM Trans. Math. Softw. 8*, 4 (Dec. 1982), 403–404.

Lewis, J. G. Remark on Algorithms 508 and 509: Matrix bandwidth and profile reduction; A hybrid profile reduction algorithm. *ACM Trans. Math Softw. 8*, 2 (June 1982), 221.

EIGENVALUES AND EIGENVECTORS OF MATRICES [F2]

Dongarra, J.J. Algorithm 589: SICEDR: A Fortran subroutine for improving the accuracy of computed matrix eigenvalues. *ACM Trans. Math. Softw. 8*, 4 (Dec. 1982), 371–375.

van Dooren, P. Algorithm 590: DSUBSP and EXCHQZ: Fortran subroutines for computing deflating subspaces with specified spectrum. *ACM Trans. Math. Softw. 8*, 4 (Dec. 1982), 376–382.

Garbow, B.S. Remark on Algorithm 535: The QZ algorithm to solve the generalized eigenvalue problem. *ACM Trans. Math. Softw. 8*, 4 (Dec. 1982), 402.

Flamm, D.S., and Walker, R.A. Remark on Algorithm 506. HQR3 and EXCHNG: Fortran subroutines for calculating and ordering the eigenvalues of a real upper Hessenberg matrix. *ACM Trans. Math. Softw. 8*, 2 (June 1982), 219–220.

SIMULTANEOUS LINEAR EQUATIONS [F4]

Paige, C.C., and Saunders, M.A. Algorithm 583: LSQR—Sparse linear equations and least squares problems. (Fortran) *ACM Trans. Math. Softw. 8*, 2 (June 1982), 195–209.

Kincaid, D.R., Respess, J.R., and Young, D.M. Algorithm 586: ITPACK 2C—A Fortran package for solving large sparse linear systems by adaptive accelerated iterative methods. (Fortran) *ACM Trans. Math. Softw. 8*, 3 (Sept. 1982), 302–322.

Hanson, R.J., and Haskell, K.H. Algorithm 587: Two algorithms for the linearly constrained least squares problem. (Fortran) *ACM Trans. Math. Softw. 8*, 3 (Sept. 1982), 323–333.

ORTHOGONALIZATION [F5]

Buckley, A. Remark on Algorithm 580: GRUP: A set of Fortran routines for updating QR factorizations. *ACM Trans. Math. Softw. 8*, 4 (Dec. 1982), 405.

SIMPLE CALCULATIONS ON STATISTICAL DATA [G1]

Hemmerle, W.J. Algorithm 591: A comprehensive, matrix-free algorithm for analysis of variance. *ACM Trans. Math. Softw. 8*, 4 (Dec. 1982), 403–404.

Frome, E.L., Algorithm 171: Fischer's exact variance test for the Poisson distributions. (Fortran) *Applied Statistics 31*, 1 (1982), 67–71.

MacKenzie, G., and O'Flaherty, M. Algorithm 173: Direct design matrix generation for balanced factorial experiments. (Fortran) *Applied Statistics 31*, 1 (1982), 74–80.

Schwertman, N.C. Algorithm 174: Multivariate multisample non-parametric tests. (Fortran) *Applied Statistics 31*, 1 (1982), 80–85.

Laurie, D.P. Algorithm 175: Cramer-Wold factorization. (Fortran) *Applied Statistics 31*, 1 (1982), 86–93.

Silverman, B.W. Algorithm 176: Kernel density estimation using the Fast Fourier Transform. (Fortran) *Applied Statistics 31*, 1 (1982), 93–99.

RANDON NUMBER GENERATORS [G5]

Tracht, A.E. Remark on Algorithm 334: Normal random deviates. *ACM Trans. Math. Softw. 8*, 1 (March 1982), 89.

OPERATIONS RESEARCH, GRAPH STRUCTURES [H]

Carpanto, G., and Toth, P. Algorithm 44: Algorithm for the solution of the bottleneck assignment problem. (Fortran) *Computing 27*, 2 (1981), 179–187.

Fayard, D., and Plateau, G. Algorithm 47: An algorithm for the solution of 0-1 knapsack problem. (Fortran) *Computing 28*, 3 (1982), 269–287.

APPROXIMATION OF SPECIAL FUNCTIONS [S17]

Anderson, W.L. Algorithm 588: Fast Hankel transforms using related and lagged convolutions. *ACM Trans. Math. Softw. 8*, 4 (Dec. 1982), 369–370.

ALL OTHERS [Z]

O'Flaherty, M., and MacKenzie, G. Algorithm 172: Direct simulation of nested Fortran DO-loops. (Fortran) *Applied Statistics 31*, 1 (1982), 71–74.

Frost, R.A. Algorithm 112: Dumping the index of a dynamic hash table. (ALGOL 68-R) *Computer Journal 24*, 4 (Nov. 1981), 383–384.

1981
Index by Subject to Algorithms

Algorithms published elsewhere are included. A cumulative index to algorithms published in *Communications*, the ACM *Transactions on Mathematical Software*, and the *ACM Transactions on Programming Languages and Systems* from 1960 through 1980 may be consulted in "Collected Algorithms from ACM," which is a looseleaf collection of all algorithms, each with certifications and remarks, if any, appended.

REAL ARITHMETIC; NUMBER THEORY [A1].
OPERATIONS ON POLYNOMIALS AND POWER SERIES [C1]

Lozier, D.W., and Smith, J.M. Algorithm 567: Extended-range arithmetic and normalized Legendre polynomials. (Fortran) *ACM Trans. Math. Softw. 7*, 1 (March 1981), 141–146.

ZEROS OF ONE OR MORE NONLINEAR EQUATIONS [C5]

More, J.J., Garbow, B.S., and Hillstrom, K.E. Algorithm 566: Fortran subroutines for testing unconstrained optimization software. (Fortran) *ACM Trans. Math. Softw. 7*, 1 (March 1981), 136–140.

Incerti, S., Zirilli, F., and Parisi, V. Algorithm 111: A Fortran subroutine for solving systems of nonlinear, simultaneous equations. (Fortran) *Computer Journal 24*, (1981), 87–91.

ORDINARY DIFFERENTIAL EQUATIONS [D2]

Ascher, U., Christiansen, J., and Russell, R.D. Algorithm 569: COLSYS—Collocation software for boundary-value ODE's. (Fortran) *ACM Trans. Math. Softw. 7*, 2 (June 1981), 223–229.

PARTIAL DIFFERENTIAL EQUATIONS [D3]

Melgaard, D.K., and Sincovec, R.F. Algorithm 565: PDETWO/PSETM/GEARB—Solution of systems of two dimensional nonlinear partial differential equations. (Fortran) *ACM Trans. Math. Softw. 7*, 1 (March 1981), 126–135.

O'Leary, D.P., and Widlund, O. Algorithm 572: Solution of the Helmholtz equation for the Dirichlet problem on general bounded three-dimensional regions. (Fortran) *ACM Trans. Math. Softw. 7*, 2 (June 1981), 239–246.

DIFFERENTIATION [D4]

Fornberg, B. Algorithm 579: CPSC: complex power series coefficients. (Fortran) *ACM Trans. Math. Softw. 7*, 4 (Dec. 1981), 542–547.

INTERPOLATION [E1]
CURVE AND SURFACE FITTING [E2]

McAllister, D.F., and Roulier, J.A. Algorithm 574: Shape-preserving osculatory quadratic splines. (Fortran) *ACM Trans. Math. Softw. 7*, 3 (Sept. 1981), 384–386.

MINIMIZING OR MAXIMIZING A FUNCTION [E4]

More, J.J., Garbow, B.S., and Hillstrom, K.E. Algorithm 566: Fortran subroutines for testing unconstrained optimization software. (Fortran) *ACM Trans. Math. Softw. 7*, 1 (March 1981), 136–140.

Dennis, J.E., Jr., Gay, D.M., and Welsch, R.E. Algorithm 573: NL2SOL—An adaptive nonlinear least-squares algorithm. (Fortran) *ACM Trans. Math. Softw. 7*, 3 (Sept. 1981), 369–383.

MATRIX OPERATIONS, INCLUDING INVERSION [F1]

Duff, I.S. Algorithm 575: Permutations for a zero-free diagonal. (Fortran) *ACM Trans. Math. Softw. 7*, 3 (Sept. 1981), 387–390.

EIGENVALUES AND EIGENVECTORS OF MATRICES [F2]

Stewart, W.J., and Jennings, A. Algorithm 570: LOPSI—A simultaneous iteration algorithm for real matrices. (Fortran) *ACM Trans. Math. Softw. 7*, 2 (June 1981), 230–232.

SIMULTANEOUS LINEAR EQUATIONS [F4]

Barrodale, I., and Stuart, G.F. Algorithm 576: A Fortran program for solving Ax = b. (Fortran) *ACM Trans. Math. Softw. 7*, 3 (Sept. 1981), 391–397.

DuCroz, J.J., Nugent, S.M., Reid, J.K., and Taylor, D.B. Algorithm 578: Solution of real linear equations in a paged virtual store. (Fortran) *ACM Trans. Math. Softw. 7*, 4 (Dec. 1981), 537–541.

ORTHOGONALIZATION [F5]

Buckley, A. Algorithm 580: QRUP; a set of Fortran routines for updating QR factorizations. (Fortran) *ACM Trans. Math. Softw. 7*, 4 (Dec. 1981), 548–549.

SIMPLE CALCULATIONS ON STATISTICAL DATA [G1]

Gardner, G., Harvey, A.C., and Phillips, G.D.A. Algorithm AS 154: An algorithm for exact maximum likelihood estimation of autoregressive-moving average models by means of Kalman filtering. (Fortran) *Applied Statistics 29* (1980), 311–322.

Davis, R. Algorithm AS 155: The distribution of a linear combination of x^2 random variables. (Algol) *Applied Statistics 29* (1980), 323–333.

Jones, B. Algorithm AS 156: Combining two component designs to form a row-and-column design. (Fortran) *Applied Statistics 29* (1980), 334–337.

Grafton, R. Algorithm AS 157: The runs-up and runs-down tests. (Fortran) *Applied Statistics 30* (1981), 81–85.

Cran, G. Algorithm AS 158: Calculation of the probabilities {P(I,k)} for the simply ordered alternative. (Fortran) *Applied Statistics 30* (1981), 85–91.

Patefield, W. Algorithm AS 159. An efficient method of generating random $R \times C$ tables with given row and column totals. (Fortran) *Applied Statistics 30* (1981), 91–97.

Lusbader, E., and Stodola, R. Algorithm AS 160: Partial and marginal association in contingency tables. (Fortran) *Applied Statistics 30* (1981), 97–105.

APPROXIMATION OF SPECIAL FUNCTIONS [S]

Hill, G.W. Algorithm 571: Statistics for von Mises' and Fischer's distributions of directions—$I_1(x)/I_0(x)$, $I_{1.5}(x)/I_{0.5}(x)$, and their inverses. (Fortran) *ACM Trans. Math. Softw. 7*, 2 (June 1981), 233–238.

Carlson, B.C., and Notis, E.M. Algorithm 577: Algorithms for incomplete elliptic integrals. (Fortran) *ACM Trans. Math. Softw. 7*, 3 (Sept. 1981), 398–403.

Hill, G.W. Remark on Algorithm 395: Student's *t*-distribution. *ACM Trans. Math. Softw. 7*, 2 (June 1981), 247–249.

Hill, G.W. Remark on Algorithm 396: Student's *t*-quantiles. *ACM Trans. Math. Softw. 7*, 2 (June 1981), 250–251.

Razaz, M., and Schonfelder, J.L. Remark on Algorithm 498: Airy functions using Chebyshev series approximations. *ACM Trans. Math. Softw. 7*, 3 (Sept. 1981), 404–405.

ALL OTHERS [Z]

Hanson, D.R. Algorithm 568: PDS—A portable directory system. (Ratfor and Fortran) *ACM Trans. Program. Lang. Syst. 3*, 2 (April 1981), 162–167.

Index By Subject To Algorithms, 1960–1980

Algorithms are grouped according to the classification system below, which is a modification of the SHARE classification system. Algorithms published elsewhere are included; see list of abbreviations for other sources.

Each entry gives the key to the classification system categories (A1, B1, . . .); the number of the algorithm if it exists; abbreviated title with language designator (A for Algol, F for Fortran, etc.—these appear on the more recent algorithms); source designator, volume, year, page (in parenthesis).

ALGORITHM 493
Zeros of a Real Polynomial [C2]

M.A. JENKINS

Queen's University

Key Words and Phrases: roots, zeros of a polynomial
CR Categories: 5.15
Language: Fortran

DESCRIPTION

The subroutine RPOLY is a Fortran program to find all the zeros of a real polynomial. The parameters are:

OP	double precision vector of coefficients in order of decreasing powers of the variable
DEGREE	integer degree of the polynomial
ZEROR, ZEROI	double precision vectors of real and imaginary parts of the zeros found by the algorithm
FAIL	logical parameter which is true only if the leading coefficient is zero or if RPOLY has found fewer than degree zeros; in the latter case the degree is reset to the number of zeros found.

The routine as written solves polynomials of degree up to 100; however, this can be modified by systematic changing of the declarations in the routines.

The program is based on the three-stage algorithm described in Jenkins and Traub [1]. The algorithm generates a sequence of polynomials of degree one less than the degree of the given polynomial from which an approximation to a zero or a quadratic factor can be extracted. The first stage is linearly convergent and involves no shift of origin. It is used primarily to bias the decision making process in the second stage in favor of the zeros of small magnitude. The second stage is also linearly convergent and involves a double shift to a complex point and its conjugate. The shift point is chosen arbitrarily on a circle whose radius is less than the magnitude of all the zeros. In most cases, either the shift is closest to a real zero, or the pair of shift points are equidistant and closest to a pair of zeros. In the former case the second stage yields an approximation to the real zero and in the latter case it yields an approximation to the real quadratic factor. The third stage involves one of two variable-shift iterations, where the latest approximation(s) is used as the shift point(s) for the generation of the next polynomial. The choice of iteration is based on which case is observed in stage two. The convergence is superquadratic and usually requires only a few steps. The decision processes are made in a fail-safe manner. If the third stage is entered prematurely or the incorrect iteration is chosen, the second stage is resumed. If no convergence is observed in the second stage after a fixed number of steps, a new shift is chosen and the second stage is restarted with a higher fixed limit. The third-stage iterations are terminated when a stopping

criterion based on roundoff error analysis has been satisfied. The real zero or quadratic factor is removed by polynomial deflation and the algorithm is repeated on the reduced polynomial.

The first statements of RPOLY set the following four constants which describe the floating-point arithmetic of the computer being used:

ETA	maximum relative representation error, which can be described as the smallest positive floating-point number such that 1 + ETA > 1 in floating-point arithmetic
INFIN	large floating-point number near the top of the range
SMALNO	small positive floating-point number near zero
BASE	exponent base for the floating-point number system.

The program is written in a portable subset of standard Fortran. It has been successfully used on the Burroughs B6700 and the IBM 360/50.

The program has been tested on a large number of polynomials, some chosen to test weaknesses common to zerofinding routines, others randomly generated by a number of techniques.

ALGORITHM 494
PDEONE, Solutions of Systems of Partial Differential Equations [D3]

RICHARD F. SINCOVEC

Kansas State University

and

NIEL K. MADSEN

Lawrence Livermore Laboratory

Key Words and Phrases: partial differential equations, method of lines, ordinary differential equations
CR Categories: 5.17
Language: Fortran

DESCRIPTION

The description of this algorithm, test results, and references are contained in the authors' paper, "Software for Nonlinear Partial Differential Equations," *ACM Trans. Math. Software 1*, 3 (Sept. 1975), 232–260.

ALGORITHM

```
      SUBROUTINE PDEONE(T, U, UDOT, NPDE, NPTS)                          PDE   10
      DIMENSION U(NPDE,NPTS), UDOT(NPDE,NPTS)                            PDE   20
C PDEONE IS AN INTERFACE SUBROUTINE WHICH USES CENTERED DIF-             PDE   30
C FERENCE APPROXIMATIONS TO CONVERT ONE-DIMENSIONAL SYSTEMS              PDE   40
C OF PARTIAL DIFFERENTIAL EQUATIONS INTO A SYSTEM OF ORDINARY            PDE   50
C DIFFERENTIAL EQUATIONS, UDOT = F(T,X,U).  THIS ROUTINE IS              PDE   60
C INTENDED TO BE USED WITH A ROBUST ODE INTEGRATOR.                      PDE   70
C INPUT..                                                                PDE   80
C  NPDE = NUMBER OF PARTIAL DIFFERENTIAL EQUATIONS.                      PDE   90
C  NPTS = NUMBER OF SPATIAL GRID POINTS.                                 PDE  100
C     T = CURRENT VALUE OF TIME.                                         PDE  110
C     U = AN NPDE BY NPTS ARRAY CONTAINING THE COMPUTED                  PDE  120
C         SOLUTION AT TIME T.                                            PDE  130
C OUTPUT..                                                               PDE  140
C  UDOT = AN NPDE BY NPTS ARRAY CONTAINING THE RIGHT HAND                PDE  150
C         SIDE OF THE RESULTING SYSTEM OF ODE*S, F(T,X,U),               PDE  160
C         OBTAINED BY DISCRETIZING THE GIVEN PDE*S.                      PDE  170
C THE USER MUST INSERT A DIMENSION STATEMENT OF THE FOLLOW-              PDE  180
C ING FORM..                                                             PDE  190
C     DIMENSION DVAL(**,**,2),UX(**),UAVG(**),ALPHA(**),                 PDE  200
C    *          BETA(**),GAMMA(**)                                       PDE  210
C THE SYMBOLS ** DENOTE THE ACTUAL NUMERICAL VALUE OF NPDE               PDE  220
C FOR THE PROBLEM BEING SOLVED.                                          PDE  230
C COMMON BLOCK MESH CONTAINS THE USER SPECIFIED SPATIAL                  PDE  240
C GRID POINTS.                                                           PDE  250
C COMMON BLOCK COORD CONTAINS 0,1, OR 2 DEPENDING ON WHETHER             PDE  260
C THE PROBLEM IS IN CARTESIAN, CYLINDRICAL, OR SPHERICAL                 PDE  270
```

ALGORITHM 495
Solution of an Overdetermined System of Linear Equations in the Chebyshev Norm [F4]

I. BARRODALE

University of Victoria, Canada

and

C. PHILLIPS

University of Liverpool, England

Key Words and Phrases: Chebyshev solution, overdetermined system, linear programming, simplex method
CR Categories: 3.15
Language: Fortran

DESCRIPTION

The algorithm calculates a Chebyshev (or l_∞) solution to an $m \times n$ overdetermined system of linear equations $Ax = b$, i.e. given equations

$$\sum_{j=1}^{n} a_{i,j} x_j = b_i , \qquad i = 1, 2, \ldots, \mathrm{m},\ m \geq n,$$

the subroutine determines a vector $x^* = [x_1^*, x_2^*, \ldots, x_n^*]^T$ which minimizes the maximum absolute value of the residuals

$$e(x) = || b - Ax ||_\infty = \max_{1 \leq i \leq m} \left| b_i - \sum_{j=1}^{n} a_{i,j} x_j \right| . \tag{1}$$

The algorithm can be used to solve the linear Chebyshev data fitting problem. Suppose that data consisting of m points (z_i, y_i) are to be approximated by a linear approximating function $\alpha_1\phi_1(z) + \alpha_2\phi_2(z) + \cdots + \alpha_n\phi_n(z)$ in the Chebyshev norm. This is equivalent to finding a Chebyshev solution to the system of linear equations

$$\sum_{j=1}^{n} \phi_j(z_i)\alpha_j = y_i , \qquad i = 1, 2, \ldots, m.$$

If the y_i values contain only small inherent errors, a Chebyshev approximation may be preferred to a least-squares or least-first-power approximation.

Received 3 June 1974 and 28 January 1975.

Authors' addresses: I. Barrodale, Department of Mathematics, University of Victoria, Victoria, B.C., Canada; C. Phillips, Department of Computational and Statistical Science, University of Liverpool, Liverpool, England.

The algorithm is a modification of the simplex method of linear programming applied to the *dual* formulation of the Chebyshev problem. It does not require that the $m \times n$ matrix of coefficients $A = \{a_{i,j}\}$ satisfy the Haar condition, nor does it require that it be of full rank. Computational experience with this and other algorithms indicates that it is efficient in both time and storage requirements. An approximate solution is determined during the first $k + 1$ iterations, where k denotes the rank of the matrix A, and in the subsequent iterations this solution is refined until either (i) a Chebyshev solution x^* is obtained which minimizes $e(x)$, or (ii) an approximate solution $\hat{x}$ is found for which

$$(e(\hat{x}) - e(x^*))/e(x^*) < RELERR \tag{2}$$

where *RELERR* is a real variable specified by the user (see below).

The parameters M and N represent the number of equations and number of unknowns, respectively. *MDIM* and *NDIM* should be set to at least $M + 1$ and $N + 3$, respectively. The simplex iterations are carried out in the two-dimensional real array A of size (*NDIM*, *MDIM*). Initially, the *transpose* of the matrix A must be stored in the first N rows and M columns of A; this arrangement allows the code to correspond closely to the formal description of the algorithm [1]. The right-hand-side vector b must be stored in the array B. These initial coefficients assigned to A and B are subsequently destroyed. *TOL* is a real variable which should be set to a small positive value; e.g. $TOL = 10^{-d+1}$ where d represents the number of decimal digits of accuracy available. (On an IBM 370 we usually set *TOL* equal to 10^{-6} when using single precision arithmetic and equal to 10^{-15} when using double precision arithmetic.) Essentially, *the subroutine cannot distinguish between zero and any quantity whose magnitude does not exceed TOL.* In particular, it will not pivot on any number whose magnitude does not exceed *TOL.* (Consequently, the subroutine may terminate prematurely if the system of equations is poorly scaled.) The parameter *RELERR* should be set to 0.0 if a Chebyshev solution x^* is required. If *RELERR* is set to a positive value, the subroutine determines an approximate solution $\hat{x}$ satisfying inequality (2); the usual effect of this option (say, with *RELERR* set to 0.1) is a saving in the number of simplex iterations required.

On exit, if *RELERR* was set to 0.0, the array X contains a Chebyshev solution x^*. However, if the initial value of *RELERR* was positive, then X contains an approximate solution $\hat{x}$. The subroutine assigns a new value to *RELERR*, smaller than its initial value, and $\hat{x}$ satisfies (2) for this new value of *RELERR*. The rank of the $m \times n$ matrix A is determined during the first k iterations and assigned to the integer *RANK*. (The rank estimate *RANK* is dependent upon *TOL*; decreasing the value of *TOL* may increase the value of *RANK*.) The residuals

$$b_i - \sum_{j=1}^{n} a_{i,j} x_j, \qquad i = 1, 2, \ldots, m \tag{3}$$

are assigned in order to the array B. *RESMAX* supplies the absolute value of the largest residual; this is the minimum value of (1) if *RELERR* was set to 0.0. If *RELERR* was set to a positive value, then *RESMAX* gives the value of (1) corresponding to the approximate solution $\hat{x}$. (The subroutine, which overwrites the original data A and b, supplies the residuals automatically. However, these automatic residuals may contain few significant figures, especially when *RESMAX* is within one or two orders of magnitude of *TOL.* Indeed, if $RESMAX \leq TOL$ the automatic residuals may all be set to zero by the subroutine. *It is therefore often advisable to obtain the residuals directly from* (3) *as an additional calculation.*) *ITER* records the number of iterations performed by the simplex method. Finally, *OCODE* is an exit code with the value 1 if a solution is calculated successfully, and 2 if the calculations are terminated prematurely. This latter condition occurs only when a pivot is encountered whose magnitude does not exceed *TOL*, and in this event all output information pertains to the last completed simplex iteration. Since a

Chebyshev solution is not necessarily unique, the subroutine attempts to determine if other optimal solutions exist. An exit code of 1 indicates that the solution is unique, while an exit code of 0 indicates that the solution is almost certainly not unique. (This uncertainty can only be resolved by a close examination of the final simplex tableau contained in A, and we do not consider such an examination to be warranted in practice). A Chebyshev solution may be nonunique simply because the matrix of coefficients A is not of full rank.

Example. Approximate $y(z) = e^z$ by $\alpha_1 + \alpha_2 z + \alpha_3 z^2 + \alpha_4 z^3$ in the Chebyshev norm on the 51 points defined by $z = 0(0.02)1$. Equivalently, calculate the Chebyshev solution to the system of equations $\sum_{j=1}^{4} z_i^{j-1} x_j = e^{z_i}$, $i = 1, 2, \ldots, 51$, where $z_i = 0.02(i - 1)$. Setting *TOL* equal to 10^{-6} and setting *RELERR* to 0.0, the subroutine gives the following solution on an IBM 370/145 using single precision arithmetic (approximately 7 decimal digits): $x_1^* = 0.999456$, $x_2^* = 1.016599$, $x_3^* = 0.421690$, $x_4^* = 0.279989$. The number of iterations required is 8, and the value of *RESMAX* is 0.000544.

ALGORITHM 496
The LZ Algorithm To Solve the Generalized Eigenvalue Problem for Complex Matrices [F2]

LINDA KAUFMAN

University of Colorado

Key Words and Phrases: eigenvalues, generalized eigenvalue problem
CR Categories: 5.14
Language: Fortran

DESCRIPTION

The program given here is an implementation of the LZ algorithm [1] for finding $\mathbf{x}$ and λ such that $A\mathbf{x} = \lambda B\mathbf{x}$, where A and B are $n \times n$ matrices. The LZ algorithm does not require matrix inversion and may be used when either or both matrices are singular. It is a generalization of Rutishauser's LR method [3] for the standard eigenvalue problem $A\mathbf{x} = \lambda\mathbf{x}$ and closely resembles the QZ algorithm given by Moler and Stewart [2] for the generalized problem given above. Since the LZ algorithm uses elementary transformations and the QZ algorithm uses orthogonal transformations, the LZ algorithm is probably more efficient when either A or B is complex.

The LZ algorithm is based on three observations:

(1) If L and M are nonsingular matrices, the eigenvalue problems $LAM\mathbf{y} = \lambda LBM\mathbf{y}$ and $A\mathbf{x} = \lambda B\mathbf{x}$ have the same eigenvalues and their eigenvectors are related by $\mathbf{x} = M\mathbf{y}$.

(2) If A is a triangular matrix with diagonal elements α_i, and B is a triangular matrix with diagonal elements β_i, then for each i, $i = 1, 2, \ldots, n$, α_i/β_i is an eigenvalue of the generalized problem if $\beta_i \neq 0$.

(3) There exist matrices L and M such that LAM and LBM are upper triangular and L and M are the products of lower triangular and permutation matrices.

The aim of the LZ algorithm is to find the matrices L and M which reduce A and B simultaneously to triangular form. It accomplishes this aim in two phases.

(1) The first phase simultaneously reduces A to upper Hessenberg form (i.e. $a_{i,j} = 0$ for $i > j$) and B to upper triangular form by (a) reducing B to triangular form as in Gaussian elimination and applying the transformations to A, and (b) reducing A to upper Hessenberg form while preserving the triangularity of B by using row transformations to zero the elements below the subdiagonal of A and column transformations to zero the subdiagonal elements of B introduced by the row transformations.

(2) The second phase iteratively reduces A to upper triangular form while preserving the triangularity of B where each iteration is given by (a) finding a shift λ_k, (b) finding a stabilized transformation $\bar{L}_k$ such that $\bar{L}_k(A_k - \lambda_k B_k)$ is

Received 21 June 1973, 6 December 1974, and 15 April 1975.

Author's address: Department of Computer Science, University of Colorado, Boulder, CO 80302.

upper triangular, (c) finding a stabilized transformation $\bar{M}_k$ such that $\bar{L}_k B_k \bar{M}_k$ is upper triangular, (d) setting $A_{k+1} = \bar{L}_k A_k \bar{M}_k$ and $B_{k+1} = \bar{L}_k B_k \bar{M}_k$.

If $\bar{L}_k$ and $\bar{M}_k$ are constructed appropriately, A_{k+1} will be upper Hessenberg and hopefully some of its subdiagonal elements will be small enough to be considered zero.

The shift λ_k is used to hasten the convergence of the algorithm. In practice it is set to the solution of the lowest 2×2 subproblem on the diagonal of $A_k - \lambda B_k$ which has not been triangularized.

Each matrix $\bar{L}_k$ is a product of matrices $L_{k,n-1} L_{k,n-2} \ldots L_{k,2} L_{k,1}$ and each $\bar{M}_k$ is a product of matrices $M_{k,1} M_{k,2} \ldots M_{k,n-1}$, where each $L_{k,i}$ and each $M_{k,i}$ is a stabilized elementary transformation (see [4]). The matrix $L_{k,1}$ is designed to annihilate the (2, 1) element of $A_k - \lambda_k B_k$. For $i \geq 1$, $M_{k,i}$ zeros the ith subdiagonal element of B introduced by $L_{k,i}$, and for $i > 1$, $L_{k,i}$ zeros the $(i + 1, i - 1)$-th element of A introduced by $M_{k,i-1}$.

The LZ algorithm determines the eigenvectors of the problem by computing the eigenvectors of the triangularized A and B and multiplying them by the product of all the column transformations.

The Fortran program given here is designed to find the eigensystem for two complex matrices A and B and consists of two subroutines which must be called separately. A user should first issue a call to LZHES to reduce A to upper Hessenberg form and B to triangular form and then issue a call to LZHES to determine the eigensystem of the reduced matrices. If A and B have already been reduced to Hessenberg and triangular form, then calling LZHES is unnecessary. In this situation, if eigenvectors are requested, the matrix X should be set to the identity matrix. The subroutine LZIT does not return the eigenvalues of the problem but the diagonal elements of the triangularized matrices. The ith eigenvalue may be found by dividing EIGA(i) by EIGB(i). The user is warned that EIGB(i) may be zero. The eigenvectors produced by LZIT are normalized so that the modulus of their largest component is 1.

Entrance to LZHES is attained by the statement

```
CALL LZHES(N,A,NA,B,NB,X,NX,WANTX)
```

where the input parameters are

N	order of the A and B matrices,
A	$n \times n$ complex matrix,
NA	row dimension of A,
B	$n \times n$ complex matrix,
NB	row dimension of B,
NX	row dimension of X (see output parameters)
WANTX	logical variable which should be set to .TRUE. if eigenvectors are wanted and otherwise set to .FALSE.,

and the output parameters are

A	complex upper Hessenberg matrix; the original A matrix is destroyed,
B	complex upper triangular matrix; the original B matrix is destroyed,
X	$n \times n$ complex array containing the transformations needed to compute the eigenvectors of the problem if WANTX was .TRUE..

Entrance to LZIT is attained by the statement

```
CALL LZIT(N,A,NA,B,NB,X,NX,WANTX,ITER,EIGA,EIGB)
```

where the input parameters are

N	order of the A and B matrices,
A	$n \times n$ complex upper Hessenberg matrix,
NA	row dimension of the A matrix,
B	$n \times n$ complex upper triangular matrix,
NB	row dimension of the B matrix,
X	$n \times n$ complex array containing the transformations to determine the

eigenvectors of the original problem if WANTX has been set to .TRUE. ,

NX row dimension of the X matrix,

WANTX logical variable which should be set to .TRUE. if eigenvectors are wanted and otherwise set to .FALSE. ,

and the output parameters are

X $n \times n$ complex array whose ith column contains the ith eigenvectors if WANTX was set to .TRUE. ,

ITER integer array of length n whose ith entry contains the number of iterations needed to find the ith eigenvalue; for any i, if iter$(i) = -1$, then after 30 iterations there was not a sufficient decrease in the last subdiagonal element of A to continue iterating so that not all the eigenvalues have been isolated,

EIGA complex array of length n containing the diagonal of the triangularized A,

EIGB complex array of length n containing the diagonal of B.

Since $| x |$, where x is a complex scalar, must be computed at least $8n$ times per iteration, the execution time of the method is dependent on the algorithm used to compute $| x |$. Replacing the true modulus by an approximation has little effect on the numerical properties but may result in a significantly more efficient code. Several versions of the LZ algorithm with different methods for computing $| x |$ were run on the IBM 360 model 67 with the Fortran H compiler opt=2. The results were interesting:

(1) The procedure CABS supplied by the manufacturer to compute $| x |$ was by far the slowest.

(2) Substituting the procedure RABS given by

```
REAL FUNCTION RABS(X)
COMPLEX X, XX
REAL T(2)
EQUIVALENCE (XX, T(1))
XX = X
RABS = ABS(T(1)) + ABS(T(2))
RETURN
END
```

for CABS decreased the time by about 20 percent when no eigenvectors were computed. When using RABS, changing the precision of the program requires very little effort.

(3) Computing $|x|$ as ABS(REAL(X)) + ABS(AIMAG(X)) as in the program given here decreased execution times from version 2 by roughly 10 percent when no eigenvectors were computed.

Although theoretically numerical growth can be quite large, our experiments have shown that the algorithm behaves like most other methods which use stabilized elementary transformations: numerical growth rarely occurs and errors rarely accumulate. The eigenvalues are usually determined to the accuracy justified by the condition of the problem.

The example shown in Figure 1 was generated in integer arithmetic by multiplying two diagonal matrices by nonsingular transformations. It was run on the CDC Run compiler. The relative residual is the quantity,

$$|| \beta_i A \mathbf{x}_i - \alpha_i B \mathbf{x}_i ||_\infty / (|| \beta_i || \, || A ||_\infty + || \alpha_i || \, || B ||_\infty)$$

where α_i and β_i are the ith diagnonal elements of the triangularized A and B matrices and $\mathbf{x}_i$ is the ith eigenvector.

ALGORITHM 497
Automatic Integration of Functional Differential Equations [D2]

KENNETH W. NEVES

Babcock & Wilcox

Key Words and Phrases: functional differential equations, automatic integration, one-step and multistep methods, time lags and retarded arguments, Volterra integro-differential equations, derivative jump discontinuities
CR Categories: 5.16, 5.17, 5.18
Language: Fortran

DESCRIPTION

This algorithm is a complement to [1] where the theoretical background and development are described.

ALGORITHM 498
Airy Functions Using Chebyshev Series Approximations

P.J. PRINCE

Teesside Polytechnic, Great Britain

Key Words and Phrases: Airy functions, Chebyshev series approximation, Chebyshev coefficients, asymptotic expansion, Taylor expansion
CR Categories: 5.12
Language: Fortran

DESCRIPTION

Purpose

This subroutine evaluates the Airy functions $\mathrm{Ai}(z)$ and $\mathrm{Bi}(z)$ and their respective derivatives Ai′ and Bi′, for all real values of z within computer capability, by means of Chebyshev series approximations.

Method

(a) For $z \leq -7$ the following asymptotic expansions are used (see [1, eqs. 10.4.60, 10.4.64, 10.4.62, and 10.4.67]):

$$\mathrm{Ai}(-z) \sim z^{-1/4}\{sf(z) - cg(z)\}, \qquad \mathrm{Ai}'(-z) \sim -z^{1/4}\{cp(z) + sq(z)\}$$

$$\mathrm{Bi}(-z) \sim z^{-1/4}\{cf(z) + sg(z)\}, \qquad \mathrm{Bi}'(-z) \sim z^{1/4}\{sp(z) - cq(z)\}$$

where $s = \sin(\zeta + \pi/4)$, $c = \cos(\zeta + \pi/4)$, $\zeta = 2/3\ z^{3/2}$, and f, g, p, and q are approximated by the following Chebyshev expansions:

$$f \simeq \sum_{r=0}^{m_1}{}' a_r T_r^*(t), \quad g \simeq \zeta^{-1} \sum_{r=0}^{m_2}{}' b_r T_r^*(t), \quad p \simeq \sum_{r=0}^{m_3}{}' c_r T_r^*(t), \quad q \simeq \zeta^{-1} \sum_{r=0}^{m_4}{}' d_r T_r^*(t)$$

where $t = -(7/z)^3$, the T_r^* are the shifted Chebyshev polynomials, and the a_r, b_r, c_r, and d_r are the prescribed Chebyshev coefficients.

(b) For $-7 < z \leq 0$ the functions are given by the following Taylor expansions (see [1, eqs. 10.4.2 and 10.4.3]):

$$\mathrm{Ai} = e_1 f(z) - e_2 g(z), \qquad \mathrm{Ai}' = e_1 f'(z) - e_2 g'(z)$$

$$\mathrm{Bi} = \sqrt{3}\{e_1 f(z) + e_2 g(z)\}, \qquad \mathrm{Bi}' = \sqrt{3}\{e_1 f'(z) + e_2 g'(z)\}$$

Received 2 August 1974 and 1 April 1975.

Author's address: Mathematics Department, Teesside Polytechnic, Middlesbrough, Cleveland, TS1 3BA, Great Britain.

where e_1 and e_2 are prescribed constants, and

$$f \simeq \sum_{r=0}^{m_1}{}' a_r T_r^*(t), \qquad g \simeq z \sum_{r=0}^{m_2}{}' b_r T_r^*(t)$$

$$f' \simeq z^2 \sum_{r=0}^{m_3}{}' c_r T_r^*(t), \qquad g' \simeq \sum_{r=0}^{m_4}{}' d_r T_r^*(t)$$

where $t = -(z/7)^3$.

(c) For $0 < z < 7$ the previous Taylor expansions do not allow the functions to be accurately calculated (unless using very high precision) at all points of the range because of the large fluctuation in magnitude of the functions over this range. To overcome this, the following Chebyshev approximations to the weighted functions are used:

$$\mathrm{Ai}\exp(1.75z) \simeq \sum_{r=0}^{m_1}{}' a_r T_r^*(t), \qquad \mathrm{Ai}'\exp(1.75z) \simeq \sum_{r=0}^{m_3}{}' c_r T_r^*(t)$$

$$\mathrm{Bi}\exp(-1.75z) \simeq \sum_{r=0}^{m_2}{}' b_r T_r^*(t), \qquad \mathrm{Bi}'\exp(-1.75z) \simeq \sum_{r=0}^{m_4}{}' d_r T_r^*(t)$$

where $t = z/7$.

(d) For $z \geq 7$ the following asymptotic approximations are used (see [1, eqs. 10.4.59, 10.4.63, 10.4.61, and 10.4.66]):

$$\mathrm{Ai}(z) \sim z^{-1/4}\exp(-\zeta) \sum_{r=0}^{m_1}{}' a_r T_r^*(t), \qquad \mathrm{Ai}'(z) \sim -z^{1/4}\exp(-\zeta) \sum_{r=0}^{m_3}{}' c_r T_r^*(t)$$

$$\mathrm{Bi}(z) \sim z^{-1/4}\exp(\zeta) \sum_{r=0}^{m_2}{}' b_r T_r^*(t), \qquad \mathrm{Bi}'(z) \sim z^{1/4}\exp(\zeta) \sum_{r=0}^{m_4}{}' d_r T_r^*(t)$$

where $t = (7/z)^{3/2}$.

In each case the degree of approximation, m_i, is such that the functions are determined accurate to at least nine significant figures if the function is greater than unity in magnitude and to nine decimal places if not. However, in case (a) the final accuracy is limited by the accuracy to which the sine and cosine of $\zeta + \pi/4$ can be computed. In the cases (a), (b), and (d) the Chebyshev coefficients were computed by rearrangement of the corresponding power series expansions using [3, p. 52, eq. 23]. In case (c) the coefficients were computed by numerical integration based on [3, p. 65, eq. 1], where the required Airy function values were computed in high precision using the Taylor expansions. In all four cases use is made of the Rice algorithm for summing the Chebyshev series (see [3, p. 57, eq. 50]).

Program

The subroutine is named AIRY and is composed of the four subroutines COEF1, COEF2, COEF3, and COEF4 corresponding, respectively, to the previous cases (a), (b), (c), and (d). The calling statement is

CALL AIRY (Z, NFUNC, ISCAL, AI, BI, AID, BID)

where the input variables Z, NFUNC, and ISCAL are defined as follows:

Z the prescribed argument

NFUNC an indicator for which of the functions are to be calculated, as follows:

NFUNC { negative, for Ai' and Bi' only;
0, for all four functions;
positive, for Ai and Bi only

ISCAL an indicator for whether or not in case (d) the following scaling is required:

$$(\mathrm{Ai}, \mathrm{Ai}') = (\mathrm{Ai}, \mathrm{Ai}') \exp(\zeta);$$
$$(\mathrm{Bi}, \mathrm{Bi}') = (\mathrm{Bi}, \mathrm{Bi}') \exp(-\zeta);$$

if ISCAL = 0 there is no scaling; otherwise, scaling as above.

The output variables will contain the respective values of Ai, Bi, Ai′, and Bi′. After the CALL statement the input parameters are left unchanged.

The relevant prescribed Chebyshev coefficients are stored in arrays A, B, C, and D corresponding, respectively, to a_r, b_r, c_r, and d_r in the previous analysis. Subroutine CHEB evaluates the sum of the required Chebyshev series given the argument $x (0 \leq x \leq 1)$ and the corresponding N Chebyshev coefficients $a_0, a_1, \ldots, a_{N-1}$ stored as $A(I)$, $I = 1, N$.

Test Results

Tests have been carried out on an ICL 1905E computer (11S floating-point arithmetic). The Wronskian relationship $W = \mathrm{AiBi}' - \mathrm{Ai}'\mathrm{Bi} = 1/\pi$ has been used to check on the results, as have the tables in [1] and the results obtained from a high precision calculation based on the Taylor expansions.

Tests have also been carried out for comparison with ACM Algorithm 301 [2], which gives at least eight-figure accuracy; the present algorithm is comparable in time for setting up large tables of the functions, and is certainly more efficient when only a small number of function evaluations are required outside the asymptotic ranges. For shorter word machines the user may truncate the given Chebyshev coefficients. The routine has run successfully on a Data General Corporation Nova 840 (7S floating-point arithmetic), with at least five-figure accuracy obtained.

REMARK ON ALGORITHM 498

Airy Functions Using Chebyshev Series Approximations [P.J. Price, *ACM Trans. Math. Softw. 1*, 4 (Dec. 1975), 372-379]

M. Razaz and J.L. Schonfelder [Received 19 March 1980, accepted 11 June 1980]

The Computer Centre, University of Birmingham, Elms Road, Birmingham, England.

Algorithm 498 presents a method for approximating the Airy functions and their first derivatives based on Chebyshev expansions. The method employed and the actual Chebyshev expansions presented give adequate routines for accuracies limited to about 8D (absolute in the negative region and relative in the positive). Such limited accuracy is adequate for single precision on 32- or 36-bit machines, that is, working precisions of 6D to 8D, approximately. Machines currently in common use regularly employ floating-point precisions of 11, 15, 17, and 18D. To cover this accuracy range and to deal with possible double-precision implementations, we have extended the accuracy capabilities of this basic algorithm to 30D

and new Chebyshev expansions have been generated to that precision [1]. This necessitated some modifications to the basic method of Algorithm 498. The most significant of such modifications was the need to introduce an additional range subdivision for the positive region.

Following as closely as possible the notation of Algorithm 498, we use for regions (a) and (b) entirely similar expansions, with the essential differences that the break point is chosen at -5 rather than -7 and we absorb the constants c_1 and c_2 of region (b) into the Chebyshev series. The former change is merely to improve the balance of the approximations for the important accuracy range 15D to 20D and to speed up the routines for the important argument range that includes the first few oscillations of the functions.

In order to increase the precision in the positive region it becomes necessary to introduce an additional region (c′), analogous to region (c). For the latter region we employ

$$Ai(z)\exp(+\alpha z) = \sum_{r=0}' a_r T_r^*(t), \qquad Ai'(z)\exp(+\beta z) = \sum_{r=0}' c_r T_r^*(t)$$

$$Bi(z)\exp(-\beta z) = \sum_{r=0}' b_r T_r^*(t), \qquad Bi'(z)\exp(-\alpha z) = \sum_{r=0}' d_r T_r^*(t)$$

with $0 < z < 4.5$, $t = z/4.5$, $\alpha = 1.5$, and $\beta = 1.375$. The prime means that the term with suffix $r = 0$ in each expansion is halved. The constants α and β were chosen to approximately minimize the variation of the function being expanded as a polynomial, this being required to give good relative error control for the resulting approximations [2]. These constants were also chosen to be exactly representable on any existing machine, thus aiding portability and preserving accuracy.

For the additional region (c′) we use

$$Ai(z)\exp(+\alpha z) = \sum_{r=0}' a_r T_r^*(t), \qquad Ai'(z)\exp(+\alpha z) = \sum_{r=0}' c_r T_r^*(t)$$

$$Bi(z)\exp(-\beta z) = \sum_{r=0}' b_r T_r^*(t), \qquad Bi'(z)\exp(-\beta z) = \sum_{r=0}' d_r T_r^*(t)$$

with $4.5 < z < 9$, $t = (z - 4.5)/4.5$, $\alpha = 2.5$, and $\beta = 2.625$.

For region (d) we use expansions as in Algorithm 498, except that the break point of 9 rather than 7 is used. This allows both slightly faster convergence for the expansions and a more efficient and accurate calculation of t to be performed. The parameter t can now be calculated as

$$t = (9/z)^{3/2} = 27/(z)^{3/2} = 18/\zeta.$$

Thus we avoid the necessity of calculating a 3/2 power more than once and/or of carrying a further nonexact constant $(7)^{3/2}$.

The modifications to the code of Algorithm 498 to employ these new expansions for obtaining a higher precision routine are fairly straightforward and the actual expansions have been published elsewhere [1]. Using these expansions the authors have produced routines that have been included in the S17 chapter of the NAG library [3]. The routines have been tested and have been shown to provide approximations accurate to within the errors expected for functions of this type for machines of precisions up to 18D, the errors being of the order of the machine precision except where losses are unavoidable. For instance, for large arguments where the errors are dominated by the imprecisions of sine, cosine, and exponential routines.

ALGORITHM 499
An Efficient Scanning Technique [Z]

W. KINSNER and E. DELLA TORRE

McMaster University, Canada

Key Words and Phrases: array scanning, pattern recognition, partial differential equations, finite-differences, Laplace's equation
CR Categories: 4.22, 5.14, 5.17, 8.2
Language: Fortran

DESCRIPTION

1. Introduction

Scanning an array refers to selecting all the elements of the array in a particular order. We shall consider two scanning techniques: a raster scan and a new contour scan. The raster scan selects the elements of a row from left to right and rows sequentially from top to bottom. The contour scan selects the elements of an array so that they are adjacent to or lie on a given boundary and so that the subsequent elements are adjacent to the previously selected points. Use of the contour scanning technique, rather than the raster scanning technique, accelerates the speed of propagation of the boundary condition effects when solving partial differential equations by finite-difference methods or other iterative methods. This technique is useful in other applications, such as pattern recognition, although the implementation discussed here refers to iterative solutions of elliptic boundary value problems.

2. Basic Concept

Let R be an open rectangular two-dimensional region with a boundary C containing an open region R_1 with boundaries C_1 and C_2 as shown in Figure 1, and let the region R be discretized with S mesh points such that $S \subset R$. The algorithm described here selects all the points S_1 in a particular order such that $S_1 \subset R_0$ where $R_0 = R_1 \cup C_2$.

The selection of the points in R_0 starts from a point adjacent to a boundary point on C_1. Then all the points in R_0 adjacent to C_1 and on C_2 are selected in a sequence as they occur in the clockwise direction of a path along C_1 and on C_2. It is noted that line segments joining all the selected adjacent points form a polygon even if the boundary C_1 and C_2 do not constitute a closed contour and intersect the boundary C. Subsequently selected points in R_0 are adjacent to the previously selected points. The procedure is repeated until the last element of S_1 is found.

Special treatment is given to multiply connected boundaries.

Received 30 August 1972 and 24 June 1974.

This work was supported by the National Research Council of Canada.

3. Implementation

The simplest scanning procedure is the raster scan since it can be implemented with two DO loops. However, this procedure has two drawbacks: less favored boundary conditions affect the solution at the very end of the scan; and for nonrectangular boundaries the raster scan samples points outside the specified region where the solution is not desired.

A scanning technique with neither drawback is the contour scan shown in Figure 2. After the scan has been initialized by the proper selection of a starting point and an initial direction, it proceeds by trying to make a left turn in a two-dimensional array. If it encounters either a point on a Dirichlet boundary or a previously scanned point, it then tries to go straight ahead. If it fails, a raster scan is used to find the next available point within the boundaries. The raster scan terminates the procedure when all the points in the array have been selected.

It is seen from Figure 2 that the complexity of the path traced by the contour scan depends on the choice of the starting point. This starting point may be specified by the user. However, a more efficient way of choosing a proper starting point and the optimum contour path is guaranteed by the subroutine CONOPT. The subroutine uses two criteria for selecting proper starting points: first, it tries to choose a point adjacent to a mesh point with the highest value of Dirichlet boundary condition; second, it tries to select a point so that the contour generated is a continuous curve. This latter criterion tends to produce a consistent ordering [2].

The subroutine HIVA locates the points with large numerical values of Dirichlet boundaries by means of the raster scan. The subroutine SPOINT then selects up to twenty choices for possible starting points. The points are chosen in such a way as to minimize the number of corners in the scan and so that the scan runs adjacent, if possible, to the entire equipotential boundary. The subroutine CONTR generates different orderings from each of these points. The subroutine CONOPT chooses either the first continuous scan, or the scan with the fewest discontinuities.

The initial direction in which the contour scan proceeds from a starting point is determined automatically in the subroutine CONTR as follows. If the Dirichlet boundary point is located at $(I - 1, J)$ and the point, $(I, J + 1)$ is an interior "free" point, the initial direction indicator, K, is set to 1, and the turn indicator, L, is set to 2, i.e. the scanning proceeds in the direction of increasing J. If this condition is not met, the previous pattern is rotated about the point (I, J). Eventually, one of four possible directions will be chosen.

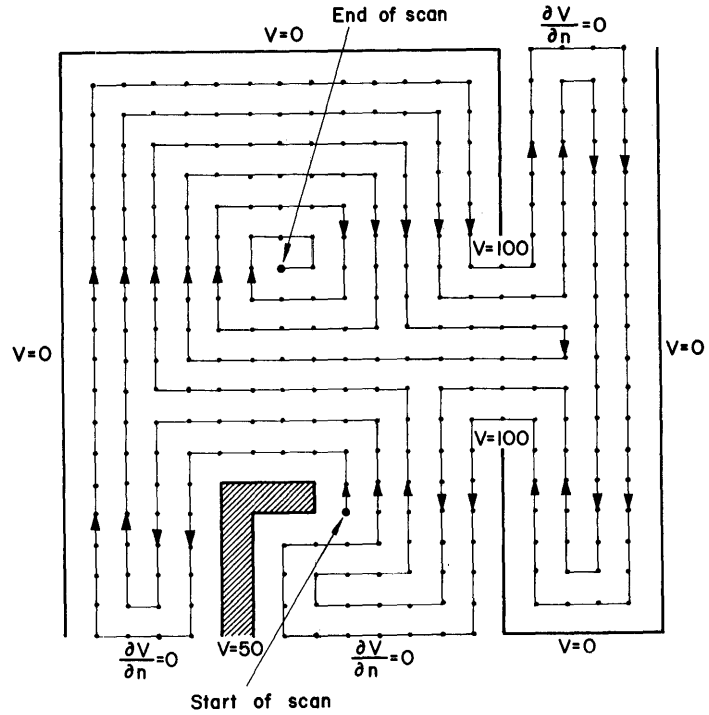

Fig. 2. Sample of boundary conditions and contour scan

The scanning path is computed only once for each different set of Dirichlet boundary values and it is stored in a tabular form. The scanning then is carried out by a single DO loop using table look-up. One can change the direction of the scan by altering the table look-up. For repeated solutions of the same problem one may punch out the selected contour scan.

4. Input-Output Considerations

In order to determine a contour scanning path, data is required in the NET array locating Dirichlet boundaries. The optimization of the contour scan requires numerical values of these boundaries. If the boundaries are piecewise linear or are described by a simple function, they may be generated by the computer. Otherwise the user has to supply them point by point. The numerical values of the boundaries are introduced in the array A and the corresponding location flags are automatically shifted in the array NET since the dimension of the array NET is greater than that of the array A. The program can handle purely Neumann problems, i.e. with the boundary consisting of C_2 only. Setting the boundary conditions in the arrays A and NET may be implemented in many different ways and it is felt that it does not belong to the described algorithm.

The intermediate results printed by the subprogram CONOPT may be suppressed by setting the flag IPRINT to zero.

5. Efficiency of the Algorithm

This algorithm has been designed to be used in iterative solutions of elliptic boundary-value problems. Therefore, its efficiency can be measured by comparing the total machine time spent for solving a given problem when using the contour scan and the raser scan. We consider two stages: selecting and storing a set of points, S_1, from the region $R_1 \cup C_2$; and solving the problem by iteration.

Since the implementation of the contour scan is more complex than the implementation of the raster scan, the first stage is more economical for the raster scan, depending on the geometry of the region R_0. Various test problems indicate that the set-up time for the contour scan is 10 to 50 times longer than that for the raster scan. However, this set-up time is only 10 to .5 times longer than the average

machine time per iteration for a small problem, as in Figure 2, and for large problems with up to 6500 points, respectively.

The average machine time per iteration during the second stage is exactly the same for both scanning techniques since the number of elements in S_1 is the same in both cases. It has been found experimentally [1] that the ordering of S_1 generating the contour scan causes a higher rate of convergence of the finite-difference methods as compared to the ordering generated by the raster scan. In all the test problems, this faster convergence resulted in 2 to 10 percent fewer iterations when using the Jacobi, Gauss-Seidel, or SOR methods. A more efficient method [1] resulted in up to 60 percent less iterations. Other scanning techniques such as the diagonal scan and the "red-black" scan [2] give the same rate of convergence as the raster scan.

The subroutine CONTR may be used as an independent subprogram for generating only one contour scanning path. In this case, it requires only 2 to 5 times more set-up time than the raster scan.

All the test problems have been run on a CDC-6400 computer.

ALGORITHM 500
Minimization of Unconstrained Multivariate Functions [E4]

D. F. SHANNO and K. H. PHUA
University of Toronto, Canada

Key Words and Phrases: minimization, optimization
CR Categories: 5.15, 5.19
Language: Fortran

DESCRIPTION

Purpose

This subroutine finds a local minimum of a nonlinear function of n variables $f(x)$ where $x = (x_1, x_2, \ldots, x_n)$, $n > 1$, can be any real numbers.

Methods

Quasi-Newton methods are iterative methods which approximate Newton's method without calculating second derivatives. The iterative sequence is defined by

$$x^{(k+1)} = x^{(k)} - \alpha^{(k)} H^{(k)} g^{(k)},$$

where $g^{(k)} = \nabla f(x^{(k)})$, the gradient of f at $x^{(k)}$, $H^{(k)}$ is a matrix which is designed to approximate the inverse Hessian matrix of f at $x^{(k)}$, and $\alpha^{(k)}$ is an appropriately chosen scalar. The sequence of matrices $H^{(k)}$ is chosen to satisfy the quasi-Newton equation $H^{(k+1)} y^{(k)} = \sigma^{(k)}$, where $\sigma^{(k)} = x^{(k+1)} - x^{(k)}$ and $y^{(k)} = g^{(k+1)} - g^{(k)}$. In general, $H^{(k+1)}$ is generated by $H^{(k+1)} = H^{(k)} + D^{(k)}$, where $D^{(k)}$ is chosen to satisfy the equation $D^{(k)} y^{(k)} = \sigma^{(k)} - H^{(k)} y^{(k)}$.

The choice of $\alpha^{(k)}$ can be accomplished either by a linear-search or a step-length method. Perhaps the most complete current reference to the general theory is Powell [8]. Two different methods for determining $\alpha^{(k)}$ are incorporated and are outlined below. The Broyden-Fletcher-Shanno (BFS) matrix update (developed by Broyden [1], Fletcher [3], Goldfarb [5], Greenstadt [6], and Shanno [9]) is used to estimate $H^{(*)}$ in each of the algorithms. Dropping the superscripts, and denoting the current point by x and the subsequent point by x^*, with the corresponding notation g and g^*, and H and H^*, the BFS formula is

$$H^* = (I - \sigma y'/\sigma' y) H (I - \sigma y'/\sigma' y) + \sigma\sigma'/\sigma' y,$$

Received 31 May 1974, 8 September 1974, and 14 March 1975.

This work was supported in part by the National Research Council of Canada under Grant NRC A7910.
Authors' present addresses: D.F. Shanno, Computer Science, School of Engineering, University of Mississippi, University, MISS 38677; K.H. Phua, Department of Computer Science, Nanyang University, Upper Jurong Rd., Singapore 22.

where $\sigma = x^* - x$, $y = g^* - g$. This form of the update formula is that suggested by Fletcher [3].

Method 1. This method incorporates an inexact linear search for $\alpha^{(k)}$ at each step. Features of the algorithm include the following.

(i) The initial approximate inverse Hessian matrix proposed by Powell [7] is used, that is, $H^{(0)} = 100 \, ||\Delta x|| / ||g^{(0)}|| \, I$, where Δx is the vector of step bounds placed on all variables x_i, $||\cdot||$ is the usual L_2-norm, and I is the $n \times n$ identity matrix.

(ii) In Shanno et al. [11], it has been shown that if α is chosen to satisfy $\sigma' g^* > \sigma' g$, then the positive definiteness of H implies that H^* is also positive definite. Thus α is chosen by the following algorithm. The quadratic extrapolation technique described in [10] is used to bracket the minimum of $f(x)$ along the search direction $s = -Hg$. Davidon's [2] cubic interpolation technique is then applied until a point is found with $f^* < f$ and $\sigma' g^* > \sigma' g$. The point x^* is then accepted as the next point in the sequence.

(iii) Suppose that the step length α along the search direction s obtained by the previous step is "good"; then the distance $\alpha^* s^*$ to be moved from x^* will presumably be about the same as αs. Thus, before applying the above linear-search technique to estimate α, the length of the search vector s is scaled by $||s^{(k)}|| = ||\sigma^{(k-1)}||$, $k = 1, \ldots, n$. Numerical results indicate that this scaling criterion improves our algorithm for most problems tested.

This program is controlled by setting MODE = 1 in the parameter list of the subroutine MINI. For convenience, we shall denote this algorithm by MINI01. According to the results presented in [12], MINI01 appears preferable to MINI02 on functions where singularity of the true Hessian occurs.

Method 2. In this method we attempt to combine the merits of linear-search methods and step-length methods. The main feature of this algorithm is that linear-search techniques are applied infrequently. Using the notation previously developed, the algorithm can be described by the following seven major steps.

(1) *Create the search direction.* Evaluate $s^* = -H^* g^*$ and scale s^* such that $||s^*||$ is equal to $||\sigma||$ from the previous iteration for the first n iterations.

(2) *Perform the first extrapolation.* Estimate the first move by calculating

$$\alpha = \max\{-2(f - \bar{f})/s'g, 1\},$$

where $\bar{f}$ is the estimated least value of $f(x)$ provided by the user.

(3) *Evaluate the function value and its gradient.* Set $x^* = x + \alpha s$ and evaluate f^* and g^*. Set $\delta f = f^* - (f + \mu s'g)$, where $\mu = 0.0001$.

(4) *Test for termination of the linear search.* If $\delta f < 0$ and $s'g^* > s'g$, then the search for α is complete. Go to step (7).

(5) *Perform Shanno and Kettler's extrapolation technique.* If $\delta f < 0$ and $s'g^* < s'g$, there exists $\hat{\alpha}$ such that $\hat{\alpha} > \alpha$ and $f(x + \hat{\alpha}s) < f^*$. In this case, apply Shanno and Kettler's [10] extrapolation technique to estimate a new step length, β, that is,

$$\beta = \alpha^2 s'g / (2(f - f^* + \alpha s'g)).$$

Set $x = x^*$ and $\alpha = \beta$, and go to (3). Else go to step (6).

(6) *Perform Davidon's cubic interpolation technique.* If $\delta f \geq 0$ or $s'g^* \geq 0$, the minimum of $f(x)$ along s has been straddled. In this case, apply Davidon's [2] cubic interpolation technique to estimate a new step length, γ, that is,

$$\gamma = (-b + \sqrt{(b^2 - 3ac)})/(3a),$$

where

$$a = (2(f - f^*) + \alpha(s'g + s'g^*))/\alpha^3,$$

$$b = (-3(f - f^*) - \alpha(2s'g + s'g^*))/\alpha^2,$$

$$c = s'g.$$

If $b^2 - 3ac \leq 0$ or $| a | < 10^{-5} | b |$, then apply a quadratic interpolation scheme to estimate γ, that is,

$$\gamma = \alpha^2 s'g/(2(f - f^* + \alpha s'g)).$$

Now set $\alpha = \gamma$ and go to step (3).

(7) *Test for convergence.* If $|| g^* || \leq \epsilon$, then convergence is assumed. Otherwise update H^* by the BFS formula and repeat the whole process from step (1). Note that this convergence criterion has been found wanting in practice for badly scaled problems. Because it is the criterion used by VMM01 and MINFA, it was necessary to incorporate it in this program in order to obtain reasonable comparisons. A safer test can be incorporated by replacing the statement before statement 400 with

```
IF(DABS(G(I)).GT.EPS*(DABS(X(I)) + .001))CONV = .FALSE.
```

This changes the criterion from an absolute criterion on the gradient to a relative criterion, or the number of positions of accuracy required in the estimates to the minimum.

Remarks

(a) We note that the change in f on an iteration according to Taylor's theorem is approximately $s'g$ when s is small, but much less than $s'g$ in absolute value when the position of the minimum along a line is overestimated. The change in f relative to $s'g$ cannot become arbitrarily small if $(f^* - f)/s'g \geq \mu$, where $0 < \mu \ll 1$ is a preassigned small quantity. For more detail about the choice of this quantity, see Fletcher [3].

(b) On each move of the linear search, α is bounded in such a way that $\alpha s_i \leq \Delta x_i$, $i = 1, 2, \ldots, n$, where Δx is the vector of step bounds placed on all variables x_i. The step bounds Δx are introduced for several reasons. First, the initial estimated step length may be far too long, so that much is wasted in finding the desired α. Second, Δx helps in maintaining each component of x within the domain of definition of $f(x)$ so that environmental difficulties such as overflow and underflow problems may be prevented.

(c) In order to expedite the process of linear search, α is only estimated approximately. In fact, the search for α is complete as soon as the conditions given in step (4) are fulfilled. As a consequence, the new step length obtained by applying the extrapolation technique as described in step (5) is restricted to be $\alpha = \min\{\beta, 10\alpha\}$, so that the use of cubic interpolation technique may be avoided.

(d) In real situations, it may happen that the interpolation process gets stuck on one side of the minimum. To overcome this difficulty, the following modification to step (6) is suggested:

$$\alpha = \begin{cases} 0.1\ \alpha & \text{if } \gamma \leq 10^{-3}\alpha \\ \gamma & \text{if } 10^{-3}\alpha < \gamma \leq (1 - 10^{-3})\alpha \\ 0.8\ \alpha & \text{otherwise.} \end{cases}$$

(e) The use of this algorithm is signified by setting MODE = 2 in the parameter list of the subroutine MINI. For convenience, we shall denote this algorithm by MINI02. According to the results presented in [12], MINI02 is generally preferable to MINI01, except when the Hessian has singularities, as noted previously. For the general user, we would recommend use of MINI02, with a switch to MINI01 if convergence appears "too slow."

Program

The program consists of two modified quasi-Newton minimization techniques (MINI01, MINI02) which are controlled respectively by setting MODE = 1 or MODE = 2 in the parameter list of the subroutine MINI. This program requires one user-supplied subroutine (CALCFG), which calculates the values of the objective function and its first partial derivatives. The use of the subroutine and the

meaning of the parameters are described in the comments at the beginning of subroutine MINI. All communication between the main program and subroutines is achieved through the subroutine argument lists. An iteration is defined as the calculations required to select a new point which yields a lower function value than that of the previous one.

Test Results

These two programs (MINI01, MINI02) have been tested over a wide range of test functions in [12]. Compared with the subroutine (VMM01) given by Fletcher [3] and the subroutine (MINFA) as suggested by Powell [7], results show that MINI02 is the best algorithm, while MINI01 places second. For user comparisons,

we list some computational results of these two programs for the following four standard test functions.

(1) Box's function, defined by

$$f(x_1, x_2) = \sum_{i=1}^{10} \left| (e^{-x_1 t_i} - e^{-x_2 t_i}) - (e^{-t_i} - e^{-10 t_i}) \right|^2,$$

where t_i ranges from .1 to 1 in steps of .1. For MINI01 and MINI02, the step bounds are set to be $\mathrm{STP}(i) = 3$, $i = 1, 2$, and $\Delta^{(0)} = 3$ for MINFA.

(2) Rosenbrock's function, defined by

$$f(x_1, x_2) = 100(x_2 - x_1^2)^2 + (1 - x_1)^2,$$

with $\mathrm{STP}(i) = 3$, $i = 1, 2$, and $\Delta^{(0)} = 3$ for MINFA.

(3) Wood's function, defined by

$$\begin{aligned} f(x_1, x_2, x_3, x_4) = {} & 100(x_2 - x_1^2)^2 + (1 - x_1)^2 + 90(x_4 - x_3^2)^2 \\ & + (1 - x_3)^2 + 10.1[(x_2 - 1)^2 + (x_4 - 1)^2] \\ & + 19.8(x_2 - 1)(x_4 - 1), \end{aligned}$$

with $\mathrm{STP}(i) = 10$, $i = 1, 2, 3, 4$, and $\Delta^{(0)} = 10$ for MINFA.

(4) Weibull's function, defined by

$$f(x_1, x_2, x_3) = \sum_{i=1}^{99} [\exp((x_3 - t_i)x^2/x_1) - y_i]^2,$$

where the y_i and t_i are perfect data generated for the 99 points corresponding to $y = .01$ to .99 in steps of .01, for the values $x_1 = 50$, $x_2 = 1.5$, $x_3 = 25$, and $\mathrm{STP}(1) = 300$, $\mathrm{STP}(2) = 3$, $\mathrm{STP}(3) = 30$, and $\Delta^{(0)} = 3$ for MINFA.

(5) Beale's function, defined by

$$f(x_1, x_2) = [1.5 - x_1(1 - x_2)]^2 + [2.25 - x_1(1 - x_2^2)]^2 + [2.625 - x_1(1 - x_2^3)]^2,$$

with $\Delta^{(0)} = 3$ for MINFA and $|\Delta x_i| \leq 3$, $i = 1, 2$, for MINI01 and MINI02.

(6) Powell's function, defined by

$$f(x_1, x_2, x_3, x_4) = (x_1 + 10x_2)^2 + 5(x_3 - x_4)^2 + (x_2 - 2x_3)^4 + 10(x_1 - x_4)^4,$$

with $\Delta^{(0)} = 3$ for MINFA, and $|\Delta x_i| \leq 3$, $i = 1, 2, 3, 4$, for MINI01 and MINI02.

(7) Cregg's function, defined by

$$f(x_1, x_2, x_3, x_4) = (e^{x_1} - x_2)^4 + 100(x_2 - x_3)^6 + \tan^4(x_3 - x_4) + x_1^8 + (x_4 - 1)^2,$$

with $\Delta^{(0)} = 3$ for MINFA, and $|\Delta x_i| \leq 3$, $i = 1, 2, 3, 4$, for MINI01 and MINI02.

All tests were run in double precision on an IBM 370/165. In all cases, convergence was assumed to have occurred when $|\partial f/\partial x_i| \leq 10^{-5}$ for each i. Each test function was started from various initial estimates and their results are listed in Table I. The table does not differentiate function from gradient calls, because all programs tested calculate both each time the function subroutine is called. For a more complete evaluation, encompassing overhead and execution time, see [12]. We note here only that more careful evaluation leaves relative rankings unchanged.

REMARK ON ALGORITHM 500

Minimization of Unconstrained Multivariate Functions [E4]
[D.F. Shanno and K.H. Phua, *ACM Trans. Math. Software 2*, 1 (March 1976), 87–94]

Charles Dunham [Recd June 7, 1976]
Computer Science Department, University of Western Ontario, London, Ont., Canada.

The arrays STP and H used as arguments to this algorithm must be declared double precision, as declared in the body (but not the published heading) of the subroutine MINI.

MINI was used to determine a best $l_{1.5}$ approximation by the approximating function

$$F(A, x) = a_1 + a_2x + a_3 \exp(a_4x)$$

on $\{0, 1/10, \ldots, 9/10, 1\}$ to the function $f(x) = x + \exp(x) + \exp(2x)/100$. This is a minimization problem with four parameters, a_1, a_2, a_3, a_4. When MINI was run initially with arguments STP single precision of dimension 4 and H single precision of dimension 10 on a CDC Cyber 73, the program hung with an error mode 2 (infinite operand). With the above change (to double precision) the program produced the approximation obtained independently by several other methods.

REMARK ON ALGORITHM 500

Minimization of Unconstrained Multivariate Functions [E4] [D.F. Shanno and K.H. Phua, *ACM Trans. Math. Softw. 2*, 1 (March 1976), 87–94.]

D.F. Shanno and K.H. Phua [Received 3 January 1979; revised 5 June 1979; accepted 26 December 1979]
D.F. Shanno, Department of Management Information Systems, College of Business and Public Administration, The University of Arizona, Tucson, AZ 85721; K.H. Phua, Department of Computer Science, Nanyang University, Upper Jurong Road, Singapore 22, Republic of Singapore.

DESCRIPTION

1. Purpose

This subroutine finds a local minimizer of a nonlinear function of n variables $f(x)$ where $x = (x_1, \ldots, x_n)$, $n \geq 1$ can be any real numbers. This algorithm is meant to supersede the algorithm documented in [11].

2. Methods

The subroutine incorporates two nonlinear optimization methods, a conjugate gradient algorithm and a variable metric algorithm, with the choice of method left to the user.

The conjugate gradient algorithm is the Beale restarted memoryless variable metric algorithm documented in Shanno [7]. This method requires approximately $7n$ double-precision words of working storage to be provided by the user. The variable metric method is the BFGS algorithm with initial scaling documented in Shanno and Phua [10], and required approximately $n^2/2 + 11n/2$ double-precision words of working storage.

Whichever method is chosen, the same linear search technique is used for both methods, with two differences. The basic linear search uses Davidon's cubic interpolation to find a step length α, which satisfies

$$f(x + \alpha d) < f(x) + \alpha d' g(x)\ 0.0001, \tag{1}$$

where d is the chosen search direction, $g(x) = \nabla f(x)$, the gradient of f at x, and $d'g(x)$, the directional derivative of $f(x)$ at x along d, is always a negative number. In addition, α must satisfy

$$| d'g(x + \alpha d)/d'g(x) | < 0.9. \tag{2}$$

The convergence of the BFGS variable metric algorithm under the conditions (1) and (2) has been studied by Powell [6], while the convergence of the conjugate gradient method has been studied by Shanno [8].

The major difference between the two methods insofar as the linear search is concerned is that if the first trial α satisfies (1) and (2), it is accepted if a variable metric method is used, but at least two trial α's are required before accepting an α satisfying (1) and (2) for the conjugate gradient method. Reasons for requiring this are detailed in Shanno [9].

The second difference between the two methods is that for a variable metric method, $\alpha = 1$ is always the initial α tried, while for the conjugate gradient method, $\alpha = 1$ is tried only for restart iterations, whereas for nonrestart iterations the initial α at step $k + 1$, denoted by α_{k+1}, is chosen to be $\alpha_{k+1} = \alpha_k\, d'_k g_k / d'_{k+1} g_{k+1}$, where d_k and g_k and d_{k+1} and g_{k+1} are the search vectors and gradients at the kth and $k + 1$st points, respectively.

The linear search contains safeguards to ensure that the search procedure cannot become stuck or attempt to move past a local maximum to a more distant local minimum.

Convergence is determined to have occurred when $\| g \| < \epsilon \max(1, \| x \|)$, where $\| \cdot \|$ is the Euclidean norm and ϵ is user supplied.

3. Test Results

Table I contains test results for a variety of test problems for both the BFGS and conjugate gradient method. The test functions are Wood's function for the listed initial estimates, the extended Rosenbrock function documented in [7], Brodlie's [1] variable-dimensioned Watson function, Oren's [5] power function, Powell's four-dimensioned function [6], Fletcher and Powell's trigonometric functions with initial estimates as in [2], and for various dimensions, the Mancino function with initial estimates as documented in [7], Moré, Garbow, and Hillstrom's [4] boundary-value problem, and Toint's variation on Broyden's function [12]. The Wood and Powell functions are documented in [3].

In the table, ITER represents the number of search directions calculated, while IFUN represents the number of function and gradient evaluations that were performed. In all cases, $\epsilon = 10^{-5}$ was used, except for the boundary value problem, where $\epsilon = 10^{-4}$.

With the exception of the power function, on which the BFGS does not perform well for reasons documented in [10], it is clear from Table I that the variable metric method is quite a bit more efficient in terms of function and gradient calls, primarily due to the fact that the first trial α can be accepted, while at least two trial α's per iteration must be tried by the conjugate gradient algorithm.

In terms of execution time, however, the issue is not so clear-cut. On a DEC-10 computer, the Broyden–Toint function with $n = 30$ took 6.49 CPU seconds for the BFGS, while the conjugate gradient method took 5.32 due to the overhead of updating the approximate Hessian at each step. However, for the 30-variable Mancino function, the BFGS took 28.12 CPU seconds, while the conjugate gradient method took 72.31. As one would expect, evaluations of the Mancino function are quite expensive, while the Broyden–Toint function evaluations are quite inexpensive.

Thus for large problems where space limitations do not preclude using the BFGS algorithm, users are urged to experiment to determine the most efficient algorithm for a particular problem. For small problems, we recommend the BFGS method, while for very large problems, memory considerations generally mandate using the conjugate gradient algorithm.

Language: Fortran

DESCRIPTION

Subprograms *APPROX* and *EXCH* fit N data pairs stored with independent variable values in array X and dependent variable values in array Y to a minimax polynomial of degree M with parity specified by variable K (0, mixed parity; 1, odd parity; 2, even parity). The polynomial coefficients are returned in ascending order in array A. The magnitude of floating point variable *EPSH* must be significant when compared with the one on the machine used. The algorithm will fail only if *ABS*(*EPSH*) is greater than *HMAX*, the maximum approximation error. Success or failure of a run is indicated in the fixed point variable *EQUAL*. All other arguments are identical with the variables in the original algorithm and must conform to the constraints mentioned there. The variable *NTAPE*, an internal constant in subroutine *APPROX*, specifies the output unit number to which error messages will be directed. To insure the widest possible utility, a primitive level of Fortran was used. By modifying the code, users with access to powerful compilers can reduce both the amount of code and execution time. In particular, the variable *ITEMP* can be eliminated. The algorithm has been used on Sigma 6, Sigma 9, and IBM 360RAX computers.

ACKNOWLEDGMENT

The author is indebted to Herbert Schmitt for suggestions which improved the subprogram.

The following should be inserted just above the statement labeled 430 in subroutine *EXCH*[1]:

```
Z(ITEMP) = Z(I)                EXC 1880
```

With this correction this algorithm has been used to fit first, second, and third degree curves to experimental data on the following machines: Harris SLASH 5, Honeywell 600 series, and Univac 1108.

[1] Subroutine *EXCH* is published in the "Collected Algorithms from ACM"; to insert line EXC 1880, see page 501-P8-R1

ALGORITHM 502
Dependence of Solution of Nonlinear Systems on a Parameter [C5]

MILAN KUBÍČEK

Prague Institute of Chemical Technology, Czechoslovakia

Key Words and Phrases: solution of nonlinear equation, differentiation with respect to a parameter, one-parameter imbedding, dependence on parameter
CR Categories: 5.15
Language: Fortran

DESCRIPTION

The Fortran algorithm *DERPAR* is a subroutine suitable for evaluation of the dependence of the solution $x_1, \ldots, x_n$ of a system of equations

$$\begin{aligned} f_1(x_1, \ldots, x_n, \alpha) &= 0 \\ &\vdots \\ f_n(x_1, \ldots, x_n, \alpha) &= 0 \end{aligned} \tag{1}$$

on the parameter α. The modified method of Daviděnko [1, 2, 3], which applies the implicit function theorem, is used in combination with the Newton method and Adams integration formulas. A similar procedure was used by Deist and Sefor [4], who made use of an introduced parameter.

To establish the dependence $x(\alpha)$, the following set of differential equations can be derived:

$$\frac{dx}{d\alpha} = -\Gamma^{-1}(x, \alpha)\frac{\partial f}{\partial \alpha}, \quad x(\alpha_0) = x_0. \tag{2}$$

Here

$$\Gamma = \left\{\frac{\partial f_i}{\partial x_j}\right\}, \quad \frac{\partial f}{\partial \alpha} = \left(\frac{\partial f_1}{\partial \alpha}, \ldots, \frac{\partial f_n}{\partial \alpha}\right)^{\mathrm{T}}, \quad f(x_0, \alpha_0) = 0.$$

If $\Gamma(x(\alpha), \alpha)$ is a regular matrix for $\langle \alpha_0, \alpha_1 \rangle$, then $x(\alpha)$ obtained by integration of (2) satisfies

$$f(x(\alpha), \alpha) = 0, \quad \alpha \in \langle \alpha_0, \alpha_1 \rangle. \tag{3}$$

However, at a branching point the matrix Γ is singular and the integration procedure mentioned above fails.

Therefore, the method must be adapted to be able to handle branching points, i.e. to evaluate the whole dependence $x(\alpha)$, which is a continuously smooth curve in the $(n + 1)$-th dimensional space $(x - \alpha)$. A parameterization with respect to

Received 27 December 1972 and 29 October 1973.

Author's address: Department of Chemical Engineering, Prague Institute of Chemical Technology, 166 28 Prague 6, Czechoslovakia.

the arc length of the solution locus seems to be a powerful technique which overcomes the difficulties [5].

Differentiation of eq. (1) with respect to t gives

$$\frac{df_i}{dt} = \sum_{j=1}^{n} \frac{\partial f_i}{\partial x_j}\frac{dx_j}{dt} + \frac{\partial f_i}{\partial \alpha}\frac{d\alpha}{dt} = 0, \quad i = 1, 2, \ldots, n. \tag{4}$$

An additional equation

$$\left(\frac{dx_1}{dt}\right)^2 + \cdots + \left(\frac{dx_n}{dt}\right)^2 + \left(\frac{d\alpha}{dt}\right)^2 = 1 \tag{5}$$

determines the parameter t as the arc length of the curve $x(\alpha)$ in the space $(x - \alpha)$. The initial conditions for eqs. (4) and (5) are in the form

$$t = 0 : x = x_0, \ \alpha = \alpha_0. \tag{6}$$

Equation (4) forms a system of n linear equations for $n+1$ unknowns dx_i/dt, $i = 1, \ldots, n$, $d\alpha/dt$, for each t. Suppose that the matrix

$$\Gamma_k = \begin{pmatrix} \frac{\partial f_1}{\partial x_1}, \ldots, \frac{\partial f_1}{\partial x_{k-1}}, \frac{\partial f_1}{\partial x_{k+1}}, \ldots, \frac{\partial f_1}{\partial x_{n+1}} \\ \frac{\partial f_2}{\partial x_1}, \ldots \\ \vdots \\ \frac{\partial f_n}{\partial x_1}, \ldots, \frac{\partial f_n}{\partial x_{k-1}}, \frac{\partial f_n}{\partial x_{k+1}}, \ldots, \frac{\partial f_n}{\partial x_{n+1}} \end{pmatrix} \tag{7}$$

is regular (for certain values of t and k, $1 \leq k \leq n + 1$). For clarity here, we have denoted

$$x_{n+1} = \alpha. \tag{8}$$

Equation (4) can then be presolved with respect to the unknowns $dx_1/dt, \ldots, dx_{k-1}/dt, dx_{k+1}/dt, \ldots, dx_{n+1}/dt$, depending on dx_k/dt in the form

$$\frac{dx_i}{dt} = \beta_i \frac{dx_k}{dt}, \quad i = 1, 2, \ldots, k-1, k+1, \ldots, n+1. \tag{9}$$

In the program the unknowns with a subscript k (dx_k/dt and x_k) are called the independent variables. The value of the subscript k is determined in the Gaussian elimination procedure using controlled pivoting. The result depends on the values of $PREF(I)$.

On substituting (9) into (5) we obtain

$$\left(\frac{dx_k}{dt}\right)^2 = \left(1 + \sum_{i=1, i\neq k}^{n+1} \beta_i^2\right)^{-1}. \tag{10}$$

$\gamma = 1000$, $B = 22$, $\beta_1 = \beta_2 = 2$, $\theta_{c1} = \theta_{c2} = 0$; $x_0 = (0;0;0;0)$, $\alpha_0 = 0$,
$PREF(I) = (1,0.1,1,1,0.02)$, $HH = 0.02$, $EPS = 10^{-4}$, $MXADMS = 4$,
$NCORR = 4$, $NCRAD = 0$, $NDIR(I) = (1,1,1,1,1)$.
Calculated points on the curve $x_2(\alpha)$ are numbered. For the points 1–12, 61–70, 114–140, 155-. . ., α was independent ($k = 5$); otherwise x_2 ($k = 2$) plays the role of an independent variable. Altogether 332 evaluations of the subroutine *FCTN* for calculation of 162 points was necessary. However, by choosing $NCORR = 0$ and $NCRAD = 1$, the number of evaluations of *FCTN* was lowered to 163, and in fact the same curve was obtained.

The sign of dx_k/dt is given by the orientation of the parameter t along the curve. All derivatives dx_i/dt are then determined by (9).

The Adams-Bashforth explicit multistep method with an automatic change in the order of approximation is used for the integration of differential equations (9) and (10). It is possible to use some other technique, e.g. the Runge-Kutta method. However, it seems that our technique is more suitable when considering the time-

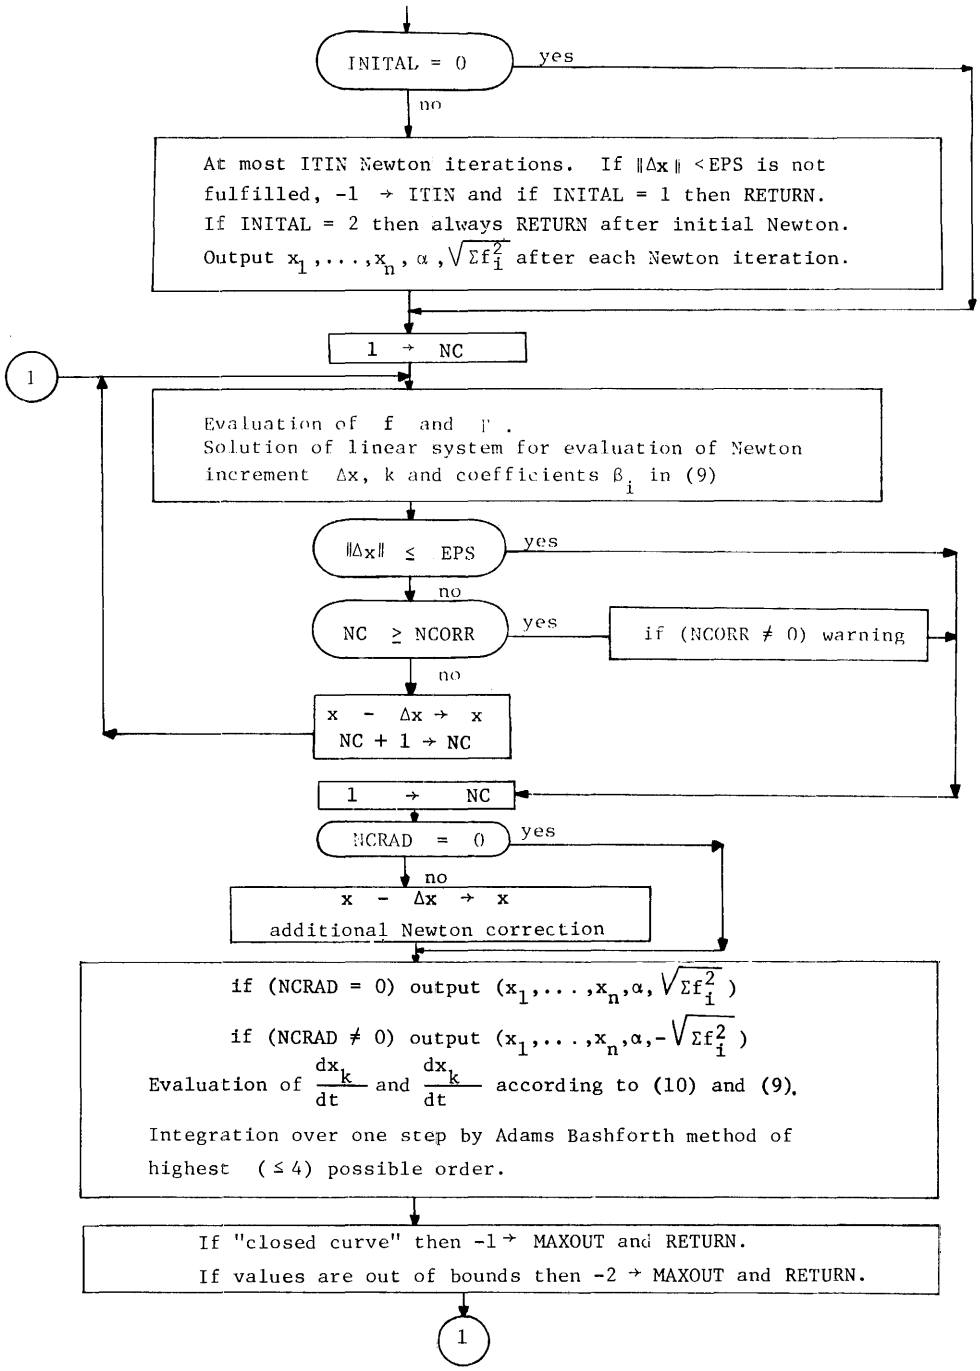

Fig. 1. Schematic flowchart of method

consuming evaluation of the Jacobian matrix and the matrix inversion procedure in each step.

In the course of integration the truncation error causes a deviation between the calculated solution $x(t)$ and the correct profiles $x(t)$. The Newton method for variables $x' = (x_1, x_2, \ldots, x_{k-1}, x_{k+1}, \ldots, x_{n+1})^T$ is therefore used to improve the calculated profiles:

$$x'_{\text{new}} - x'_{\text{old}} = -\Gamma_k^{-1} f.$$

The higher accuracy of numerical integration lowers the computer time expenditure only because of the low number of Newton iterations.

The algorithm is described by means of the schematic flow diagram given in

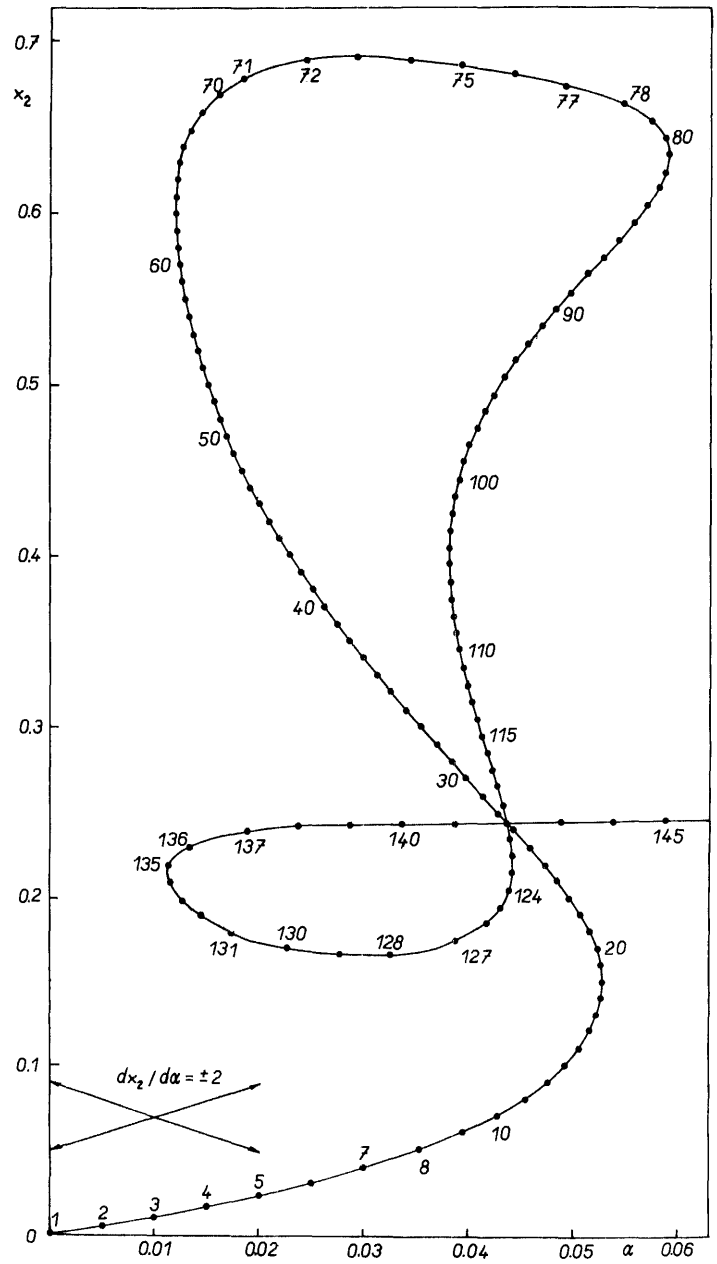

Fig. 2. The dependence $x_2(\alpha)$

Figure 1. The specification of the individual dummy (formal) parameters of the subroutine *DERPAR* is given in the subroutine heading.

The particular form of eq. (1) has to be programmed by the user as a subroutine *FCTN*. To illustrate the construction of the subroutine *FCTN*, an example is presented for a set of four nonlinear equations:

$$f_1 = \alpha(1 - x_3) \exp\,(10x_1/(1 + 10x_1/\gamma)) - x_3 = 0$$

$$f_2 = \alpha B(1 - x_3) \exp\,(10x_1/(1 + 10x_1/\gamma)) + \beta_1\theta_{c1} - 10(1 + \beta_1)x_1 = 0$$

$$f_3 = x_3 - x_4 + \alpha(1 - x_4) \exp\,(10x_2/(1 + 10x_2/\gamma)) = 0$$

$$f_4 = 10x_1 - 10(1 + \beta_2)x_2 + \alpha B(1 - x_4) \exp\,(10x_2/(1 + 10x_2/\gamma)) + \beta_2\theta_{c2} = 0.$$

Here γ, B, β_1, β_2, θ_{c1}, θ_{c2}, and α are physical parameters. The dependence $x_2(\alpha)$ is shown in Figure 2. Generally speaking, it is always convenient to transform the unknowns $x_1, x_2, \ldots, x_n, \alpha$ so that their values are of similar magnitude.

Applicability. This program can be used in the computation of the dependence of a solution on a parameter for sets of nonlinear equations, for nonlinear boundary value problems for ordinary differential equations [6, 7], for difference equations [8], etc.

ACKNOWLEDGMENTS

The author would like to thank the referee for his very valuable comments.

ALGORITHM 503
An Automatic Program for Fredholm Integral Equations of the Second Kind [D5]

KENDALL ATKINSON

University of Iowa

Key Words and Phrases: numerical analysis, linear integral equations, automatic algorithm, Nyström method
CR Categories: 5.18
Language: Fortran

DESCRIPTION

The two algorithms given here, *IESIMP* and *IEGAUS*, are a complement of [1] where the theoretical development is described.

ALGORITHM 504
GERK: Global Error Estimation for Ordinary Differential Equations [D]

L. F. SHAMPINE and H. A. WATTS

Sandia Laboratories

Key Words and Phrases: ordinary differential equations, initial value problems, global error estimation, Runge-Kutta-Fehlberg method, Fortran code GERK
CR Categories: 3.20, 5.17
Language: Fortran

DESCRIPTION

This algorithm is a complement to [1] where the theoretical development is described.

ALGORITHM 505
A List Insertion Sort for Keys With Arbitrary Key Distribution [S20]

WOLFGANG JANKO
Hochschule für Welthandel, Austria

Key Words and Phrases: sorting, searching, linked lists, lists, insertion
CR Categories: 5.31, 4.49, 3.74
Language: Basic Fortran

DESCRIPTION

The description of this algorithm, the experimental results, and the references are given in the author's paper, "A List Insertion Sort for Keys With Arbitrary Key Distribution," *ACM Trans. Math. Software 2*, 2(June 1976), 143–153.

ALGORITHM

```

ALGORITHM 506
HQR3 and EXCHNG: Fortran Subroutines for Calculating and Ordering the Eigenvalues of a Real Upper Hessenberg Matrix [F2]

G. W. STEWART
University of Maryland

Key Words and Phrases: eigenvalue, QR-algorithm
CR Categories: 5.14
Language: Fortran

DESCRIPTION

1. Usage

HQR3 is a Fortran subroutine to reduce a real upper Hessenberg matrix A to quasi-triangular form B by a unitary similarity transformation U:

$$B = U^T A U.$$

The diagonal of B consists of 1×1 and 2×2 blocks as illustrated below:

$$\begin{bmatrix} x & x & x & x & x & x \\ 0 & x & x & x & x & x \\ 0 & x & x & x & x & x \\ 0 & 0 & 0 & x & x & x \\ 0 & 0 & 0 & 0 & x & x \\ 0 & 0 & 0 & 0 & x & x \end{bmatrix}$$

The 1×1 blocks contain the real eigenvalues of A, and the 2×2 blocks contain the complex eigenvalues, a conjugate pair to each block. The blocks are ordered so that the eigenvalues appear in descending order of absolute value along the diagonal. The transformation U is postmultiplied into an array V, which presumably contains earlier transformations performed on A.

The decomposition produced by *HQR3* differs from the one produced by the *EISPACK* subroutine *HQR2* [2] in that the eigenvalues of the final quasi-triangular matrix are ordered. This ordering makes the decomposition essentially unique, which is important in some applications (e.g. see [4]). It should also be noted that when the eigenvalues $\lambda_1, \lambda_2, \ldots, \lambda_n$ of A are ordered so that $|\lambda_1| \geq |\lambda_2| \geq \cdots \geq |\lambda_n|$, and if $|\lambda_i| > |\lambda_{i+1}|$, then the first i columns of U form an orthonormal basis for the invariant subspace corresponding to $\lambda_1, \lambda_2, \ldots, \lambda_i$. In applications where it is desired to work with the matrix A in such a dominant invariant subspace,

*HQR*3 provides a convenient means for calculating a basis. The corresponding leading principal submatrix of B is a representation of A in that subspace. When an ordered quasi-triangular form is not required, the *EISPACK* program *HQR*2 will be slightly more efficient than *HQR*3.

The calling sequence for *HQR*3 is:

```
CALL HQR3 (A,V,N,NLOW,NUP,EPS,ER,EI,TYPE,NA,NV)
```

with (parameters preceded by an asterisk are altered by the subroutine):

*A	A doubly subscripted real array containing the matrix to be reduced. On return, A contains the final quasi-triangular matrix. The elements of the array below the third subdiagonal are unaltered by the subroutine.
*V	A doubly subscripted real array into which the reducing transformation is postmultiplied.
N	An integer containing the order of A and V.
NLOW, NUP	Integers prescribing what part of A is to be reduced. Specifically A(NLOW,NLOW−1) and A(NUP+1,NUP) are assumed zero and only the block from NLOW through NUP is reduced. However, the transformation is performed on all of the matrix A so that the final result is similar to A.
EPS	Convergence criterion. Maximal accuracy will be attained if EPS is set to β^{-t}, where β is the base of the floating-point word and t is the length of its fraction. Smaller values of EPS will increase the amount of work without significantly improving the accuracy.
*ER	A singly subscripted real array containing the real parts of the eigenvalues.
*EI	A singly subscripted real array containing the imaginary parts of the eigenvalues.
*TYPE	A singly subscripted integer array whose ith entry is: 0 if the ith eigenvalue is real; 1 if the ith eigenvalue is complex with positive imaginary part; 2 if the ith eigenvalue is complex with negative imaginary part; −1 if the ith eigenvalue was not successfully calculated. The entry 1 is always followed by a 2. Only elements NLOW through NUP of ER, EI, and TYPE are set by *HQR*3.
NA	The first dimension of the array A.
NV	The first dimension of the array V.

*HQR*3 can be used together with the *EISPACK* programs *ORTHES* and *ORTRAN* [2] to reduce a full matrix A to quasi-triangular form with the eigenvalues appearing in descending order of absolute value along the diagnonal,

```
CALL ORTHES(NA,N,NLOW,NUP,A,P)
CALL ORTRAN(NA,N,NLOW,NUP,A,P,V)
CALL HQR3(A,V,N,NLOW,NUP,EPS,ER,EI,TYPE,NA,NA)
```

where P is a singly subscripted scratch array of order N.

*HQR*3 requires the subroutines *EXCHNG*, *SPLIT*, and *QRSTEP*.

EXCHNG is a Fortran subroutine to interchange consecutive 1×1 and 2×2 blocks of an upper Hessenberg matrix. Specifically it is supposed that the upper Hessenberg matrix A has a block of order $b1$ starting at the lth diagonal element and a block of order $b2$ starting at the $(l + b1)$-th diagonal element (illustrated below for $n = 5, l = 2, b1 = 2, b2 = 1$):

$$\begin{array}{cc} & \begin{matrix} l & & & & \end{matrix} \\ \begin{matrix} \\ l \\ \\ \\ \\ \end{matrix} & \begin{bmatrix} x & x & x & x & x \\ 0 & x & x & x & x \\ 0 & x & x & x & x \\ 0 & 0 & 0 & x & x \\ 0 & 0 & 0 & 0 & x \end{bmatrix} \end{array}$$

EXCHNG produces an orthogonal similarity transformation W such that W^TAW has consecutive blocks of order $b2$ and $b1$ starting at the lth diagonal element (illustrated from the example above):

$$\begin{array}{cc} & \begin{matrix} l & & & & \end{matrix} \\ \begin{matrix} \\ l \\ \\ \\ \\ \end{matrix} & \begin{bmatrix} x & x & x & x & x \\ 0 & x & x & x & x \\ 0 & 0 & x & x & x \\ 0 & 0 & x & x & x \\ 0 & 0 & 0 & 0 & x \end{bmatrix} \end{array}$$

The eigenvalues associated with each block are interchanged along with the blocks. The transformation W is postmultiplied into the matrix V.

EXCHNG can be used to rearrange the blocks of the quasi-triangular matrix produced by *HQR*3. For example, one might wish to cluster a group of nearly equal eigenvalues at the top of the matrix before applying a deflation technique to uncouple them from the rest of the problem.

The calling sequence for *EXCHNG* is:

```
CALL EXCHNG(A,V,N,L,B1,B2,EPS,FAIL,NB,NV)
```

with (parameters preceded by an asterisk are altered by the subroutine):

*A	A doubly subscripted real array containing the matrix whose blocks are to be interchanged. Only rows and columns L through L + B1 + B2 − 1 are transformed. Elements of the array A below the third subdiagonal are not altered.
*V	A doubly subscripted array containing the matrix V into which the reducing transformation is to be accumulated. Only columns L through L + B1 + B2 − 1 are altered.
N	An integer containing the order of A and V.
L	An integer containing the leading diagonal position of the blocks.
B1	An integer containing the size of the first block.
B2	An integer containing the size of the second block.
EPS	A convergence criterion (cf. EPS in the calling sequence for *HQR*3).
*FAIL	A logical variable that on normal return is false. If the iteration to interchange the blocks failed, it is set to true.
NA	The first dimension of the array A.
NV	The first dimension of the array V.

By repeated applications of *EXCHNG* the eigenvalues of a quasi-triangular matrix can be arranged in any desired order.

EXCHNG requires the subroutine *QRSTEP*.

2. Method and Programming Details

*HQR*3 uses the implicit double-shift *QR* algorithm to reduce A to quasi-triangular form (for the theoretical background see [3, 5]). The program is essentially a Fortran variant of part of the Algol program *hqr*2 in the *Numerische Mathematik* handbook series [1] with these differences:

(1) The calling sequence is somewhat different.

(2) Eigenvectors are not computed.

(3) The parameters NLOW and NUP are not comparable to the parameters *low* and *upp* of *hqr*2. Specifically, in *HQR*3 rows 1 through N of V are transformed; whereas in *hqr*2 only rows *low* through *upp* are transformed.

(4) The code that performs the *QR* iterations in *hqr*2 is replaced by a call to the subroutine *QRSTEP*.

(5) After a 1×1 or 2×2 block has been isolated, the subroutine *EXCHNG* is used to position it correctly among the previously isolated blocks. It should be realized that *EXCHNG* is a numerical algorithm and may change an ill-conditioned eigenvalue in a block significantly. This means that after interchanging two blocks with ill-conditioned eigenvalues that are very nearly equal in absolute value, the eigenvalues may still not be in descending order of absolute value. Since numerically the absolute values of these eigenvalues cannot be told apart, this phenomenon is not of much importance.

The convergence criterion is the same for both programs. A subdiagonal element A(I + 1, I) is regarded as negligible it it is less than or equal to EPS * (ABS(A(I, I)) + ABS(A(I + 1, I + 1))). If 10 or 20 iterations are performed without convergence, an ad hoc shift is introduced to break up any cycling. If 30 iterations are performed without convergence, the subroutine gives up. Although when this happens the matrix returned is not quasi-triangular, it is still almost exactly similar to the original matrix, and the similarity transformation has been accumulated in V.

EXCHNG works as follows. The first block is used to determine an implicit *QR* shift. An arbitrary *QR* step is performed on both blocks to eliminate the uncoupling between them. Then a sequence of *QR* steps using the previously determined shift

is performed on both blocks. Except in ill-conditioned cases, a block of size $B1$ having the eigenvalues of the first block will emerge in the lower part of the array occupied by both blocks, usually in one or two steps. If 30 iterations pass without convergence (the criterion is the same as in *HQR3*), the subroutine gives an error return.

Both *HQR3* and *EXCHNG* use the subroutine *QRSTEP* to perform the *QR* iterations. In addition, *HQR3* uses the subroutine *SPLIT* to separate real eigenvalues of a 2×2 block.

HQR3 and EXCHNG: Fortran Subroutines for Calculating and Ordering the Eigenvalues of a Real Upper Hessenberg Matrix [G.W. Stewart, *ACM Trans. Math. Softw. 2*, 3(Sept. 1976), 275-280]

David S. Flamm and Robert A. Walker [Received 21 September 1981, accepted 20 February 1982]

D.S. Flamm, Aerospace Corporation, P.O. Box 92957, Los Angeles, CA 90009; R.A. Walker, Integrated Systems, 151 University Avenue, Suite 400, Palo Alto, CA 94301.

The following four corrections should be made to program HQR3 [1, 2]:

(1) Line HQR 720 in [2] should have the comparison ".LE." instead of ".LT.".
(2) Line HQR 1850 in [2] should branch to "220" instead of "230".
(3) Line HQR 2130 should read "DO 250 I = NLOW, NU", instead of "DO 250 I = 1, NU".
(4) Line EXC 410 should read "R = AMAX1(ABS(P), ABS(Q))" instead of "R = AMAX1(P,Q)".

The following example illustrates why the first two corrections are necessary. Apply HQR3 to the matrix

$$\begin{bmatrix} 0 & -2 & 0 & 0 & 0 & 0 \\ 3 & 5 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 4 & 0 & 0 \\ 0 & 0 & -4 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & -1 & 0 \end{bmatrix}.$$

An uncorrected version of HQR3 will yield a division by zero in line HQR 1060 of [2] as a result of the test in (1). In checking for a zero subdiagonal element, the criterion is the sum of the magnitudes of the two diagonals. As the example shows, when both diagonals are zero, the .LT. test fails for an exactly zero subdiagonal element.

Without correction (2), when exchanging two upper real roots with a lower 2 × 2 block, only the bottom root is tested and exchanged, leaving the possibility of misordering of the top root. The example above also demonstrates this problem.

Without correction (3), the program would give the wrong diagonals in an unusual case where part of a matrix was being triangularized and the routine failed to converge.

Correction (4) is necessary when the superdiagonal element is zero between two real roots, leaving the possibility that the maximum of (P,Q) is P = 0 for Q negative. (If (P,Q) are both zero, no exchange is required and the program properly returns.)

DESCRIPTION

1. Introduction

The purpose of the procedures presented here is to determine the interpolating quintic natural spline function $S(x)$ for the set of data points (x_i,y_i), $i = N1, N1+1, \ldots, N2$, where it is assumed that $x_{N1} < x_{N1+1} < \cdots < x_{N2}$. The interpolating quintic natural spline function $S(x)$ with the knots $x_{N1}, \ldots, x_{N2}$ has the following properties: (i) $S(x)$ is a polynomial of degree 5 in each interval (x_i, x_{i+1}), $i = N1, \ldots, N2-1$. (ii) $S(x)$ and its derivatives $S'(x)$, $S''(x)$, $S'''(x)$, and $S''''(x)$ are continuous in $[x_{N1},x_{N2}]$. (iii) $S'''(x_{N1}) = S'''(x_{N2}) = S''''(x_{N1}) = S''''(x_{N2}) = 0$. (iv) $S(x_i) = y_i$, $i = N1, \ldots, N_2$. It is known that if $N2 > N1+1$, then there is a unique quintic natural spline function which has the properties (i)–(iv). (See, for example, Greville [3, 4].) This spline function can be represented in the form

$$S(x) = y_i + B_i t + C_i t^2 + D_i t^3 + E_i t^4 + F_i t^5 \qquad (1)$$

with $t = x - x_i$ for $x_i \leq x < x_{i+1}$, $i = N1, \ldots, N2-1$.

The procedure *QUINAT* computes the coefficients B_i, C_i, D_i, E_i, F_i of the quintic natural spline represented as in eq. (1) for an arbitrary set of data points (x_i,y_i) as previously specified. This procedure is much faster than the procedure *NATSPLINE* of ACM Algorithm 472 [6] with $m = 3$. An even faster procedure, *QUINEQ*, is provided for the case in which the knots x_i are known to be equidistant. In this case it is not necessary to specify the values of x_i. The representation (1) is still used, but now $t = (x-x_i)/h$, where $h = x_{i+1}-x_i$, the constant spacing of the knots.

If at one or more of the knots x_i one also specifies the derivative y_i', thus requiring $S'(x_i) = y_i'$, then one has to give up the condition that $S''''(x)$ be continuous at the knot x_i. If the second derivative y_i'' is also specified, thus requiring $S''(x_i) = y_i''$, then one must also give up the condition that $S'''(x)$ be continuous at x_i. *QUINAT* is designed so that it can be used in these cases with the convention that if two consecutive knots are equal, say $x_j = x_{j+1}$, then $S(x_j) = y_j$ and $S'(x_j) = y_{j+1}$, and if three consecutive knots are equal, say $x_j = x_{j+1} = x_{j+2}$, then $S(x_j) = y_j$, $S'(x_j) = y_j$, and $S''(x_j) = y_{j+2}$. Thus in order to use *QUINAT* in the case that both the value y_j and the first derivative y_j' are specified at x_j, one increases the number of knots by 1 setting $x_{j+1} = x_j$ (and renumbering the knots and values to the right). Then one chooses $y_{j+1} = y_j'$. The spline function computed by *QUINAT* will have the property $S(x_j) = y_j$ and $S'(x_j) = y_{j+1}$. One may use *QUINAT* in a similar manner if the second derivative is also specified at a knot x_j. Complete details are given in the comment of the procedure *QUINAT*.

If the values of the function y_i and the values of the first derivative y_i' are specified at all the knots x_i, then $S''''(x)$ need not be continuous at the knots and $S''''(x_{N1})$ and $S''''(x_{N2})$ need not be zero. Such a spline is said to be of deficiency 2. The procedure *QUINDF* computes the coefficients of the quintic natural spline of deficiency 2 when the values of the function y_i and the values of the first derivative y_i' are given at each knot. Although *QUINAT* could be used for this case as just described, *QUINDF* is much faster and needs much less storage space.

It is not of interest to specify the values of the function and its first and second derivatives at each knot, because in this case the quintic polynomial is completely determined in each interval independently of all other intervals.

2. Method of Calculation

QUINAT. As in the general case of Algorithm 472 [6], the calculation of the coefficients of the spline function is carried out in a numerically stable manner following a method described by Anselone and Laurent [1]. The basic ideas on which the method is based were given earlier by Schoenberg [7]. The method is specialized to the case of the quintic natural spline and uses minimum support B-splines [2, 3] of degree 2 to form a basis for the class of third derivatives of the quintic natural splines. Instead of specializing the formulas of Algorithm 472 [6] by setting $m = 3$, we derive the necessary formulas directly and we choose a different numbering and a different normalization for the B-splines.

We first assume that the knots are strictly monotone increasing, that is, $x_{N1} < x_{N1+1} < \cdots < x_{N2}$. In order to simplify the notation, we choose $N1 = 0$ and let $N2 = n$, so that the data points are denoted by (x_i, y_i), $i = 0, 1, \ldots, n$. We denote by $M_i(x)$ the B-spline of degree 2, vanishing outside the interval (x_{i-1}, x_{i+2}). We let $h_i = x_{i+1} - x_i$, $t = x - x_{i-1}$, $u = x - x_i$, $v = x - x_{i+1}$.

Then we have

$$\begin{aligned} M_i(x) &= At^2, && x_{i-1} \le x < x_i, \\ &= B + Cu - Du^2, && x_i \le x < x_{i+1}, \\ &= E(v - h_{i+1})^2, && x_{i+1} \le x < x_{i+2}, \end{aligned} \tag{2}$$

where

$$A = 1/[h_{i-1}(h_{i-1} + h_i)], \quad B = h_{i-1}/(h_{i-1} + h_i), \quad C = 2/(h_{i-1} + h_i), \tag{3}$$

$$D = (h_{i-1} + 2h_i + h_{i+1})/[(h_{i-1} + h_i)h_i(h_i + h_{i+1})], \quad E = 1/[h_{i+1}(h_i + h_{i+1})].$$

Now since the third derivative $S'''(x)$ vanishes outside the interval (x_0, x_n), it has a unique representation of the form

$$S'''(x) = \sum_{j=1}^{n-2} 60\gamma_j M_j(x). \tag{4}$$

In order to determine the γ_j, we make use of the relation

$$\int_{-\infty}^{\infty} M_i(x) S'''(x) dx = 2(S(x_i, x_{i+1}, x_{i+2}) - S(x_{i-1}, x_i, x_{i+1})) \tag{5}$$

using the usual notation for divided differences. This relation is easily obtained by integration by parts. If we multiply eq. (4) by $\frac{1}{2}M_i(x)$, $i = 1, 2, \ldots, n-2$, and integrate, we obtain a well-conditioned positive definite pentadiagonal system of linear equations for the determination of the γ_j:

$$\begin{aligned}
d_1\gamma_1 + e_1\gamma_2 + f_1\gamma_3 &= c_1 \\
e_1\gamma_1 + d_2\gamma_2 + e_2\gamma_3 + f_2\gamma_4 &= c_2 \\
f_{i-2}\gamma_{i-2} + e_{i-1}\gamma_{i-1} + d_i\gamma_i + e_i\gamma_{i+1} + f_i\gamma_{i+2} &= c_i, \quad i = 3, 4, \ldots, n-4 \qquad (6) \\
f_{n-5}\gamma_{n-5} + e_{n-4}\gamma_{n-4} + d_{n-3}\gamma_{n-3} + e_{n-3}\gamma_{n-2} &= c_{n-3} \\
f_{n-4}\gamma_{n-4} + e_{n-3}\gamma_{n-3} + d_{n-2}\gamma_{n-2} &= c_{n-2}
\end{aligned}$$

where

$$\begin{aligned}
d_i &= T_1 + T_2 + T_3, & i &= 1,2,\ldots,n-2, \\
e_i &= T_4 + T_5, & i &= 1,2,\ldots,n-3, \\
f_i &= T_6, & i &= 1,2,\ldots,n-4, \\
c_i &= y_{i,i+1,i+2} - y_{i-1,i,i+1}, & i &= 1,2,\ldots,n-2.
\end{aligned}$$

Here $y_{i,i+1,i+2}$ denotes the second divided difference of the given $\{y_i\}$, and for the T_i one finds, after some algebraic manipulation, the following formulas:

$$\begin{aligned}
T_1 &= 6h_{i-1}^3/(h_{i-1} + h_i)^2 \\
T_2 &= h_i\{30h_{i-1}^2h_{i+1}^2 + (h_{i-1} + h_{i+1})h_i(40h_{i-1}h_{i+1} + 14h_i^2) \\
&\quad + h_i^2[16(h_{i-1}^2 + h_{i+1}^2) + 42h_{i-1}h_{i+1} + 4h_i^2]\}/[(h_{i-1} + h_i)^2(h_i + h_{i+1})^2] \\
T_3 &= 6h_{i+1}^3/(h_i + h_{i+1})^2 \\
T_4 &= h_i^2[h_{i-1}(h_i + h_{i+1}) + 3(h_{i-1} + h_i)(h_i + 3h_{i+1})]/[(h_{i-1} + h_i)(h_i + h_{i+1})^2] \\
T_5 &= h_{i+1}^2[h_{i+2}(h_i + h_{i+1}) + 3(h_{i+1} + h_{i+2})(3h_i + h_{i+1})]/[(h_i + h_{i+1})^2(h_{i+1} + h_{i+2})] \\
T_6 &= h_{i+1}^3/[(h_i + h_{i+1})(h_{i+1} + h_{i+2})].
\end{aligned}$$

Note that all terms in these expressions are positive; consequently no cancellations can occur. The system of equations (6) can be solved for the γ_j by using Gaussian elimination without pivoting. When the coefficients γ_j have been found, $S'''(x)$ is given by eq. (4). Remembering that $M_j(x)$ vanishes outside the interval (x_{j-1}, x_{j+2}) and making use of eqs. (1) through (4), we easily find that

$$\left.\begin{aligned}
D_i/10 &= (\gamma_{i-1}h_i + \gamma_i h_{i-1})/(h_{i-1} + h_i) \\
E_i/5 &= (\gamma_i - \gamma_{i-1})/(h_{i-1} + h_i) \\
F_i &= (1/h_i)[(\gamma_{i+1} - \gamma_i)/(h_i + h_{i+1}) \\
&\quad - (\gamma_i - \gamma_{i-1})/(h_{i-1} + h_i)].
\end{aligned}\right\} \quad i = 2, 3, \ldots, n-3.$$

These formulas can also be used for $i = 0, 1, n-2, n-1$ by adding the convention that $\gamma_{-1} = \gamma_0 = \gamma_{n-1} = \gamma_n = 0$. (Note that $D_0 = E_0 = 0$ as they should.) Finally we make use of the continuity of $S(x)$ and its first four derivatives at x_i to obtain the following formulas for B_i and C_i:

$$\begin{aligned}
B_i &= \frac{h_{i-1}}{h_{i-1} + h_i}\frac{y_{i+1} - y_i}{h_i} + \frac{h_i}{h_{i-1} + h_i}\frac{y_i - y_{i-1}}{h_{i-1}} - D_ih_{i-1}h_i + E_ih_{i-1}h_i(h_{i-1} - h_i) \\
&\quad - \frac{h_{i-1}h_i}{h_{i-1} + h_i}(F_{i-1}h_{i-1}^3 + F_ih_i^3) \\
C_i &= \frac{1}{h_{i-1} + h_i}\left(\frac{y_{i+1} - y_i}{h_i} - \frac{y_i - y_{i-1}}{h_{i-1}}\right) + D_i(h_{i-1} - h_i) \\
&\quad - E_i\frac{h_{i-1}^3 + h_i^3}{h_{i-1} + h_i} + \frac{1}{h_{i-1} + h_i}(F_{i-1}h_{i-1}^4 - F_ih_i^4).
\end{aligned}$$

These formulas are valid for $i = 1, 2, \ldots, n-1$. In addition, we have for the endpoints:

$$C_0 = C_1 - 10F_0h_0^3, \qquad B_0 = (y_1 - y_0)/h_0 - C_0h_0 - F_0h_0^4,$$

$$C_n = C_{n-1} + 10F_{n-1}h_{n-1}^3, \qquad B_n = (y_n - y_{n-1})/h_{n-1} + C_n h_{n-1} - F_{n-1}h_{n-1}^4.$$

In the preceding discussion we have assumed that the knots were distinct. We can relax this condition and allow two or three consecutive knots to be equal. The procedure *QUINAT* has been written in such a way that if $x_j = x_{j+1}$, then $S(x_j) = y_j$ and $S'(x_j) = y_{j+1}$, and if $x_j = x_{j+1} = x_{j+2}$, then, in addition, $S''(x_j) = y_{j+2}$. The use of *QUINAT* in these cases is fully explained in its comment.

QUINEQ. The calculation of the coefficients in *QUINEQ* for the case of equidistant knots is carried out in the same manner as is the calculation of the coefficients in *QUINAT* for the general case. However, there are a number of simplifications which result in considerable economy of computational effort. It is not necessary to specify x_i. Hence we can assume $x_i = i$. Then $h_i = 1$ for all i, and the coefficients of $M_i(x)$ are independent of i as are also the d_i, e_i, f_i of the pentadiagonal system (6) for the γ_i. Thus eqs. (2) reduce to

$$M_i(x) = \begin{cases} \frac{1}{2}t^2, & i-1 \le x < i, \\ \frac{1}{2} + u - u^2, & i \le x < i+1, \\ \frac{1}{2}(v-1)^2, & i+1 \le x < i+2, \end{cases}$$

with $t = x - (i-1)$, $u = x - i$, $v = x - (i+1)$.

Instead of eq. (4) it is convenient to take

$$S'''(x) = \sum_{j=0}^{n-3} 120\gamma_j M_{j+1}(x).$$

The divided differences become ordinary differences so that eq. (5) becomes:

$$\int_{-\infty}^{\infty} M_i(x)S'''(x)\,dx = \Delta^3 S(x_{i-1}).$$

The pentadiagonal system (6) for the determination of γ_j becomes:

$$\begin{aligned}
66\gamma_0 + 26\gamma_1 + \gamma_2 &= \Delta^3 y_0 \\
26\gamma_0 + 66\gamma_1 + 26\gamma_2 + \gamma_3 &= \Delta^3 y_1 \\
\gamma_{i-2} + 26\gamma_{i-1} + 66\gamma_i + 26\gamma_{i+1} + \gamma_{i+2} &= \Delta^3 y_i, \quad i = 2, 3, \ldots, n-5 \\
\gamma_{n-6} + 26\gamma_{n-5} + 66\gamma_{n-4} + 26\gamma_{n-3} &= \Delta^3 y_{n-4} \\
\gamma_{n-5} + 26\gamma_{n-4} + 66\gamma_{n-3} &= \Delta^3 y_{n-3}.
\end{aligned}$$

The equations for the determination of the spline function coefficients then become:

$$\begin{aligned}
D_i/10 &= \gamma_{i-2} + \gamma_{i-1} & B_i &= \tfrac{1}{2}(y_{i+1} - y_{i-1} - F_{i-1} - F_i) - D_i \\
E_i/5 &= \gamma_{i-1} - \gamma_{i-2} & C_i &= \tfrac{1}{2}(y_{i+1} + y_{i-1} + F_{i-1} - F_i) - y_i - E_i. \\
F_i &= \gamma_i - \gamma_{i-1} - \gamma_{i-1} + \gamma_{i-2}
\end{aligned}$$

These formulas are valid for $i = 1, 2, \ldots, n-1$ with the convention that $\gamma_{-1} = \gamma_{n-2} = \gamma_{n-1} = 0$. The formula for F_i can be used for $i = 0$ by setting $\gamma_{-2} = 0$. (Note that $D_0 = E_0 = 0$ as they should.) Finally the coefficients B_i and C_i at the endpoints are given by

$$\begin{aligned}
C_0 &= C_1 - 10F_0, & B_0 &= y_1 - y_0 - C_0 - F_0, \\
C_n &= C_{n+1} + 10F_{n-1}, & B_n &= y_n - y_{n-1} + C_n - F_{n-1}.
\end{aligned}$$

QUINDF. We now assume $S(x_i) = y_i$ and $S'(x_i) = y_i'$ are specified at each of the knots. We must exclude the possibility that $x_i = x_{i+1}$ as this would imply a multiplicity of 4, which is not feasible for quintic splines.

We could proceed as in the calculation of *QUINAT* by using minimum support B-splines of degree 2 to form a basis for the class of third derivatives of the quintic natural splines. Of course, the B-splines would also have to be of deficiency 2. We

would again obtain a pentadiagonal system of equations which could be solved and then the coefficients for the deficient quintic natural spline could be calculated. An algorithm based on this method was developed and tested by the present authors [5].

However, we have found that we can obtain a more efficient algorithm by imposing the appropriate continuity conditions directly on eq. (1) at the knots. A similar method was used by Späth [8] to obtain an algorithm for the deficient quintic spline but with different end conditions. (He specified the second derivatives at the endpoints of the interval instead of requiring the third derivative to be zero at the endpoints as for the natural spline.)

Using eq. (1) we see at once that $S'(x_i) = y_i'$ implies $B_i = y_i'$. Then imposing the requirement that $S(x)$, $S'(x)$, and $S''(x)$ be continuous at x_{i+1}, $i = 0, 1, \ldots, n-2$, we obtain by setting $t = h_i = x_{i+1} - x_i$ in eq. (1):

$$\begin{aligned} y_{i+1} &= y_i + B_i h_i + C_i h_i^2 + D_i h_i^3 + E_i h_i^4 + F_i h_i^5 \\ B_{i+1} &= B_i + 2C_i h_i + 3D_i h_i^2 + 4E_i h_i^3 + 5F_i h_i^4 \\ C_{i+1} &= C_i + 3D_i h_i + 6E_i h_i^2 + 10F_i h_i^3. \end{aligned} \tag{7}$$

If we multiply these three equations by $10/h_i^3$, $-4/h_i^2$, $1/h_i$, respectively, and add the results, we eliminate E_i and F_i and obtain

$$D_i = 10\,\frac{y_{i+1} - y_i}{h_i^3} - \frac{4B_{i+1} + 6B_i}{h_i^2} + \frac{C_{i+1} - 3C_i}{h_i}. \tag{8}$$

We note that $D_i = S'''(x_i + 0)/6$. In order to obtain a similar expression for $S'''(x_i - 0)/6$, we replace the subscript $i+1$ by $i-1$ consistently (noting that then $h_i = x_{i+1} - x_i$ is to be replaced by $x_{i-1} - x_i = -h_{i-1}$). We obtain

$$\tfrac{1}{6}S'''(x_i - 0) = 10\,\frac{y_i - y_{i-1}}{h_{i-1}^3} - \frac{6B_i + 4B_{i-1}}{h_{i-1}^2} + \frac{3C_i - C_{i-1}}{h_{i-1}}. \tag{9}$$

Now since the third derivative is continuous at x_i, we can equate the values of $S'''(x_i + 0)/6$ and $S'''(x_i - 0)/6$ in eqs. (8) and (9) to obtain the following set of equations for the C_i:

$$\begin{aligned} -\frac{1}{h_{i-1}} C_{i-1} + \left(\frac{3}{h_{i-1}} + \frac{3}{h_i}\right) C_i - \frac{1}{h_i} C_{i+1} \\ = 10\left(\frac{y_{i+1} - y_i}{h_i^3} - \frac{y_i - y_{i-1}}{h_{i-1}^3}\right) - \frac{4B_{i+1} + 6B_i}{h_i^2} + \frac{6B_i + 4B_{i-1}}{h_{i-1}^2}. \end{aligned}$$

These equations hold for $i = 1, 2, \ldots, n-1$. Two additional equations can be obtained from the conditions $S'''(x_0) = S'''(x_n) = 0$ by setting $i = 0$ in eq. (8) and by setting $i = n$ in eq. (9):

$$\begin{aligned} \frac{3}{h_0} C_0 - \frac{1}{h_0} C_1 &= 10\,\frac{y_1 - y_0}{h_0^3} - \frac{4B_1 + 6B_0}{h_0^2}, \\ -\frac{1}{h_{n-1}} C_{n-1} + \frac{3}{h_n} C_n &= -10\,\frac{y_n - y_{n-1}}{h_{n-1}^3} + \frac{6B_n + 4B_{n-1}}{h_{n-1}^2}. \end{aligned}$$

This system of $n+1$ equations is solved to obtain the C_i. If we make the substitutions

$$\begin{aligned} x &= D_i, & p &= (y_{i+1} - y_i - B_i h_i - C_i h_i^2)/h_i^3, \\ y &= E_i h_i, & q &= (B_{i+1} - B_i - 2C_i h_i)/h_i^2, \\ z &= F_i h_i^2, & r &= (C_{i+1} - C_i)/h_i, \end{aligned}$$

then for each i eqs. (7) form a system of three equations in the three unknowns x, y, z, and the system is solved by Gaussian elimination. The backward substitution

yields formulas for z, y, x in the following order:

$$\begin{cases} g &= q - 3p \\ z &= r - 3(p + g) \\ y &= g - z - z \\ x &= p - y - z \\ F_i &= z/h_i^2 \\ E_i &= y/h_i \\ D_i &= x. \end{cases}$$

3. Tests

These procedures have been tested in Algol 60 on the Telefunken TR-440 computer at the Leibniz-Rechenzentrum of the Bavarian Academy of Sciences, Munich, and in Algol W on the IBM 360/67 at the Stanford Center for Information Processing. The latter tests included timing tests of the procedures with the number of knots $N = N2 - N1 + 1$ ranging up to 1000. The time was found to be approximately proportional to the number N of knots. The time T in seconds for the execution of the procedure *QUINAT* was found to be approximately $T = .00193N$, whereas for the procedure *NATSPLINE* of Algorithm 472 [6] with $m = 3$ it was found to be $T = .0120N$, or over six times as great. For the procedure *QUINEQ* the time was approximately $T = .00064N$, whereas for the procedure *NATSPLINEEQ* of Algorithm 472 [6] with $m = 3$ it was $T = .0038N$, or nearly six times as great. For the procedure *QUINDF* the time was approximately $T = .00087N$, whereas for the procedure *QUINAT* with $2N$ knots, consecutive knots being equal in pairs, the time was $T = .00325N$, or nearly four times as great. Moreover, to compute the same results the procedure *QUINAT* requires approximately twice as much storage for the arrays used as does the procedure *QUINDF*. Note also that from the preceding formula for the time required by the procedure *QUINAT*, the time for $2N$ distinct knots would be $T = .00386N$, which can be compared with $T = .00325N$ given above for N pairs of equal knots. The reduction for the case of double knots occurs because some calculations are omitted when knots are coincident.

These timing comparisons show that it is definitely advantageous to use these special procedures for the quintic natural spline rather than the general cases given in Algorithm 472 [6] with $m = 3$.

Tests of the accuracy and correctness of the coefficients computed by the procedures *QUINAT*, *QUINEQ*, and *QUINDF* were carried out as described in Algogorithm 472 [6]. Table I shows the results of a typical run using *QUINDF* for 5 nonequidistant points. The values of the function and its first derivatives were specified. The first line of each entry gives the tabulated quantities at the given

Table I. Quintic Spline Calculated by *QUINDF*
(Machine precision approximately 7 decimal digits.)

x	S(x)	S'(x)	S"(x)/2	S"'(x)/6	S""(x)/24	$S^V(x)/120$

	29.00000	-30.00000	-7.754811	-1.907349'-06	11.26443	6.509618
4.000000	29.00000	-30.00000				

value of x which is the lefthand endpoint of the subinterval; the second line of each entry gives the tabulated values at the righthand endpoint of the same subinterval. The close agreement of the quantities $S(x)$, $S'(x)$, $S''(x)/2$, and $S'''(x)/6$ shows that the quintic spline function and its derivatives satisfy the required continuity conditions. This is a good indication of the correctness of the results. Note that the fourth and fifth derivatives are discontinuous. Essentially the same results were obtained by using *QUINAT* with 10 knots, in equal pairs. In addition, accuracy and timing tests were carried out for large values of N, including $N = 1000$ and 5000, and produced very satisfactory results.

ALGORITHM

```
PROCEDURE QUINAT(INTEGER VALUE N1,N2; REAL ARRAY X,Y,B,C,D,E,F(*));
COMMENT  QUINAT COMPUTES THE COEFFICIENTS OF A QUINTIC NATURAL SPLINE
   S(X) INTERPOLATING THE ORDINATES Y(I) AT POINTS X(I), I = N1
   THROUGH N2.  FOR XX IN (X(I),X(I+1)) THE VALUE OF THE SPLINE
   FUNCTION S(XX) IS GIVEN BY THE FIFTH DEGREE POLYNOMIAL:
   S(XX) = ((((F(I)*T+E(I))*T+D(I))*T+C(I))*T+B(I))*T+Y(I)
   WITH T = XX - X(I).
   INPUT:
     N1,N2  SUBSCRIPT OF FIRST AND LAST DATA POINT RESPECTIVELY,
            IT IS REQUIRED THAT N2 > N1 + 1,
     X,Y(N1::N2)  ARRAYS WITH X(I) AS ABSCISSA AND Y(I) AS ORDINATE
            OF THE I-TH DATA POINT.  THE ELEMENTS OF THE ARRAY X
            MUST BE STRICTLY MONOTONE INCREASING (BUT SEE BELOW FOR
            EXCEPTIONS TO THIS).
   OUTPUT:
     B,C,D,E,F(N1::N2)  ARRAYS COLLECTING THE COEFFICIENTS OF THE
            QUINTIC NATURAL SPLINE S(XX) AS DESCRIBED ABOVE.
            SPECIFICALLY  B(I) = S'(X(I)),  C(I) = S"(X(I))/2,
            D(I) = S"'(X(I))/6,  E(I) = S""(X(I))/24,
            F(I) = S""'(X(I)+0)/120.  F(N2) IS NEITHER USED OR
            ALTERED.  THE ARRAYS B,C,D,E,F MUST ALWAYS BE DISTINCT.
   OPTIONS:
     1.  THE REQUIREMENT THAT THE ELEMENTS OF THE ARRAY X BE
         STRICTLY MONOTONE INCREASING CAN BE RELAXED TO ALLOW TWO
         OR THREE CONSECUTIVE ABSCISSAS TO BE EQUAL AND THEN
         SPECIFYING VALUES OF THE FIRST AND SECOND DERIVATIVES OF
         THE SPLINE FUNCTION AT SOME OF THE INTERPOLATING POINTS.
         SPECIFICALLY
         IF X(J) = X(J+1) THEN S(X(J)) = Y(J) AND S'(X(J)) = Y(J+1),
         IF X(J) = X(J+1) = X(J+2) THEN IN ADDITION S"(X(J)) =Y(J+2).
         NOTE THAT S""(X) IS DISCONTINUOUS AT A DOUBLE KNOT AND IN
         ADDITION S"'(X) IS DISCONTINUOUS AT A TRIPLE KNOT.  AT A
         DOUBLE KNOT, X(J) = X(J+1), THE OUTPUT COEFFICIENTS HAVE THE
         FOLLOWING VALUES:
           B(J) = S'(X(J))       = B(J+1)
           C(J) = S"(X(J))/2     = C(J+1)
           D(J) = S"'(X(J))/6    = D(J+1)
           E(J) = S""(X(J)-0)/24     E(J+1) = S""(X(J)+0)/24
           F(J) = S""'(X(J)-0)/120  F(J+1) = S""'(X(J)+0)/120
         THE REPRESENTATION OF S(XX) REMAINS VALID IN ALL INTERVALS
         PROVIDED THE REDEFINITION Y(J+1) := Y(J) IS MADE
```

```
          IMMEDIATELY AFTER THE CALL OF THE PROCEDURE QUINAT.  AT A      42.
          TRIPLE KNOT, X(J) = X(J+1) = X(J+2), THE OUTPUT COEFFICIENTS   43.
          HAVE THE FOLLOWING VALUES:                                     44.
            B(J) = S'(X(J))        = B(J+1) = B(J+2)                     45.
            C(J) = S"(X(J))/2      = C(J+1) = C(J+2)                     46.

REMARK ON ALGORITHM 507

Procedures for Quintic Natural Spline Interpolation
[J.G. Herriot and C.H. Reinsch, *ACM Trans. Math. Softw. 2*, 3 (June 1976), 281–289.]

R.J. Hanson [Received 10 March 1982; accepted 10 March 1982]
Numerical Mathematics Division 5642, Sandia National Laboratories, Albuquerque, NM 87185

Line number 82. of Algorithm 507

IF R ¬= 0.0 THEN D(M) := D(M) + 6.0*R*R2/(QR*QR)

is changed to the mathematically equivalent line

IF ABS(R) > 0.0 THEN D(M) := D(M) + 6.0*R*R2/(QR*QR)

The change is made for this reason: the character "¬" will often not transmit correctly in the *Collected Algorithms from ACM* distribution process.

ALGORITHM 508
Matrix Bandwidth and Profile Reduction [F1]

College of William and Mary

Key Words and Phrases: bandwidth reduction, diameter of a graph, profile reduction, sparse matrices
CR Categories: 5.14, 5.32
Language: Fortran

DESCRIPTION

Introduction

This program, REDUCE, reduces the bandwidth and profile of sparse symmetric matrices, using row and corresponding column permutations. It is a realization of the algorithm described by the authors in [4]. It was extensively tested and compared with several other programs [5] and was found to be considerably faster than the others, generally superior for bandwidth reduction and as satisfactory as any other for profile reduction.

Outline of the Method

Only an outline of the algorithm is given here; a detailed description can be found in [4]. The algorithm can best be described in terms of the *adjacency graph* G, which has the characteristic that there is an edge in G between vertices v_i and v_j if and only if $a_{ij} \neq 0$ and $i \neq j$.

Step 1. Find the endpoints of a *pseudodiameter*, i.e. a pair of vertices that are at nearly maximal distance apart. This is done by a finite, iterative process of determining a vertex that is a maximum distance away from a given vertex.

Step 2. Given pseudodiameter endpoints u and v of distance k apart, partition the set of vertices into *levels* $L_1, L_2, \ldots, L_k$ such that adjacent vertices in G are in the same or adjacent levels and such that $\max_i | L_i |$ is nearly minimized.

Step 3. Number the vertices of G, level by level, beginning at an endpoint of the pseudodiameter.

Matrix Data Structure

Sparse matrices are typically stored in some compact form which takes advantage of the sparsity. The data structure assumed here is one which is commonly used in

Received 17 May 1975 and 3 March 1976.

Authors' addresses: H.L. Crane Jr., Comptek Research, Inc., Hyattsville, MD 20782; N.E. Gibbs, W.G. Poole Jr., P.K. Stockmeyer, Department of Mathematics, College of William and Mary, Williamsburg, VA 23185.

bandwidth and profile schemes, e.g. [1], [2], [3], and [6]. Subroutine REDUCE accepts as input a *connection table*, C, representing the indices of the nonzero elements of the $n \times n$ matrix A. The connection table has n rows and m columns where m is the number of off-diagonal nonzero elements in the row which has a maximum number of off-diagonal nonzero elements (i.e. the maximum degree of the graph G). The entries in row i of C are the column indices of the nonzero elements in row i of the matrix A. For example, if

$$A = \begin{bmatrix} X & X & 0 & 0 & X \\ X & X & 0 & X & X \\ 0 & 0 & X & X & 0 \\ 0 & X & X & X & 0 \\ X & X & 0 & 0 & X \end{bmatrix}$$

where X represents a nonzero element, then

$$C = \begin{bmatrix} 2 & 5 & 0 \\ 1 & 4 & 5 \\ 4 & 0 & 0 \\ 2 & 3 & 0 \\ 1 & 2 & 0 \end{bmatrix}.$$

The order of indices in a row of C is immaterial. The nonzero elements of the matrix A are never needed, only their indices.

Test Results

REDUCE was tested on an IBM System/360 (model 50) computer using the Fortran IV G and H compilers and on a CDC 6600 computer using the Fortran (RUN) and Fortran extended (FTN) compilers.

In another paper [5], the authors compared the execution times, bandwidths, and profiles produced by REDUCE with those of five other programs on a wide range of problems. REDUCE typically produced the smallest bandwidths; it produced profiles which were on the average as small as those for any other program; and REDUCE was faster than all the others by at least an order of magnitude.

REMARK ON ALGORITHMS 508 AND 509

Matrix Bandwidth and Profile Reduction [H.L. Crane, Jr., N.E. Gibbs, W.G. Poole, Jr., and P.K. Stockmeyer, *ACM Trans. Math. Softw. 2*, 4 (Dec. 1976), 375–377] and A Hybrid Profile Reduction Algorithm [N.E. Gibbs, *ACM Trans. Math. Softw. 2*, 4 (Dec. 1976), 378–387]

John G. Lewis [Received 28 May 1980; revised 6 January 1982; accepted 10 January 1982]

Boeing Computer Services Co., Mail Stop 9C-01, 565 Andover Park West, Tukwila, WA 98188.

A new implementation of the Gibbs–Poole–Stockmeyer and Gibbs–King algorithms is available as Algorithm 582. This new implementation is faster, more robust, and requires less storage than the previous implementation of the Gibbs–Poole–Stockmeyer algorithm [1], distributed as Algorithm 508, and of the Gibbs–King algorithm [2], distributed as Algorithm 509. The mathematical capabilities of Algorithm 582 are identical to those of Algorithms 508 and 509. References [3] and [4] give the implementation details and documentation for the new implementation.

College of William and Mary

Key Words and Phrases: bandwidth reduction, graph, King algorithm, leveling, profile reduction, sparse matrix
CR Categories: 5.14, 5.32
Language: Fortran

DESCRIPTION

1. Introduction

Large sparse matrix problems arise in many applications areas, such as structural engineering, fluid dynamics, and network analysis. Many algorithms for automatically reordering the rows and columns of the matrix in order to reduce bandwidth and/or profile have been published. Recently, Gibbs et al. [4] concluded that of the many reduction algorithms available, theirs (as described in [3] and implemented as a Fortran program in [1]) and King's (as described in [5] and implemented as a Fortran program as described in [4]) were superior for profile reduction. Although the King algorithm produced the best profile in many cases, it sometimes exhibited erratic behavior due to the strategy of reducing the profile globally by reducing the profile well locally. Furthermore, they found a large class of problems (wide cylinders—Type E3 in [4]) for which there is no good single starting point for the King algorithm.

In this paper a new "hybrid" algorithm for reducing profile is presented. This algorithm combines the better features of [3] and [5] by first finding a pseudodiameter to produce a leveling and then numbering the leveling level by level according to King's criteria.

Section 2 describes the new profile reduction algorithm. In Section 3 it is compared in production mode with the better algorithms reported on in [4]. A listing of the Fortran subprogram used to implement the new algorithm is given in Appendix A. The changes which must be made to the Fortran subroutine REDUCE [1] to implement the algorithm are given in Appendix B.

2. Description of the Algorithm

Let $Ax = b$ be an $n \times n$ sparse nonsingular system of linear algebraic equations. To define the profile of A, first define $f_i = \min \{j : a_{ij} \neq 0\}$ for $i = 1, 2, \ldots, n$ (it is assumed that $a_{ii} \neq 0$). This locates the leftmost nonzero element in each row.

Received 31 August 1975 and 3 March 1976.

Now set $\delta_i = i - f_i$. The *profile* is defined to be $\sum_{i=1}^{n} \delta_i$. Given such a matrix A, we define a *graph* $G = \langle V, E \rangle$ where V has n *vertices*, $\{v_1, v_2, \ldots, v_n\}$ and $\{v_i, v_j\} \in E$ if $a_{ij} \neq 0$ and $i \neq j$. It is well known (see, for example [3]) that the problem of matrix profile reduction can be restated as a problem of graph profile reduction. The algorithm presented here is described in terms of graphs and is directly applicable to graphs.

We assume that the reader is familiar with Algorithms I and II of Gibbs et al. [3] and with King's algorithm [5]. The reader is referred to [3] for the definitions and notation used below.

Algorithms I and II accept as input a connected graph and produce as output a leveling. A *leveling* of a graph $G = \langle V, E \rangle$ is a partition of the vertices V into levels $L_1, L_2, \ldots, L_k$ such that

(1) all vertices adjacent to vertices in level L_1 are either in level L_1 or level L_2;
(2) all vertices adjacent to vertices in level L_k are either in level L_{k-1} or level L_k;
(3) for $1 < i < k$, all vertices adjacent to vertices in level L_i are in either level L_{i-1}, level L_i, or level L_{i+1}.

The new algorithm, Algorithm P, described below is applied to the leveling of a connected component of a graph. The following assumptions are made.

(1) $L_1, L_2, \ldots, L_k$ is a leveling produced by algorithms I and II and the number of levels, k, must be at least two.
(2) On input the variable *nextnum* is initialized to the next available integer to be assigned to this connected component. On output *nextnum* will be set to the next available integer to be assigned to the next connected component.
(3) The variables $S2$, $S3$, and Q represent queues of integers. If X is a queue of integers and x is an integer variable, then:
    (a) $X \leftarrow X - \{x\}$ means remove the integer x from the queue X (treating X as a set).
    (b) $X \Leftarrow x$ means place the integer x at the rear of the queue X.
    (c) $x \Leftarrow X$ means set the variable x to the integer at the front of the queue X after removing it from X.
    (d) $X \leftarrow \emptyset$ means empty the queue X.
    (e) $| X |$ represents the current size of the queue X.
(4) Algorithm P produces as output a vector *new*, where $new(i) = j$ means that the old vertex labeled with the integer i should be relabeled with the integer j.

ALGORITHM P. PROFILE REDUCTION

P0. [Initialization.] Set $S2 \leftarrow L_1$ and $i \leftarrow 1$.
P1. [Form the next level and empty Q.] Set $S3 \leftarrow L_{i+1}$ and $Q \leftarrow \emptyset$.
P2. [Find the next vertex to be numbered according to King's criteria.] Set m equal to the first element of $S2$ which has fewest connections to $S3$. Set C equal to the set of elements of $S3$ which are joined by an edge to m.
P3. [Numbering.] Set $new(m) \leftarrow nextnum$, $S2 \leftarrow S2 - \{m\}$, $nextnum \leftarrow nextnum + 1$, and for each element $c \in C$ set $Q \Leftarrow c$ and $S3 \leftarrow S3 - \{c\}$.
P4. [Is $S2$ empty?] If $| S2 | = 0$ goto step P7.
P5. [$S2$ is not empty. Is $S3$ empty?] If $| S3 | > 0$ return to step P2.
P6. [$S2$ is not empty, but $S3$ is empty.] For $j = 1, 2, \ldots, | S2 |$ set $s \Leftarrow S2$, $new(s) \leftarrow nextnum$, and $nextnum \leftarrow nextnum + 1$. Goto step P8.
P7. [$S2$ is empty. If $S3$ is not empty place the rest of S3 in Q.] If $| S3 | > 0$ then set $q \Leftarrow S3$, $Q \Leftarrow q$, and repeat step P7.
P8. [$S2$ and $S3$ are empty.] Set $i \leftarrow i + 1$. If $i < k$ (the last level) then set $S2 \leftarrow Q$ and return to step P1.
P9. [All levels are numbered except the last level which is in Q.] If $| Q | = 0$ then terminate the algorithm; otherwise set $q \Leftarrow Q$, $new(q) \leftarrow nextnum$, $nextnum \leftarrow nextnum + 1$, and repeat step P9.

Algorithm P assigns consecutive integers, level by level, to the leveling according to King's criteria. In fact, this algorithm is the King algorithm restricted to assigning consecutive integers to the vertices in one level at a time. If initially $S2$ was a single vertex v, $S3$ was set to $V - \{v\}$, and the elements of C were placed directly into $S2$ instead of Q in step P3 we would, in essence, have King's algorithm.

It turns out that reversing the numbering *new* by setting $new(j) \leftarrow n - new(j) + 1$ for $j = 1, 2, \ldots, n$ sometimes improves profile. We have not been able to predict a priori when reversing helps, so every numbering is reversed and the numbering that gives smaller profile is chosen (see subroutine CHECK in Appendix A.)

3. Test Results in Production Mode

The new algorithm as described above and implemented as a Fortran subroutine named PROFIT (see Appendix A) was integrated into the Fortran package described in [1]. A parameter was added to subroutine REDUCE so that the user can specify whether profile reduction is more important than bandwidth reduction or if bandwidth reduction is more important than profile reduction. The changes which were made to REDUCE are described in Appendix B.

As stated in [3], every practical bandwidth or profile reduction algorithm is heuristic in the sense that one cannot make absolute a priori statements concerning the performance of the algorithm; the performance is data dependent. In order to relate this work to previous work the new algorithm was tested on the same test data described in [4]. Tables I and II summarize the results. These tables show how subroutine REDUCE with subroutine PROFIT performed relative to Gibbs et al. (GPS [1, 3]) and King (KNG [5, 4]), with respect to bandwidth reduction, profile reduction, and time. The times are relative to 1.00 for GPS.

4. Conclusions

Although the new algorithm takes more time than GPS, it is clear that it is superior to GPS in reducing profile. The new algorithm yields profile comparable to KNG, but takes less time and does not exhibit KNG's erratic behavior.

In retrospect, the good performance of GPS for bandwidth reduction and the new algorithm for profile reduction can be explained. The Cuthill-McKee [2] and King algorithms do a good job of reducing bandwidth and profile respectively by numbering well locally. Since these algorithms examine the graph's structure locally, they sometimes behave erratically. The algorithms for producing a leveling by first finding a pseudodiameter and then using it to minimize level width take the entire structure of the graph into account and thus, when the Cuthill-McKee or King numbering is imposed on a leveling one obtains comparable bandwidth or profile respectively. The GPS algorithm and the new algorithm give superior bandwidth or profile reduction on those cases where global strategy is necessary.

APPENDIX B. SUMMARY OF CHANGES TO FORTRAN SUBROUTINE REDUCE NECESSARY TO IMPLEMENT ALGORITHM P

There are seven changes which have to be made to REDUCE to use the subprograms given in Appendix A. The first is to add the variable OPTPRO to REDUCE's argument list. One change, the sixth, requires adding a statement number. The remaining five changes require inserting statements in the proper place in REDUCE. The update cards are underlined and at least one line of REDUCE before and after each alteration is given.

REMARK ON ALGORITHMS 508 AND 509

Matrix Bandwidth and Profile Reduction [H.L. Crane, Jr., N.E. Gibbs, W.G. Poole, Jr., and P.K. Stockmeyer, *ACM Trans. Math. Softw. 2*, 4 (Dec. 1976), 375–377] and A Hybrid Profile Reduction Algorithm [N.E. Gibbs, *ACM Trans. Math. Softw. 2*, 4 (Dec. 1976), 378–387]

John G. Lewis [Received 28 May 1980; revised 6 January 1982; accepted 10 January 1982]

Boeing Computer Services Co., Mail Stop 9C-01, 565 Andover Park West, Tukwila, WA 98188.

A new implementation of the Gibbs–Poole–Stockmeyer and Gibbs–King algorithms is available as Algorithm 582. This new implementation is faster, more robust, and requires less storage than the previous implementation of the Gibbs–Poole–Stockmeyer algorithm [1], distributed as Algorithm 508, and of the Gibbs–King algorithm [2], distributed as Algorithm 509. The mathematical capabilities of Algorithm 582 are identical to those of Algorithms 508 and 509. References [3] and [4] give the implementation details and documentation for the new implementation.

Algorithm 510
Piecewise Linear Approximations to Tabulated Data [E2]

D. G. WILSON
Oak Ridge National Laboratory

Key Words and Phrases: approximation, first degree spline, linear, piecewise linear
CR Categories: 5.13
Language: Fortran

DESCRIPTION

This algorithm generates a piecewise linear approximation to tabulated data which is within specified tolerances of the data points. There are eight options available. The approximation may be required to be continuous or not, a single tolerance or a tolerance for each data point may be specified, and the approximation may or may not be restricted to the piecewise linear "tolerance band" centered at the data points with edges determined by the tolerances at the data points. Among approximations of the kind requested, the algorithm gives one of fewest line segments.

The algorithm processes data in order of increasing abscissa values, successively finding the longest approximating segment by a systematic search technique. This algorithm is a descendent of the one given in [1] and the systematic search technique is the same. The specified options determine where a new segment begins and whether or not successive segments intersect.

Even if a continuous approximation is not requested, the algorithm determines whether or not successive segments would intersect at an acceptable point if the partition point between them were adjusted. If this is the case, the adjustment is made. This means that the algorithm may give a continuous approximation when one was not requested even in cases where the algorithm of [1] would not. However it does not mean that the algorithm will necessarily give a continuous approximation when one is not requested even though there may exist a continuous approximation of the same number of line segments.

In many cases there is considerable freedom of choice in determining the last segment or two of the approximation. The criteria used to make these choices are continuity first and nearness of approach to the data second.

The algorithm will accept any nonnegative tolerances. If all tolerances are zero, then the approximation linearly interpolates the data.

When the approximation is required to be continuous and not restricted to the tolerance band, the algorithm gives a first degree spline which approximates the data within the specified tolerances and is of fewest line segments.

Received 14 December 1972.

The inputs and outputs including the form of the approximation generated are described after the calling sequence, which is:

CALL STL2(X,Y,E,M,U,V,W,K,IP)

X, Y, E, and M contain input data; U, V, K, and possibly W contain output; and IP contains a parameter which specifies the options desired.

X and Y are real arrays of M elements. X(I) and Y(I) contain the abscissa and ordinate respectively of the I-th data point. M is an integer variable containing the dimension of the arrays X and Y.

E may be a single real variable or an M-element array depending on the value of IP. E contains the nonnegative tolerance or tolerances. If E is an array, then E(I) is the tolerance associated with (X(I), Y(I)) for I = 1, . . . , M.

U and V are real arrays of at least K + 1 elements. (Since K, the number of approximating segments, is not known a priori, the dimension of U and V must be "sufficiently large.") After STL2 has executed, U will contain a partition of the interval [X(1),X(N)] with U(1) = X(1) and U(K + 1) = X(N). V(I) is an ordinate to be associated with U(I) in the approximation. If a continuous approximation is requested, then V(I) is "the" ordinate to be associated with U(I).

If a continuous approximation is requested, then W is not used. In this case the I-th approximating segment is the straight line from (U(I),V(I)) to (U(I + 1), V(I + 1)).

If a continuous approximation is not requested, then W is a real array of at least K elements. In this case the I-th approximating segment is the straight line from (U(I),W(I)) to (U(I + 1),V(I + 1)), and V(1) is set equal to W(1).

K is an integer variable. After STL2 has executed, K will contain either the number of approximating line segments or zero. K will be set to zero in case of an error return.

Call STL2(X,Y,E,M,X,Y,E,M,IP) will not cause problems provided that either a continuous approximation is requested, or E is a sufficiently large real array.

IP is an integer variable. The content of IP is the product of three indicators: I1, I2, and I3. I1 indicates whether or not E is an array of tolerances. I1 = −1 indicates that E is an array. I1 = +1 indicates that E is a single variable. I2 indicates whether or not the approximation is to be restricted to the tolerance band about the data. I2 = 1 indicates that the approximation is *not* to be restricted to the tolerance band. I2 = 2 indicates that the restriction *is* to be so restricted. I3 indicates whether or not the approximation is required to be continuous. I3 = 1 indicates that the approximation *need not be* continuous. I3 = 3 indicates that the approximation *must be* continuous.

The program performs the following data checks: Are the abscissa values stored in order of increasing magnitude? Is the tolerance (or are the tolerances) nonnegative? Is the number of data points greater than 1? If the answer to any of these questions is no, then the program returns with K set to zero. In this case no further processing is attempted.

TEST RESULTS

This algorithm has successfully approximated 10 sets of data specifically designed to test various parts of the program. The main routine was written to repeat each data set with the ordinate values replaced by their negatives. This provides a new approximation problem for the algorithm, essentially doubling the number of data sets, but one for which the result is known. In addition, each data set was run with each possible option. Thus roughly 150 approximations have been generated for data sets of typically 12 points.

These tests were performed on IBM 360 model 75 and model 91 computers. Execution time is highly dependent on the data; however the model 91 processed 80 approximation problems of 10 to 12 points each in 2.04 seconds. Since the processing associated with terminating and initiating segments is nonnegligible and since in these constructed test cases the ratio of approximating segments to data points was almost .5, one would expect the program to do slightly better for smoother data.

ALGORITHM 511
CDC 6600 Subroutines IBESS and JBESS for Bessel Functions $I_\nu(x)$ and $J_\nu(x)$, $x \geq 0$, $\nu \geq 0$ [S18]

D. E. AMOS, S. L. DANIEL, and M. K. WESTON
Sandia Laboratories

Key Words and Phrases: Bessel functions of the first kind, modified Bessel function, Airy functions, uniform asymptotic expansion
CR Categories: 5.12
Language: Fortran

DESCRIPTION

This algorithm is a complement to [1], where the theoretical background and development are described.

ALGORITHM 512
A Normalized Algorithm for the Solution of Positive Definite Symmetric Quindiagonal Systems of Linear Equations [F4]

A. BENSON and D. J. EVANS
Loughborough University of Technology, England

Key Words and Phrases: linear equations, normalized solution, periodic quindiagonal, symmetric positive definite
CR Categories: 5.14, 5.17
Language: Fortran

DESCRIPTION

In the finite difference solution of elliptic partial differential equations using block iterative methods, there occurs within the iteration scheme a need to solve many subsets of the resulting set of linear equations for each block and for each iteration. The form of the coefficient matrix B of such subsets of equations depends on the particular differential equation and the region of integration and on the way in which the grid points in the finite difference scheme are ordered. In this algorithm we are concerned with the case when B is symmetric, positive definite, and of the form

$$\begin{pmatrix} c_1 & b_1 & a_1 & & & & & a_{N-1} & b_N \\ b_1 & c_2 & b_2 & a_2 & & & & & a_N \\ a_1 & b_2 & c_3 & b_3 & a_3 & & & & \\ & a_2 & & & & & & & \\ & & \ddots & \ddots & \ddots & \ddots & & & \\ & & & \ddots & \ddots & \ddots & \ddots & & \\ & & & & \ddots & \ddots & \ddots & \ddots & \\ & & & a_{N-4} & b_{N-3} & c_{N-2} & b_{N-2} & a_{N-2} & \\ a_{N-1} & & & & a_{N-3} & b_{N-2} & c_{N-1} & b_{N-1} & \\ b_N & a_N & & & & a_{N-2} & b_{N-1} & c_N & \end{pmatrix} \tag{1}$$

Such systems arise, for example, from a two-line grouping of the mesh points for a self-adjoint partial differential equation in a rectangular region with periodic boundary conditions in one or both coordinate directions. Similar systems also arise in the solution of the biharmonic equation in a rectangular region subject to periodicity conditions [4]. For nonsymmetric matrices such as might occur if the differential equation were not self-adjoint or for circular regions [1], an algorithm has been given [2]. For the symmetric, positive definite case, however, it is worth-

Authors' address: Department of Computer Studies, Loughborough University of Technology, Leicestershire, England.

while to consider a normalized form of the algorithm following Cuthill and Varga [3]. This approach makes use of the result:

If A is a real $N \times N$, symmetric positive definite matrix, then there exists a unique, positive, diagonal matrix D and a unique, real, upper triangular matrix T, with unit diagonal elements such that

$$A = DT'TD \tag{2}$$

where T' denotes the transpose of T.

Assume, then, that in the system of equations

$$B\phi = \mathbf{s} \tag{3}$$

the matrix B is symmetric, positive definite, and of the form given by (1). Then B has the unique factorization

$$B = DT'TD$$

where

$$D = \text{diag}\,\{d_1, d_2, d_3, \ldots, d_N\} \tag{4}$$

and T is given by

$$T = \begin{pmatrix}
1 & e_1 & f_1 & & & & & g_1 & & h_1 & \\
 & 1 & e_2 & f_2 & & & & g_2 & & h_2 & \\
 & & \cdot & \cdot & \cdot & & & \cdot & & \cdot & \\
 & & & \cdot & \cdot & \cdot & & \cdot & & \cdot & \\
 & & & & \cdot & \cdot & \cdot & \cdot & & \cdot & \\
 & & & & & 1 & e_{N-4} & f_{N-4} & g_{N-4} & & h_{N-4} \\
 & & & & & & 1 & e_{N-3} & (f_{N-3} + g_{N-3}) & h_{N-3} & \\
 & & & & & & & 1 & (e_{N-2} + g_{N-2}) & (f_{N-2} + h_{N-2}) & \\
 & & & & & & & & 1 & (e_{N-1} + h_{N-1}) & \\
 & & & & & & & & & 1 &
\end{pmatrix}. \tag{5}$$

The elements of the matrices D and T are given by the following relations.

For the first $(N - 2)$ columns, the factorization is straightforward, as there is no interaction between the elements in T; so that

$$d_1 = (c_1)^{1/2}, \quad d_2 = (c_2 - b_1^2/d_1^2)^{1/2}, \quad e_1 = b_1/d_1\,d_2,$$

and for $i = 3, 4, \ldots, N - 2$

$$u = a_{i-2}/d_{i-2}; \quad v = b_{i-1}/d_{i-1} - e_{i-2}u$$

and

$$d_i = (c_i - u^2 - v^2)^{1/2}, \quad f_{i-2} = u/d_i, \quad e_{i-1} = v/d_i.$$

For the last two columns auxiliary vectors $\mathbf{x}$ and $\mathbf{y}$ are used; so that for column $(N - 1)$ if

$$u = a_{N-3}/d_{N-3}, \quad v = b_{N-2}/d_{N-2} - e_{N-3}u,$$

$$x_1 = a_{N-1}/d_1, \quad x_2 = -e_1x_1,$$

and for $i = 3, 4, \ldots, N - 2$

$$x_i = -e_{i-1}x_{i-1} - f_{i-2}x_{i-2},$$

then

$$d_{N-1} = \left\{c_{N-1} - \left[\sum_{i=1}^{N-4} x_i^2 + (x_{N-3} + u)^2 + (x_{N-2} + v)^2\right]\right\}^{1/2},$$

$$f_{N-3} = u/d_{N-1},$$

$$e_{N-2} = v/d_{N-1},$$

and for $i = 1, 2, \ldots, N-2$

$$g_i = x_i/d_{N-1}.$$

For the final column, we set

$$u = a_{N-2}/d_{N-2}, \quad v = b_{N-1}/d_{N-1} - e_{N-2}u,$$

$$y_1 = b_N/d_1, \quad y_2 = a_N/d_2 - e_1y_1,$$

and for $i = 3, 4, \ldots, N-1$

$$y_i = -e_{i-1}y_{i-1} - f_{i-2}y_{i-2},$$

and finally

$$y_{N-1} = y_{N-1} - \sum_{i=1}^{N-2} g_iy_i - g_{N-2}u.$$

Then

$$d_N = \{c_N - \sum_{i=1}^{N-3} y_i^2 - (y_{N-2} + u)^2 - (y_{N-1} + v)^2\}^{1/2},$$

$$f_{N-2} = u/d_N,$$

$$e_{N-1} = v/d_N,$$

and for $i = 1, 2, \ldots, N-1$

$$h_i = y_i/d_N.$$

The factorization stage is then complete. To solve the linear system (3), with coefficient matrix B as given by (1), we rewrite it in the equivalent form:

$$DT'TD\boldsymbol{\phi} = \mathbf{s} \quad \text{i.e.} \quad T'T(D\boldsymbol{\phi}) = D^{-1}\mathbf{s}\,; \tag{6}$$

so that putting

$$D\boldsymbol{\phi} = \mathbf{z}, \quad D^{-1}\mathbf{s} = \mathbf{q}\,, \tag{7}$$

the system becomes

$$T'T\mathbf{z} = \mathbf{q}\,,$$

which may be solved directly for $\mathbf{z}$ in terms of the auxiliary vector $\mathbf{p}$ whose elements are given by

$$p_1 = q_1, \quad p_2 = q_2 - e_1p_1\,,$$

and for $i = 3, 4, \ldots, N-2$

$$p_i = q_i - e_{i-1}\,p_{i-1} - f_{i-2}\,p_{i-2}\,.$$

Finally,

$$p_{N-1} = q_{N-1} - (e_{N-2} + g_{N-2})p_{N-2} - (f_{N-3} + g_{N-3})p_{N-3} - \sum_{i=1}^{N-4} g_ip_i\,,$$

$$p_N = q_N - (e_{N-1} + h_{N-1})p_{N-1} - (f_{N-2} + h_{N-2})p_{N-2} - \sum_{i=1}^{N-3} h_ip_i\,.$$

The elements of $\mathbf{z}$ are then obtained by a back substitution process so that

$$z_N = p_N\,,$$

$$z_{N-1} = p_{N-1} - (e_{N-1} + h_{N-1})z_N\,,$$

$$z_{N-2} = p_{N-2} - (e_{N-2} + g_{N-2})z_{N-1} - (f_{N-2} + h_{N-2})z_N\,,$$

and for $i = N - 3, \ldots, 3, 2, 1$

$$z_i = p_i - e_i z_{i+1} - f_i z_{i+2} - g_i z_{N-1} - h_i z_N .$$

The final solution $\boldsymbol{\phi}$ is then obtained from $\boldsymbol{\phi} = D^{-1}\mathbf{z}$ using only one division per component.

Storage Management Used in the Program

The algorithm has been written in the form of three subroutines, as follows.

1. FACTOR(A,B,C,G,H,N)

This subroutine performs the factorization stage. A matrix of the form (1) is input as three vectors **a**, **b**, **c**, which are overwritten during the course of the factorization. The diagonal elements of D, i.e. d_1 to d_n, replace the coefficients c_1 to c_n; in the vectors **b** and **a** are stored the elements e_1 to e_{n-1} and f_1 to f_{n-2}, respectively, which occur in the matrix T. In the factorization formulas two vectors **x** and **y** are used, but in the program these are replaced by **g** and **h** which are in turn overwritten by the g_1 to g_{n-2} and h_1 to h_{n-1} values which occur in the last two columns of T.

2. RHS(D,S,N)

This subroutine forms $D^{-1}\mathbf{s}$, where D is a diagonal matrix whose elements are stored in a vector **d**. The input vector **s** is overwritten by the result vector.

3. SOLVE(E,F,G,H,Q,N)

This subroutine solves the set of equations $T'T\mathbf{z} = \mathbf{q}$ for T as given by (5). The solution is effected in two stages, viz. a forward substitution for **p** where $T'\mathbf{p} = \mathbf{q}$ and a backward substitution for **z** where $T\mathbf{z} = \mathbf{p}$. The input vector **q** is overwritten first by the intermediate solution **p** and finally by the result **z**.

To solve (3) directly with B as given by (1) would then require the subroutine calls:

```
CALL FACTOR(A,B,C,G,H,N)
CALL RHS(C,S,N)
CALL SOLVE(B,A,G,H,S,N)
CALL RHS(C,S,N)
```

The reason for the three subroutines (instead of a single one), however, is that in a typical block successive overrelaxation process the three stages need to be performed at different points and possibly a different number of times. For instance, if the matrix B remains the same for each block, then the factorization need be performed only once. Moreover, the set of equations (3) is typically solved as part of an iterative procedure so that for block r, if k represents the iteration count then we have for successive block overrelaxation

$$B_r \boldsymbol{\phi}_r^{(k+1)} = \mathbf{s}(\boldsymbol{\phi}_{r-1}^{(k+1)}, \boldsymbol{\phi}_r^{(k)}, \boldsymbol{\phi}_{r+1}^{(k)}).$$

However, if $D_r \boldsymbol{\phi}_r^{(k)} = \mathbf{z}_r^{(k)}$, then the iteration is carried out in the transformed variable **z**, so that

$$T_r' T_r \mathbf{z}_r^{(k+1)} = \mathbf{q}(\mathbf{z}_{r-1}^{(k+1)}, \mathbf{z}_r^{(k)}, \mathbf{z}_{r+1}^{(k)})$$

until for some value K of k, $\mathbf{z}_r^{(K+1)}$ and $\mathbf{z}_r^{(K)}$ agree to some specified accuracy for all values of r. The final result is then obtained from $\boldsymbol{\phi} = D^{-1}\mathbf{z}$. The process is considered to be a normalized Choleski technique used in an inner loop where the need to include the division is eliminated until the final result is achieved.

Normalized Algorithm Versus Choleski Factorization

Let us briefly consider the differences between using the normalized factorization $B = DT'TD$ as opposed to a standard Choleski factorization $B = LL'$ which takes into account the structure of the nonzero elements of B.

The normalized form is clearly similar to a Choleski factorization since DT' is a lower triangular matrix, say $\tilde{L}$, so that $B = \tilde{L}\tilde{L}'$.

Moreover, if we consider $B = LL'$, then the formulas for determining the elements of L are very similar to those already given for the elements of D and T.

However, a work count of the two algorithms shows that the normalized version requires $2n$ more divisions than the Choleski form, this extra work occurring in the factorization stage. Having factorized B, the two solution processes for determining $\boldsymbol{\phi}$ from $B\boldsymbol{\phi} = \mathbf{s}$ require the same amount of work. Consequently, for the straightforward solution of a set of equations $B\boldsymbol{\phi} = \mathbf{s}$ with B as in (1), the Choleski factorization is preferable because less work is involved.

However, as we have seen, the B matrices are likely to occur in problems where the solution of $B\boldsymbol{\phi} = \mathbf{s}$ is incorporated into an iterative procedure. In this case for the normalized version, n divisions per block would be saved in each iteration in excess of one (since the iteration is effected in a transformed variable thus saving the final division). Let us consider all possible cases for the B matrices, i.e.

(i) $B = B_r^{(k)}$: the matrices change from block to block and with each iteration;
(ii) $B = B^{(k)}$: the matrices change with each iteration but not from block to block;
(iii) $B = B_r$: the matrices change from block to block but not with each iteration;
(iv) $B = B$: the matrices remain constant throughout the process.

Cases (iii) and (iv) are the most likely to occur in practice.

For (i), the Choleski factorization always involves less work.

For (ii), the Choleski form is more efficient if the number of blocks is less than three. For three or more blocks, the normalized form is more efficient if the number of iterations exceeds two.

For (iii) and (iv), i.e. the most likely cases, the normalized form is more efficient, from the point of view of number of operations involved, if the number of iterations is again more than two.

Consequently we conclude that for the majority of problems involving a block overrelaxation technique in which the blocks have a coefficient matrix of the form (1), the normalized algorithm as presented here would involve less work than a sparse Choleski form.

Key Words and Phrases: transposition in place, matrix transposition, permutation
CR Categories: 4.49, 5.9, 5.30
Language: Fortran

DESCRIPTION

Algorithms for in-place matrix transposition make use of the cyclic structure of the transposition mapping. A clear introduction to the process was given in 1958 by Windley [6]. In 1968 Boothroyd presented ACM Algorithm 302 [1]. Then in 1970 Laflin and Brefner presented ACM Algorithm 380 which they showed to be significantly faster than Algorithm 302 [4].

In this paper a number of theoretical results describing the transposition process are derived. Algorithms 302 and 380 are described and applications of some of the theoretical results to accelerate both algorithms are described. Finally, experimental comparison of the performance of Algorithm 380 and the improved version is presented.

Theoretical Development

Fortran conventions are assumed. The $m \times n$ matrix A is stored by column in a vector $\bar{y}$ of adjacent storage locations. It is convenient to number components of $\bar{y}$ from 0 to $mn - 1$. Using this convention, matrix element $A(I, J)$ is stored in y_k, where $k = m(J - 1) + I - 1$. The transposition process moves the contents of y_k to y_p where $p = n(I - 1) + J - 1$. Thus the transposition process can be regarded as a permutation mapping acting on the indices of $\bar{y}$. The symbol π is used to denote this mapping, and the set of indices which π permutes is denoted by S. With this notation, $S = [0, 1, \ldots, mn - 1]$ and the formal equation $\pi(k) = p$ indicates that the contents of storage location y_k is moved to location y_p in the transposition process.

The theoretical material is organized in three sections: additional notation, development of general properties of π, and description of the fixed point properties of π.

Notation

Symbols used in this paper are as follows.

$C(x)$ Cycle of π containing element $x \in S$. $C(x)$ is generated by repeated application of π to x., i.e. $C(x) = [x, \pi(x), \pi^2(x), \ldots]$.

$L(x)$ Length of the cycle $C(x)$.

Received 11 September 1975 and 1 April 1976.

Author's address: Boeing Computer Services, Inc., P.O. Box 24346, Seattle, WA 98124.

$P(d)$ Number of cycles of length d.

$\mu(n)$ Möbius function; for n having prime factorization, $n = P_1^{e_1} \dots P_k^{e_k}$,

$$\mu(n) = \begin{cases} 1 & \text{if } n = 1, \\ (-1)^k & \text{if } e_1 = e_2 = \cdots = e_k = 1, \\ 0 & \text{otherwise.} \end{cases}$$

$[a, b]$ Greatest common divisor of a and b.

$d \mid u$ d is a divisor of u.

General Properties of π

An analytic expression for π is given in [1]. That is, for $x \in S$,

$$\pi(x) = \begin{cases} nx \bmod mn - 1 & \text{if } x \neq mn - 1, \\ mn - 1 & \text{if } x = mn - 1. \end{cases} \tag{1}$$

In this paper the symbols x and y represent any element of S except $mn - 1$, and all algebraic expressions involving these are assumed evaluated mod $mn - 1$.

That π is a linear mapping is obtained directly from (1). That is,

$$(ax + by) = a\pi(x) + b\pi(y). \tag{2}$$

This property is used to relate π to its fixed points.

The inverse mapping is used in both Algorithms 302 and 380 to traverse the cycles in the reverse direction.

THEOREM 1. $\pi^{-1}(y) = \begin{cases} my & \text{for } y \in s,\ y \neq mn - 1, \\ mn - 1 & \text{for } y = mn - 1. \end{cases}$

PROOF. $\pi^{-1}(\pi(y)) = \pi(\pi^{-1}(y)) = mny \bmod mn - 1 = ((mn - 1)y + y) \bmod mn - 1 = y$.

The transposition algorithms depend upon the cyclic structure of π. Two theorems are presented which describe the properties of these cycles. Theorem 2 shows how to find the length of the longest cycle (i.e. the cycles starting with $x = 1$, $A(2, 1)$). It also demonstrates that the length of any cycle must be a divisor of the length of the longest cycle. Theorem 3 provides a number theoretic formula which gives the number of cycles of any length. No application has been found for Theorem 3, but it may be of interest to other researchers. The interested reader is referred to [2] for the proof.

THEOREM 2. *The order of π is $L(1)$.*

PROOF. The order of a permutation mapping is the least common multiple of the lengths of its cycles [5]. Let $d = L(1)$. Then $n^d = 1 \bmod mn - 1$. It is sufficient to show, for any $y \in S$, that $\pi^d(y) = y$. If $y = mn - 1$, then the theorem is trivially true. For $y \neq mn - 1$, $\pi^d(y) = n^d y \bmod mn - 1 = y$.

THEOREM 3. *Assume that $k > 1$. The number of cycles of length k, $P(k)$, is given by $P(k) = k^{-1} \sum_{d \mid k} \mu(k/d)[n^d - 1, mn - 1]$.*

The number of fixed points ($k = 1$) is discussed in the next section.

Fixed Point Properties of π

It is mainly through the symmetry with respect to the fixed points that computational leverage is gained. The mapping always has at least two fixed points, 0 and $mn - 1$. If S has a midpoint, then the midpoint is also a fixed point. Formally,

THEOREM 4. *If m and n are odd, then $\frac{1}{2}(mn - 1)$ is a fixed point.*

PROOF. Let $n = 2k + 1$. By eq. (1), $\pi[\frac{1}{2}(mn - 1)] = \frac{1}{2}(2k + 1)(mn - 1) = \frac{1}{2}(mn - 1)$

Two formulas for calculation of the number of fixed points of π are now given. Let n_f represent the number of fixed points of π.

THEOREM 5. $n_f - 1 = [n - 1, mn - 1] = [m - 1, mn - 1]$, *and the fixed points are uniformly spaced at 0, d, $2d$, ..., where $d = (mn - 1)/(n_f - 1)$.*

PROOF. Because of eq. (1), all the fixed points of π except $mn - 1$ satisfy the congruence $x(n - 1) = 0 \bmod mn - 1$. The solutions of this congruence are 0, d, $2d, \dots$, where $d = (mn - 1)/[n - 1, mn - 1]$. (See [5, ch. 8].) Clearly π and π^{-1} have the same fixed points; so $n_f - 1 = [m - 1, mn - 1]$ by symmetry.

THEOREM 6. $n_f - 1 = [m - 1, n - 1]$.

PROOF. Let $d = [m - 1, n - 1]$. By Theorem 5, $(n_f - 1) \mid d$. Conversely, the identity $(n - 1)(m + 1) = mn - 1 + ((n - 1) - (m - 1))$ shows that $d \mid mn - 1$. This and Theorem 5 show that $d \mid (n_f - 1)$. Hence $d = n_f - 1$.

The mapping π is symmetric with respect to fixed points in the sense that for fixed point a, where $a \neq mn - 1$,

$$\pi(a \pm x) = a \pm \pi(x). \tag{3}$$

The fixed point 0 is usually the only fixed point satisfying eq. (3). That is, if $m \neq 1$ and $n \neq 1$, the probability that π has exactly two fixed points (0 and $mn - 1$) is the probability that $m - 1$ and $n - 1$ are relatively prime (Theorem 6). This probability is $6/\pi^2 = .608$ [3, ch. 18]. The symmetry with respect to 0 is applied in Algorithm 380 and extended in this paper.

When $a = 0$, the nontrivial part of eq. (3) is

$$\pi(-x) = -\pi(x). \tag{4}$$

It is evident from eq. (4) that $C(-x) = -C(x)$, and consequently that $L(x) = L(-x)$. Equation (4) was proved by Laflin and Brefner [4] by more complicated methods and was the basis for their improved algorithm. We call the symmetric cycle $C(-x)$ the companion cycle. The cycle and the companion cycle in some cases coincide. In this event the length of the cycle is an even integer, and x and $-x$ are separated by half the cycle. That is,

THEOREM 7. *$C(x) = C(-x)$ if and only if $-x = n^k x$, where $k = L(x)/2$.*

PROOF. Since $-x \in C(x)$ there is a smallest integer k such that $-x = n^k x$. This implies that $x = n^k(-x)$, which in turn implies that $x = n^k(n^k(x))$. Thus $L(x) \mid 2k$. Since $k < L(x)$, we must have $L(x) = 2k$. Conversely, if $n^k x = -x$, then $-x \in C(x)$ and $C(x) = C(-x)$.

Algorithm Improvement

Algorithms 302 and 380 are now described. For each algorithm, efficiency improvements based on the theoretical development in the previous section are discussed. Finally, timing comparisons are given.

Algorithm 302 [1]. For $i = 1, \ldots, mn - 1$, compute the index $j = \pi^{-1}(i)$ and exchange y_i and y_j, provided $j \geq i$. The case $j < i$ indicates that the element originally in y_j is now elsewhere following previous exchanges. Then search the cycle $C(j)$ for the first index $jr \geq i$ and exchange y_{jr} and y_i. It terminates when y_{mn-2} is filled.

Symmetry with respect to the fixed point 0 [eq. (4)] can be exploited to accelerate Algorithm 302. The idea is to process the array from both ends toward the middle simultaneously. That is, process element i and $-i$ mod $(mn - 1)$ concurrently. This reduces the time spent searching cycles. The revised algorithm is then:

1. Set $i = 0$.
2. Increment i. If $i > (mn/2 - 1)$, terminate. Otherwise, perform step 3 ($mn/2$ is truncated to integer value because of Theorem 4).
3. Compute j as follows: Let r be the smallest positive integer such that $i \leq \pi^{-r}(i) \leq mn - 1 - i$. Then $j = \pi^{-r}(i)$.
4. If $j = i$, return to step 2. Otherwise, exchange y_i and y_j and perform step 5.
5. If $j = mn - 1 - i$, return to step 2. Otherwise, perform the symmetric exchange of y_{mn-1-j} and y_{mn-1-i}. (If $j = mn - 1 - i$, this exchange was already performed in step 4.) Return to step 2.

Algorithm 380 [4]. First the number of fixed points is determined by testing each element in the array to see if $\pi(i) = i$. Then the array is scanned from lowest to nighest subscript. Each array subscript in turn is checked to see if that subscript is the smallest subscript in its cycle. Whenever such an element is found, the entire cycle is moved. If the companion cycle is distinct, then the companion cycle is moved after movement of the cycle is complete. The algorithm keeps track of the total number of elements moved and terminates when all (mn) elements have

been moved. It is interesting to note that Algorithm 380 works its way backwards around each cycle, using the inverse, saving itself a fetch and store for each element moved. Algorithm 380 can achieve greater efficiency if scratch storage is available. The scratch storage is utilized to keep track of the elements which have already been moved.

The improvements to Algorithm 380 are based again on the symmetry with respect to 0 and upon the calculations of the number of fixed points. Theorem 6 allows use of Euclid's algorithm to calculate the number of fixed points. Theorem 7 and eq. (4) allow the processing of a cycle and its companion concurrently. When the cycle and its companion coincide, the process is terminated halfway through the cycle (Theorem 7). We also used the linearity to calculate $\pi(x + 1) = \pi(x) + n$ to start the next cycle. It is interesting to note that on the computer used (CDC 6600 using the RUN compiler), the calculation of $mx \bmod mn - 1$ using the system modulo functions is slower than using the formulation used in Algorithm 380.

Timing Comparisons

The timing tests utilized a set of 21 test matrices which were presented in [4]. The per-element transposition time is defined to be the time required to transpose a matrix divided by the number of elements in the matrix. Each algorithm was tested on the complete set of test matrices and the average per-element transposi-

* Times are given in seconds/100.

tion time was calculated. These are summarized in Table I. A detailed comparison of the best algorithms (380 and the revised 380) is presented in Table II in the format utilized in [4]. All tests were performed using a CDC 6600, with compilation performed by the RUN compiler.

The simple modification of Algorithm 302 resulted in about a 25-percent efficiency improvement (Table I). The performance improvement of the revised Algorithm 380 varied from 20 percent to 70 percent on individual test matrices (Table II) with an average of about 35 percent.

It is somewhat distressing to note the publication of Algorithm 513. While the algorithm is, as claimed, an improvement over Algorithm 380 [1], it is by no means as good as Algorithm 467, which was published long before Algorithm 513 was even submitted for publication. A reanalysis of the timing figures in Algorithms 467 and 513 suggests very strongly that Algorithm 467 is superior to Algorithm 513 except, possibly, when the modulus of the generating function for the transposition permutation is prime.

A direct comparison of the algorithms was performed using the Fortran G (nonoptimized) compiler on an IBM 370/158 running under VM/CMS. The results, reported in Table I, indicate quite clearly that Algorithm 467 enjoys a nearly 2:1 advantage except when the modulus is prime. It should be noted that it is not so much that Algorithm 467 is degraded in this case as that Algorithm 513 performs exceptionally well.

ALGORITHM 514
A New Method of Cubic Curve Fitting Using Local Data [E2]

T. M. R. ELLIS and D. H. McLAIN
University of Sheffield, England

Key Words and Phrases: interpolation, cubic splines, local data
CR Categories: 5.13
Language: Algol

DESCRIPTION

This algorithm is a local interpolation method to find an approximating function $y = f(x)$ through a set of given data points (x_i, y_i) with $x_1 < \cdots < x_i < x_{i+1} < \cdots$. Probably the best known methods for this are cubic splines [3, 6, 7] and the "classical" Lagrangian polynomial interpolation, of which Aitken's method is perhaps the most stable implementation [2]. Both of these methods are nonlocal, i.e. the interpolated values depend on all the data points. Under many circumstances, however, it is desirable to use a local interpolation method for which the values of the interpolating function depend only on a few of the nearest data points. For example, a local method may be preferred in an interactive system where one does not want to recalculate a complete picture when one point is changed, or where one wants to save storage in multidimensional interpolation.

The method used in our algorithm is similar to cubic spline interpolation in that different cubic, or third degree, polynomials $y = f_i(x)$ represent the function between different pairs of data points $(x_i, y_i) - (x_{i+1}, y_{i+1})$ and in that the coefficients are chosen to ensure continuity of the function and its first derivative at each data point. We have, however, sacrificed the spline's continuity of the second derivative in order to ensure that the coefficients depend only on the local data points.

A similar approach is described by Maude [4] which also ensures the continuity of the function and its first derivative at each data point. However, Maude's functions, at their simplest, reduce to quintic (fifth degree) polynomials, whereas ours are cubic polynomials with resulting computational advantages. Another method with a similar goal is due to Akima [1]. But whereas Akima's method is designed from geometrical considerations, ours is algebraic and appears to have some practical advantages. Thus our method gives an exact fit to the original polynomial $f(x)$ if the data points satisfy a cubic equation $y_i = f(x_i)$. As a result, in general it is more accurate for data of mathematical origin, or where smooth curves are expected. Our algorithm also appears to give more spline-like functions than Akima's, and in particular tends to produce much smaller discontinuities in

Received 20 November 1974 and 30 April 1976.

Authors' address: Computing Services, University of Sheffield, Sheffield S10 2TN, England.

the second derivatives at the data points. This is particularly important when interpolating surfaces, $z = f(x, y)$, by interpolating successively in two independent directions, x and y; for when depicting a perspective view of the surface, for example, a discontinuity in the second derivative of the function often results in a noticeable irregularity (a kink) in a visible edge.

Tables I and II compare the performance of our algorithm with other interpolation methods, and give the results obtained from a program run on a Control Data 7600 which applies six methods to data generated from five mathematical functions. Table I shows the average deviation found between the interpolated result and the true value from the original function, while Table II gives the average discontinuity of the second derivative at the nodes. The data used for the interpolations were generated for the following 18 unequally spaced values of x: -2.95, -2.6, -2.1, -1.8, -1.4, -1.0, -0.75, -0.3, -0.05, 0.2, 0.55, 0.9, 1.25, 1.6, 1.7, 2.1, 2.4, 3.0.

The first three methods are nonlocal ones: Aitken's method and two cubic spline methods. The first of the two cubic splines (a) is as implemented in Späth [7] and is probably the most used of the spline routines in the NAG Library [5], while the second cubic spline (b) was implemented by Reid [6]. They differ mainly in their treatment of the end intervals: Späth sets the second derivative at the endpoints to zero; Reid forces the third derivative at the points adjacent to the ends to be continuous. The second three methods given in Table I are local ones: Akima's, Maude's, and the method described below.

Our method is implemented in the two procedures described here. For each point (x_i, y_i) the first procedure, *find gradients at nodes*, initially finds that cubic poly-

Table I. Average Deviation from Original Function for Various Interpolation Methods ($\times 10^6$)

	Method					
	Nonlocal			Local		
Function	Aitken's	Cubic splines (a)	Cubic splines (b)	Akima's	Maude's	Present
x^3	0	28051	0	25709	8172	0
x^4	0	165921	4561	112169	68566	6434
$e^{-x^2/2}$	36	164	76	1260	640	78
tanh x	10409	140	147	833	619	214
sin x	0*	297	116	1531	1055	176

* The actual value was 0.011 ($\times 10^{-6}$). Aitken's method gives a remarkably accurate fit for sin x and a remarkably poor one for tanh x.

Table II. Average Discontinuity of Second Derivative at Data Points ($\times 10^4$)

	Method			
	All nonlocal methods as in	Local		
Function	Table I	Akima's	Maude's	Present

sin x	0	6293	0	198

nomial which passes through the three points (x_{i-1}, y_{i-1}), (x_i, y_i), (x_{i+1}, y_{i+1}) and which gives a least squares fit to the two neighboring data points (x_{i-2}, y_{i-2}), (x_{i+2}, y_{i+2}). As written, in the least squares fitting the weights given to the last two points are not equal, but are inversely proportional to the squares of their distances from x_{i-1} and x_{i+1}, respectively; we have found experimentally that such weighting leads to smaller discontinuities in the second derivatives at the nodes. The gradient of this cubic at the central point (x_i, y_i) is then calculated. This process is repeated for all the points (x_i, y_i), except for the first two and the last two data points for which the subscripts x_{i-2} etc. or x_{i+2} etc. would be out of range; for these extreme points a cubic is fitted exactly through the first four or the last four points as appropriate.

The second procedure, *coeffs*, then constructs as the approximating function for the interval $x_i \leq x \leq x_{i+1}$ that cubic polynomial which has the correct ordinates y_i and y_{i+1} and the calculated gradients at the two endpoints. The procedure calculates the four coefficients c_0, c_1, c_2, c_3 for which the approximating polynomial may be expressed in the form

$$f(x) = c_0 + c_1(x - x_i) + c_2(x - x_i)^2 + c_3(x - x_i)^3.$$

This is preferred to the form $a_0 + a_1x + a_2x^2 + a_3x^3$ which is more unstable against roundoff errors.

Normally the procedure *find gradients at nodes* need only be called once for any given set of x_i, y_i, thus avoiding unnecessary repetition of calculation; the gradients it calculates are then used by the procedure *coeffs* for any required interval.

We have also found the method useful in two-dimensional interpolation to fit a surface $z = f(x, y)$ through data on a rectangular grid (x_i, y_j, z_{ij}). This may be achieved by first applying the method to all the rows of data, keeping y_j fixed and varying i, and then by applying it again to the resulting four sets of coefficients, but this time keeping x_i fixed and varying j.

ACKNOWLEDGMENTS

We would like to thank M.J.D. Powell and the referees for a number of valuable suggestions. We also would like to acknowledge the assistance provided by Mrs. S. Costello in the computation of the various figures shown in the tables.

ALGORITHM 515
Generation of a Vector from the Lexicographical Index [G6]

B. P. BUCKLES AND M. LYBANON
Computer Sciences Corporation

Key Words and Phrases: combinations
CR Categories: 5.39
Language: Fortran

DESCRIPTION

Let $C = \{C_1, C_2, \ldots, C_m\}$ be the set of combinations of n items taken p at a time and arranged in lexicographical order. Given an integer, i ($1 \leq i \leq m$, $n \geq p > 0$), the algorithm derives C_i. Previous algorithms [1, 3, 6] have accomplished this by the generation of all vectors between an initial point in the combination space and the desired vector. The cited algorithms are computationally advantageous if all combinations or a sequential subset are required. However, the algorithm given here is advantageous if a few randomly selected combinations are needed and each selection is not based on the previous selection history.

A one-to-one correspondence between the universe of n items and the first n natural numbers is established. The combinations produced by the algorithm are selections of p of the first n integers in lexicographical order [2, 5]. Thus the combinations produced by the algorithm may be regarded equivalently as pointers to combinations of any objects. If the combinations are generated sequentially (according to the index), exactly the same order is achieved as that of Mifsud's algorithm [4].

Vector generation is performed by probing the combination space and sequentially reducing the interval of uncertainty within which the indexed vector resides. Beginning with the leftmost vector position, trial values in ascending order for the digits are tested by computing the index of the (partial) trial vector, using essentially the method of Walter [7]. The lexicographical index, i, for a combination C_i is computed as follows: Let the elements of the combination vector be denoted $X_1, X_2, \ldots, X_p$. Using $X_0 = 0$, the index i is

$$i = 1 + \sum_{j=1}^{p} Q_j; \quad Q_j = \begin{cases} \sum_{k=X_{j-1}+1}^{X_j-1} \binom{n-k}{p-j} & \text{if } X_{j-1} + 1 \leq X_j - 1 \\ 0 & \text{otherwise.} \end{cases}$$

This formula is the inverse of the present algorithm. The technique consists of accumulating terms of the form of those in the expression for Q_j until a total greater than or equal to the desired vector index is reached. The value causing this condition is X_j. The sum is reduced by the amount of the last term (so that Q_j only contains terms through $X_j - 1$) and the search resumes at the next position to the right. The probing halts when there are no positions remaining. A previous ACM algorithm [8] is used to compute the binomial coefficients.

Once a value has been eliminated from a position, it is eliminated from all following positions since the values are produced in ascending order. Thus the number of probes required to find a vector is exactly the numeric value of the last element. That is, the vector {1, 3, 7} will be found in seven probes given any combination space containing seven or more things taken three at a time. This leads to an expression for the average number of probes required to find a vector based entirely on the frequency of values occurring as the last element:

$$\binom{n}{p}^{-1} \sum_{m=0}^{n-p} \binom{n-1-m}{p-1} (n - m).$$

It can be seen that each nonzero term in Q_p (i.e. Q_j for $j = p$) equals unity. If the first term (1) in the expression for i is combined with Q_p, it can be written in the form

$$Q_p = X_j - X_{j-1}.$$

Taking advantage of this identity, an improvement in performance may be obtained by computing

$$C_p = C_{p-1} + L - K,$$

where L and K are variables given within the algorithm.

ACKNOWLEDGMENT

The authors wish to thank the referees for their thought-provoking and helpful comments. In particular, a remark of one of the referees prompted an observation leading to the improvement expressed in the last equation.

ALGORITHM 516
An Algorithm for Obtaining Confidence Intervals and Point Estimates Based on Ranks in the Two-Sample Location Problem [G1]

J. W. McKEAN and T. A. RYAN, JR.
Pennsylvania State University

Key Words and Phrases: asymptotic linearity, confidence interval, Illinois method, point estimate, ranks, regula falsi, robust, Wilcoxon-Mann-Whitney rank test
CR Categories: 5.5
Language: Fortran

DESCRIPTION

Suppose we are sampling from two populations which have the same continuous distribution except for a possible shift in location. For notational convenience let $X_1, \ldots, X_m$ be a random sample from $F(x)$ and let $Y_1, \ldots, Y_n$ be a random sample from $F(x - \theta)$. In testing hypotheses concerning θ the robust two-sample rank test (Wilcoxon-Mann-Whitney) is often used, but the related point estimate and confidence intervals are used relatively rarely. The reasons for this are primarily computational. While it has been practical to carry out the test for large sample sizes, it has not been practical for the estimates.

The most common method for computing the estimates is based on the $m \cdot n$ ordered differences $D_{ij} = Y_j - X_i$ (for instance, see Noether [5, p. 138]). These differences can be quickly obtained and ordered for small m and n; however, for large m and n they may be costly to obtain, even with the use of a computer. The storage is high (for example, if m and n are 1000, then 1,000,000 words of storage are needed); furthermore, computation time is high (of order $m \cdot n$, even if the samples are ordered in a preliminary step).

One way of avoiding the computation difficulty is to modify the estimate, for instance, as Antille [1] did in one sample problem. We propose instead an iteration procedure based on the function $U(\theta) = \#(Y_j - X_i \leq \theta)$. This is the Mann-Whitney test statistic for testing that the shift is θ; it differs only by a constant from the Wilcoxon rank sum statistic. It is an increasing function of θ which steps up one unit at each difference $Y_j - X_i$. The point estimate and confidence interval can be found by essentially inverting this function; for example, the point estimate of θ is $\hat{\theta}$ = median (D_{ij}), which can be found by solving the equation $U(\theta) = mn/2$ (the middle such value if it is not unique). The endpoints of the

Received 22 August 1975 and 10 May 1976.

Authors' present addresses: J.W. McKean, Department of Mathematical Sciences, University of Texas at Dallas, 2601 N. Floyd Rd., Richardson, TX 75080; T.A. Ryan, Jr., Department of Statistics, College of Science, Pennsylvania State University, 219 Pond Laboratory; University Park, PA 16802.

confidence interval can be obtained similarly. See Hettmansperger and McKean [3] for a graphical view of $U(\theta)$.

The algorithm given here finds the point estimate and confidence interval by solving such equations. Since $U(\theta)$ is monotone, methods such as regula falsi (linear interpolation) may be used. Of the methods tried, we have found the Illinois method, a modification of the regula falsi method outlined by Dowell and Jarratt [2], to be the best. The number of iterations is reduced by a factor of 2 or 3 when it is compared to regula falsi; hence we have incorporated it into the algorithm. The algorithm requires a preliminary and separate ordering of the X and Y. We have found that this ordering allows an algorithm for calculating $U(\theta)$ which saves a considerable amount of time.

The algorithm eliminates the storage problem. Furthermore, we feel the algorithm obtains the estimates quickly enough to make them more attractive. The time for an evaluation of $U(\theta)$ is linear in sample size but the number of iterations decreases due to the asymptotic linearity of $U(\theta)$ (see Jureckova [4]). For example, in a test run with $m = 1000$ and $n = 1200$ the computation time was 0.19 CPU seconds to obtain both the point estimate and confidence interval on an IBM 370 Model 168 (this costs about $0.02).

ALGORITHM 517
A Program for Computing the Condition Numbers of Matrix Eigenvalues Without Computing Eigenvectors [F2]

S. P. CHAN, R. FELDMAN, and B. N. PARLETT
University of California

Key Words and Phrases: eigenvalue, condition number
CR Categories: 5.14
Language: Fortran

DESCRIPTION

1. Theoretical Background

1.1 *The Sensitivity of Eigenvalues.* Several good programs are available for the computation of the eigenvalues of real and complex matrices [2, 3, 7]. Because of the limitations of finite precision arithmetic, these programs cannot produce, in general, the exact eigenvalues of the given matrix A. However the computed numbers are always (very close to) the eigenvalues of a matrix $A + E$ which is very close to A. This matrix E is not unique and error analyses [6] have shown the existence of E's with satisfactorily small upper bounds on $\| E \| / \| A \|$. Here $\| \cdot \|$ denotes an appropriate matrix norm.

It follows from these remarks that a good program will not always deliver accurate approximations to the eigenvalues of A. It can happen that some, or all, of the eigenvalues are very sensitive to changes in the matrix elements; so some, or all, of the eigenvalues of $A + E$ may differ sharply from those of A. Actually this is true only for non-normal matrices. Real symmetric matrices—indeed all normal matrices—determine their eigenvalues very well; the change induced in an eigenvalue of such an A cannot exceed the spectral norm of E (which is defined below).

Two questions arise: How can this sensitivity be measured, and how cheaply can it be computed?

Simple eigenvalues. To any simple eigenvalue λ of A there correspond both a column vector x and a row eigenvector y^* (the conjugate transpose of y) which are unique to within a scalar multiple. Thus

$$Ax = x\lambda, \qquad y^*A = \lambda y^* \tag{1}$$

Received 22 March 1976 and 7 September 1976.

This research was sponsored by the Office of Naval Research under Contract N00014-69-A-0200-1017.
Authors' present addresses: S.P. Chan, Burroughs Corp., Paoli, PA; R. Feldman and B. N. Parlett, Department of Mathematics, University of California, Berkeley, CA 94720.

and $x = y$ if A is normal (i.e. $A^*A = AA^*$). The most popular measure of the sensitivity of λ was called the spectral condition number cond (λ) by Wilkinson [6]. Let θ denote the acute angle between x and y; then

$$\text{cond } (\lambda) \equiv \text{secant } \theta = \| y \| \cdot \| x \| / | y^*x |$$

where

$$\| v \| = \sqrt{(v^*v)}. \tag{2}$$

This definition gives a number in $[1, \infty)$ which increases monotonically with the sensitivity of λ to changes in A.

In order to justify this definition two popular matrix norms will be used:

$$\begin{aligned} \| M \| &\equiv \max_{v \neq 0} \| Mv \| / \| v \| = \sqrt{(\lambda_{\max}(M^*M))}, \\ \| M \|_E &\equiv \sqrt{(\sum_i \sum_j | m_{ij} |^2)} = \sqrt{(\text{trace } (M^*M))}. \end{aligned} \tag{3}$$

Let $| \delta\lambda |$ be the change in λ corresponding to a change δA in A. It can be shown that

$$\text{cond } (\lambda) = \sup | \delta\lambda | / \| \delta A \|_E \tag{4}$$

over all non-null infinitesimal δA.

Another useful characterization of cond (λ) is the following: The spectral projector P_λ of λ is the matrix which projects every vector into a multiple of the eigenvector of λ. It is easy to verify that for simple λ

$$P_\lambda = xy^*/y^*x \tag{5}$$

where y^*x is a scalar, and by using the fact that P_λ is of rank 1, one can show that

$$\text{cond } (\lambda) = \| P_\lambda \|_E = \| P_\lambda \|. \tag{6}$$

It is this characterization which can be generalized.

Multiple eigenvalues. When λ has geometric multiplicity m, almost all perturbations of A break λ into m simple eigenvalues in such a way that $\sup | \delta\lambda | / \| \delta A \|$ is unbounded. Thus it is customary to set cond $(\lambda) = \infty$ in this case.

There is more to be said however. A reasonable definition (see Kahan [4]) puts

$$\text{cond } (\lambda) \equiv \sup | \delta\lambda | / \| \delta A \| \tag{7}$$

over all non-null infinitesimal δA which preserve the multiplicity of λ. This number can be estimated because cond $(\lambda) \leq \| P_\lambda \|_E / m$ where the spectral projector P_λ satisfies $AP_\lambda = P_\lambda A = \lambda P_\lambda + N_\lambda$ and N_λ is nilpotent (i.e. $N_\lambda{}^m = 0$). Moreover P_λ can be found from the expression

$$P_\lambda = X(Y^*X)^{-1}Y^* \tag{8}$$

where the columns of X and rows of Y^* are bases for the invariant subspaces of λ.

We have followed the usual practice (of setting the condition number equal to infinity) in our program CONDIT but wish to point out that it is feasible to bring into adjacent positions on the diagonal of the Schur form any associated ill-conditioned eigenvalues. The spectral projector for this group of eigenvalues can then be found from (8), and if its norm is small, the group can be designated as a cluster. That is another project.

If more specific information is required, then the individual elements of P_λ will be involved because

$$\partial\lambda/\partial a_{ij} = e_j{}^* P_\lambda e_i \tag{9}$$

with λ simple.

A warning should be offered at this point. The measures presented above are based on the Euclidean vector norm and the convention that A acts on vectors in Euclidean n-space. It can happen that this model is quite inappropriate for certain applications and then the conventional condition numbers will be irrelevant. However it is only the order of magnitude (base 10) of cond (λ) which is wanted, in most cases, and this will be constant over a large range of norms.

1.2 *Invariance Properties.* When the role of the matrix is to be stressed the condition number is written cond (λ, A).

THEOREM. *If Q is unitary, i.e. $Q^*Q = QQ^* = I$, and λ is a simple eigenvalue of A, then*

$$cond\ (\lambda, QAQ^*) = cond\ (\lambda, A).$$

PROOF. Let $Ax = x\lambda$, $y^*A = \lambda y^*$. Then

$$(QAQ^*)(Qx) = (Qx)\lambda, \qquad (y^*Q^*)(QAQ^*) = \lambda(y^*Q^*).$$

Because λ is simple, $y^*x \neq 0$ and

$$\begin{aligned} \text{cond}\ (\lambda, QAQ^*) &= \| y^*Q^* \| \cdot \| Qx \| / | (y^*Q^*)(Qx) |, \\ &= \| y^* \| \cdot \| x \| / | y^*x |, \\ &= \text{cond}\ (\lambda, A), \end{aligned}$$

because the Euclidean norm is unitarily invariant. □

COROLLARY. *If a given matrix B is reduced to Hessenberg form H by unitary similarities (such as Householder transformations) and the QR algorithm is applied to H to produce, in the limit, a quasi-triangular matrix T, then*

$$cond\ (\lambda, B) = cond\ (\lambda, T).$$

1.3 *The Use and Cost of Condition Numbers.* A computed eigenvalue λ of a given matrix A is an exact eigenvalue of many matrices including some close to A. Let $A + E$ designate one of the closest matrices. Provided $(\| E \|_E / \| A \|_E)^2$ is negligible, the error in λ is bounded by cond $(\lambda) \| E \|_E$. Error analyses [6] give an upper bound β on $(\| E \|_E / \| A \|_E)$ when the Householder/QR method is used. It follows that $\log_{10} (| \lambda | / \beta \cdot \text{cond}\ (\lambda) \cdot \| A \|_E)$ gives the number of decimal digits in λ which are assuredly correct.

When no figures in λ can be relied on, then a warning tag should be attached to λ for most applications. Conversely, when an adequate number of figures are certified as correct in each eigenvalue of A, then the subsequent calculations are placed on a sounder footing.

These estimates of the number of correct figures have proved useful in the comparison of rival eigenvalue programs and in debugging big programs of which the eigenvalue calculations were merely a part.

A natural question at this stage is how much extra does it cost to compute cond (λ) as well as λ? The answer must depend on whether the user also computes x and/or y along with λ. We focus on real matrices and real arithmetic.

(1) If a complete Jordan factorization $A = X\Lambda Y^*$ $(Y^*X = I)$ is computed then each cond (λ_i) can be found from the definition $\| x_i \| \| y_i^* \| / | y_i^*x |$ at negligible extra cost in storage and time. No special program is needed and this case will not be considered further. Few dependable Jordan factorization routines are currently available.

(2) If a program is used which yields X and Λ but not Y^*, then it is necessary to compute the triangular factorization L_xU_x and store it in an extra array. Then cond $(\lambda_i) = \| e_i^*X^{-1} \| \cdot \| Xe_i \|$. To invert X costs n^3 basic operations whereas X and Λ may be found in approximately $7n^3$ operations using the double QR transformation.

No special program is needed. The time penalty is slight but the extra storage requirement is substantial. This case will not be discussed further.

(3) The eigenvalues λ of A may be found (EISPACK path, ELMHES, HQR) in under $4\frac{1}{6}n^3$ operations with no supplementary $n \times n$ storage arrays provided A can be overwritten. This is the most interesting case. No extra arrays are needed for the computation of cond (λ_i), $i = 1, \ldots, n$, but the multiplication count rises to approximately $7n^3$. See Section 1.4 for more details. The $O(n^2)$ terms bring down the ratio of running times; the increase is approximately 50 percent (± 15 percent).

Our method is easily described. The given matrix A is reduced to Hessenberg form H by *orthogonal* similarity transformations. Then H is transformed to quasi-triangular Schur form T by the double QR algorithm working on the whole of H and not just the remaining principal submatrices. None of the orthogonal transforming matrices is retained. Finally the column and row eigenvectors of T are found, for each λ, by back substitution and then discarded immediately after cond (λ) has been calculated.

By Theorem 1, cond (λ, T) = cond (λ, A).

For simplicity all condition numbers exceeding 10^{30} are recorded as 10^{30}.

The program uses only real arithmetic even if A has complex eigenvalues.

1.4 *Operation Counts.* In [5] Parlett and Wang point out that straightforward counts of multiplications and additions are unreliable indicators of running times. Nevertheless they are good to within a factor of 2 and they do give insight into the way the algorithm spends its time. An op is defined as a scalar multiplication or division followed by an addition.

ORTHES. The $(n - j)$th step transforms the last j rows and columns while reducing column $(n - j)$ to upper Hessenberg form.

Row operations: $A \to A' = A - w\gamma(w^{\mathrm{T}}A)$, $\gamma = 2/w^{\mathrm{T}}w$, $w^{\mathrm{T}} = (0, \ldots, 0, x, \ldots, x)$

Computation	γ	$w^{\mathrm{T}}A$	$v^{\mathrm{T}} = \gamma(w^{\mathrm{T}}A)$	$A - wv^{\mathrm{T}}$	Total
Cost	j	j^2	j	j^2	$2j(j + 1)$

Column operations: $A' \to A'' = A' - \gamma A'ww^{\mathrm{T}}$

Computation	γ	$A'w$	$u = \gamma A'w$	$A' - uw^{\mathrm{T}}$	Total
Cost	0	nj	n	nj	$n(2j +)$

Grand total: $\sum_{j=1}^{n-1} n(2j + 1) + 2j(j + 1) = \frac{4}{3}n(n^2 - 1)$

The program ELMHES is approximately twice as fast as ORTHES but will not preserve condition numbers.

CONDIT. It suffices to assume that all eigenvalues are real. To find the column and row eigenvectors for the jth eigenvalue requires backsolving triangular systems of $(j - 1)$ and $(n - j - 1)$ equations, respectively.

Computation	x	y^*	Cond
Cost	$\sum_{i=1}^{j-1} i$	$\sum_{i=1}^{n-j-1} i$	n

Grand total: $\frac{1}{3}n^3 + \frac{1}{2}n^2 + \frac{1}{6}n$

HQR. A typical double QR transformation acts on a $j \times j$ submatrix of a Hessenberg matrix. To restore column k to Hessenberg form requires the following operations for $k \leq j - 2$. For $k = j - 1$ the cost is $3j + 6$ ops.

Computation	Key quantities	Row operations	Column operations
Cost	9	$\sum_{l=k}^{j} 5$	$\sum_{l=1}^{\min(k+3,j)} 5$

Total: $\sum_{k=1}^{j-2} [9 + 5(j - k + 1) + 5(k + 3)] + 3j + 6 = 5j^2 + 22j - 54$

Assume four initial full transformations with $j = n$ and then two iterations per eigenvalue.

Grand total: $\frac{10}{3}n^3 + 47n^2 + \frac{11}{3}n - 182$

QR2N0Z. The same transformations as in HQR must act on the whole matrix. This changes the range of the row operation and not the column because the $j \times j$ submatrix being transformed is the leading principal submatrix.

Computation	Key quantities	Row operations	Column operations
Cost	9	$\sum_{l=k}^{n} 5$	$\sum_{l=1}^{\min(k+3,j)} 5$

Total: $\sum_{k=1}^{j-2} [9 + 5(n - k + 1) + 5(k + 3)] + 3n + 21 = (5n + 29)(j - 2) + (3n + 21)$

With the same assumptions as above,

Grand total: $5n^3 + 40n^2 + 23n - 300$

A summary of operation counts is:

ELMHES + HQR:	$4\frac{1}{6}n^3 + 47n^2 + 3n - 182$;
ORTHES + HQR:	$5n^3 + 47n^2 + 2n - 182$;
ORTHES + QR2N0Z + CONDIT:	$7n^3 + 40\frac{1}{2}n^2 + 21\frac{1}{2}n - 300$.

The actual timings were more favorable to our program than these operation counts suggest. The assumption of two iterations per eigenvalue is unrealistic. In practice there are more iterations with larger values of j and fewer with small values. With $20 \leq n \leq 60$ our program ran, on the average, 50 percent longer than did ELMHES + HQR; the worst case ran 65 percent longer.

2. Applicability

The program accepts real square matrices which can be stored in the high speed memory of the computer.

The condition numbers of all eigenvalues of all normal matrices (and this includes symmetric matrices) are unity and consequently the program is intended for use with non-normal matrices.

Before our programs QR2N0Z and CONDIT are used, A should be reduced to Hessenberg form H by orthogonal congruences. We recommend the procedure ORTHES described in [7] and its Fortran counterpart ORTHES described in [2, p. 297].

Our program QR2N0Z is an adaptation of HQR2 [2, p. 248] and is designed to avoid the formation of the product of all the similarity transformations used in the double QR algorithm and the calculation of the eigenvectors of the final matrix of the QR sequence.

3. Organizational Details

3.1 *Standardization.* (i) In the course of the QR algorithm applied to H it is possible for two real eigenvalues to be found at the same time as the roots of a 2×2 diagonal block

$$\begin{pmatrix} \alpha & \beta \\ \gamma & \delta \end{pmatrix}.$$

It is convenient in such cases to do a supplementary plane rotation which will reduce this diagonal block to upper triangular form and change the corresponding rows and columns of H accordingly.

If this transformation is done at the time the eigenvalues λ_1 and λ_2 are recorded then some of the quantities which determine the correct angle of rotation will be available.

This device is employed in HQR2 and has been carried over to QR2N0Z. The details are given below.

The parameters $c = \cos\theta$, $s = \sin\theta$ are determined so that

$$\begin{pmatrix} c & -s \\ s & c \end{pmatrix}\begin{pmatrix} \alpha & \beta \\ \gamma & \delta \end{pmatrix}\begin{pmatrix} c & s \\ -s & c \end{pmatrix}$$

is upper triangular. Thus $\gamma c^2 - dcs - \beta s^2 = 0$, $d = \delta - \alpha$. Let $t = (d/2)^2 + \beta\gamma$; then $\cot\theta = (d/2 + \text{sign}\,(d)\,\sqrt{t})/2\gamma$, $s = \text{sign}\,(\cot\theta)(1 + \cot^2\theta)^{-1/2}$, $c = s\cdot\cot\theta$.

(ii) It is also convenient to perform a supplementary plane rotation after a pair of complex conjugate eigenvalues, $\lambda \pm i\mu$, has been recorded in the course of the QR algorithm. In this case the transformation of the diagonal block is

$$\begin{pmatrix} c & s \\ -s & c \end{pmatrix}\begin{pmatrix} \alpha & \beta \\ \gamma & \delta \end{pmatrix}\begin{pmatrix} c & -s \\ s & c \end{pmatrix} = \begin{pmatrix} \lambda & \theta \\ \xi & \lambda \end{pmatrix}$$

where $\xi\theta = -\mu^2$. This device is not used in HQR2.

Note that it is not in general possible to transform

$$\begin{pmatrix} \alpha & \beta \\ \gamma & \delta \end{pmatrix} \rightarrow \begin{pmatrix} \lambda & -\mu \\ \mu & \lambda \end{pmatrix}$$

using *orthogonal* similarity transformations.

The purpose of the transformation is to yield a simple solution to certain systems of linear equations which must be solved. The supplementary plane rotation is done at the stage when the eigenvalues are being recorded in QR2N0Z. In this case $t \equiv p^2 + \beta\gamma < 0$, $p = (\alpha - \delta)/2$. We want to choose $c = \cos\theta$ and $s = \sin\theta$ so that

$$\alpha c^2 + (\beta + \gamma)cs + \delta s^2 = \delta c^2 - (\beta + \gamma)cs + \alpha s^2.$$

Hence

$$\tan 2\theta = 2sc/(c^2 - s^2) = -2p/\sigma = (2 \mid p \mid / \mid \sigma \mid) \operatorname{sign}(-p\sigma), \quad \sigma = \beta + \gamma.$$

Let $\tau = \sqrt{(\sigma^2 + 4p^2)}$. Then

$$\cos\theta = q = \sqrt{(\tfrac{1}{2}(1 + \cos 2\theta))} = \sqrt{((1 + \mid \sigma \mid / \tau)/2)},$$

$$\sin\theta = \sin 2\theta/2 \cos\theta = \mid p \mid \operatorname{sign}(-p\sigma)/\tau q.$$

3.2 *The Computation of the Eigenvectors of a Standardized Real, Block Upper Triangular Matrix.* For each real eigenvalue λ the eigenvectors u, w^* satisfy $Tu = u\lambda$, $w^*T = \lambda w^*$.

For each complex conjugate pair of eigenvalues, $\lambda \pm i\mu$, the eigenvectors $u_1 \pm iu_2$ ${w_1}^* \mp i{w_2}^*$ satisfy $T(u_1, u_2) = (u_1, u_2)\hat{E}$, $(w_1, w_2)^*T = \hat{E}(w_1, w_2)^*$, where

$$\hat{E} = \begin{pmatrix} \lambda & \mu \\ -\mu & \lambda \end{pmatrix}.$$

In effecting the back substitution process in real arithmetic there are four different cases which can occur, depending on whether the matrices D and E shown below are 1×1 or 2×2:

$$T = \begin{pmatrix} \cdot & \cdot & \cdot & \cdot & \cdot \\ & D & \cdot & \cdot & \cdot \\ & & \cdot & \cdot & \cdot \\ & & \mathrm{O} & E & \cdot \\ & & & & \cdot \end{pmatrix} \qquad D = \begin{cases} \alpha \text{ or} \\ \begin{pmatrix} \alpha & \beta \\ \gamma & \alpha \end{pmatrix} \end{cases}$$

$$E = \begin{cases} \lambda \text{ or} \\ \begin{pmatrix} \lambda & \phi \\ \theta & \lambda \end{pmatrix} \end{cases}$$

where $\theta\phi = -\mu^2$. The positions of D and E should be exchanged when considering the row eigenvectors.

Type 1. *pair-pair* (E *is* 2×2, D *is* 2×2). Imagine that the elements of u_1, u_2 in the same row as D are about to be computed. All elements below these have already been found, the elements below E being zero.

Let $j1, j2$ be the rows of T in which D lies. Then the unknowns are

$$V = \begin{pmatrix} u_1(j1) & u_2(j1) \\ u_1(j2) & u_2(j2) \end{pmatrix}.$$

The equation to be solved in the column case is $-DV + V\hat{E} = R$, where

$$R = \begin{pmatrix} r_1(j1) & r_2(j1) \\ r_1(j2) & r_2(j2) \end{pmatrix}, \quad r_\nu(m) = \sum_{k=j2+1}^{i+1} t_{m,k}u_\nu(k), \begin{cases} m = j1, j2, \\ \nu = 1, 2. \end{cases} \tag{10}$$

In the row case let

$$V = \begin{pmatrix} w_1(j1) & w_2(j1) \\ w_1(j2) & w_2(j2) \end{pmatrix};$$

then the equations to be solved are

$$-V^{T}D + \hat{E}V^{T} = R^{T}, \tag{11}$$

where R is as above except that k runs from i to $j1 - 1$. Transposing yields

$$-D^{T}V + V\hat{E}^{T} = R.$$

Comparing this with the column case we see that it is only necessary to transpose D and $\hat{E}$ (i.e. to exchange β, γ and $\mu, -\mu$) in order to use the same code for both cases.

The way in which these four linear equations in four unknowns are solved is described in Section 3.3.

Type 2. *pair-single* (E *is* 2×2, D *is* 1×1). The relevant equations are

$$-\alpha(u_1(j), u_2(j)) + (u_1(j), u_2(j))\hat{E} = (r_1(j), r_2(j))$$

and

$$-\alpha(w_1(j), w_2(j)) + (w_1(j), w_2(j))\hat{E}^{T} = (r_1(j), r_2(j)).$$

Let $d = \lambda - \alpha$, den $= d^2 + \mu^2$, val $= \begin{cases} \mu \text{ (for column)} \\ -\mu \text{ (for row)}. \end{cases}$ The solution for both cases is

$$\begin{aligned} v_1 &= (r_1 \cdot d + r_2 \cdot \text{val})/\text{den}, \\ v_2 &= (-r_1 \cdot \text{val} + r_2 \cdot d)/\text{den}. \end{aligned} \tag{12}$$

Type 3. *single-pair* (E *is* 1×1, D *is* 2×2). The relevant equations are

$$-D\begin{pmatrix} u_1(j1) \\ u_1(j2) \end{pmatrix} + \begin{pmatrix} u_1(j1) \\ u_1(j2) \end{pmatrix}\lambda = \begin{pmatrix} r_1(j1) \\ r_1(j2) \end{pmatrix}$$

and the same equation for w_1 with D^{T} in place of D. Set $d = \lambda - \alpha$, den $= d^2 - \beta\gamma$. The solution is

$$\begin{aligned} v_1 &= (r_1(j1) \cdot d + r_1(j2) \cdot \tilde{\beta})/\text{den}, \\ v_2 &= (r_1(j1) \cdot \tilde{\gamma} + r_1(j2) \cdot d)/\text{den}, \end{aligned} \tag{13}$$

where $\tilde{\beta} = \begin{Bmatrix} \beta & \text{(for column)} \\ \gamma & \text{(for row} \end{Bmatrix}$ and $\tilde{\gamma} = \begin{Bmatrix} \gamma & \text{(for column)} \\ \beta & \text{(for row} \end{Bmatrix}$. In practice $\tilde{\beta} = T(JJ, J), \tilde{\gamma} = T(J, JJ)$ and the indices J and JJ are given the values of $J1$ and $J2$ in the appropriate order.

Type 4. *single-single* (E *is* 1×1, D *is* 1×1). $v_1 = r_1(j)/\text{den}$, den $= \lambda - \alpha$.

Type 5. *formula breakdown.* If in any of the previous cases $D = E$ then the formulas for solution break down. There are two cases to consider.

(i) Linear Independence. Any element v_j for which the formula yields 0/0 can be set to any value, the most convenient is 0. This represents the existence of a whole space of eigenvectors associated with E.

(ii) Defective Case. Any element v_j for which the formula yields a value exceeding 1/TOL will cause the condition number to exceed 1/TOL. If this case is detected computation is interrupted, the condition number is set to 1/TOL, and the program proceeds to the next eigenvalue.

We propose that TOL $= 10^{-30}$ will be suitable for most applications and most computers.

These tests make the code simple and machine independent. However, it is possible to devise matrices for which the given value 1/TOL for the condition is very misleading. We know of no failsafe procedure which does not involve deciding the rank of $T - \xi$ for all ξ in a neighborhood of λ. This is a costly, difficult, and often unrewarding task.

3.3 *Closed Form Solution for Equations of Type* 1. The equations to be solved are of the form $-DV + V\hat{E} = R$, where

$$D = \begin{pmatrix} \alpha & \beta \\ \gamma & \alpha \end{pmatrix}, \quad \hat{E} = \begin{pmatrix} \lambda & \mu \\ -\mu & \lambda \end{pmatrix}, \quad R = \begin{pmatrix} r_{11} & r_{12} \\ r_{21} & r_{22} \end{pmatrix}.$$

The standardization of the block triangular matrix T forces the diagonal elements of D to be equal. This yields simple formulas for the elements of V.

Rewrite the equation as

$$(v_{11}\ v_{12}\ v_{21}\ v_{22})\begin{pmatrix} B & -\gamma I_2 \\ -\beta I_2 & B \end{pmatrix} = (r_{11}\ r_{12}\ r_{21}\ r_{22}) = r^{\mathrm{T}},$$

where

$$B = \begin{pmatrix} \lambda - \alpha & \mu \\ -\mu & \lambda - \alpha \end{pmatrix}.$$

Observe that

$$\begin{pmatrix} B & -\gamma I_2 \\ -\beta I_2 & B \end{pmatrix}\begin{pmatrix} B^{\mathrm{T}} & \gamma I_2 \\ \beta I_2 & B^{\mathrm{T}} \end{pmatrix} = \tau I_4 + 2\mu J_4,$$

where $\tau = (\lambda - \alpha)^2 + \mu^2 - \beta\gamma$, with $\beta\gamma < 0$,

$$J_4 = \begin{pmatrix} 0 & 0 & 0 & \gamma \\ 0 & 0 & -\gamma & 0 \\ 0 & \beta & 0 & 0 \\ -\beta & 0 & 0 & 0 \end{pmatrix},$$

and I_k is the $k\times k$ identity matrix. Further, $(\tau I_4 + 2\mu J_4)(\tau I_4 - 2\mu J_4) = [\tau^2 - 4\mu^2(-\beta\gamma)]I_4$. Hence

$$(v_{11}\ v_{12}\ v_{21}\ v_{22})(\tau^2 + 4\mu^2\beta\gamma) = r^{\mathrm{T}}\begin{pmatrix} B^{\mathrm{T}} & \gamma I_2 \\ \beta I_2 & B^{\mathrm{T}} \end{pmatrix}(\tau I_4 - 2\mu J_4)$$

$$= r^{\mathrm{T}}\begin{pmatrix} e & -f & \gamma g & -\gamma h \\ f & e & \gamma h & \gamma g \\ \beta g & -\beta h & e & -f \\ \beta h & \beta g & f & e \end{pmatrix}$$

where $d = \lambda - \alpha$, $e = d\tau$, $f = \mu(\tau + 2\beta\gamma)$, $g = \tau - 2\mu^2$, and $h = 2\,d\mu$. Note that

$$\begin{aligned} \tau^2 + 4\mu^2\beta\gamma &= (d^2 + \mu^2 - \beta\gamma)^2 + 4\mu^2\beta\gamma \\ &= g^2 + h^2 \\ &(= 0 \quad \text{if and only if} \quad \alpha = \lambda,\ \mu^2 = -\beta\gamma). \end{aligned}$$

These same formulas will be valid for the row eigenvectors provided we exchange (β, γ) and $(\mu, -\mu)$.

The alternative to using this closed form solution is to code a special version of Gaussian elimination with pivoting. It is the pivoting which would lengthen the code considerably.

3.4 *The Condition Number of Conjugate Pairs of Eigenvalues.* Let $\lambda \pm i\mu$ be a complex pair of eigenvalues of the real Schur matrix T obtained by the QR algorithm. In the course of the algorithm the following real equations are solved for real n-vectors u_1, u_2, w_1, w_2 :

$$T(u_1, u_2) = (u_1, u_2)\begin{pmatrix} \rho & \mu \\ -\mu & \rho \end{pmatrix}, \quad (w_1, w_2)^* T = \begin{pmatrix} \rho & \mu \\ -\mu & \rho \end{pmatrix}(w_1, w_2)^*. \tag{5}$$

Thus span (u_1, u_2) and span (w_1^*, w_2^*) are real invariant subspaces under T. However, $\{u_1, u_2\}$ and $\{w_1^*, w_2^*\}$ are very special bases of these spaces.

LEMMA. *With the notation given above, $u_1 \pm iu_2$ and $w_1^* \mp iw_2^*$ are the column and row eigenvectors belonging to $\lambda \pm i\mu$.*

PROOF. From (5),

$$\begin{aligned} Tu_1 &= u_1\lambda - u_2\mu, \quad w_1^* T = \lambda w_1^* + \mu w_2^*, \\ Tu_2 &= u_1\mu + u_2\lambda, \quad w_2^* T = -\mu w_1^* + \lambda w_2^*. \end{aligned}$$

Hence

$$T(u_1 + iu_2) = u_1(\lambda + i\mu) + iu_2(i\mu + \lambda),$$

then the equations to be solved are

$$-V^{\mathrm{T}}D + \hat{E}V^{\mathrm{T}} = R^{\mathrm{T}}, \tag{11}$$

where R is as above except that k runs from i to $j1 - 1$. Transposing yields

$$-D^{\mathrm{T}}V + V\hat{E}^{\mathrm{T}} = R.$$

Comparing this with the column case we see that it is only necessary to transpose D and $\hat{E}$ (i.e. to exchange β, γ and μ, $-\mu$) in order to use the same code for both cases.

The way in which these four linear equations in four unknowns are solved is described in Section 3.3.

Type 2. *pair-single* (E *is* 2×2, D *is* 1×1). The relevant equations are

$$-\alpha(u_1(j), u_2(j)) + (u_1(j), u_2(j))\hat{E} = (r_1(j), r_2(j))$$

and

$$-\alpha(w_1(j), w_2(j)) + (w_1(j), w_2(j))\hat{E}^{\mathrm{T}} = (r_1(j), r_2(j)).$$

Let $d = \lambda - \alpha$, den $= d^2 + \mu^2$, val $= \begin{cases} \mu \text{ (for column)} \\ -\mu \text{ (for row)}. \end{cases}$ The solution for both cases is

$$\begin{aligned} v_1 &= (r_1 \cdot d + r_2 \cdot \text{val})/\text{den}, \\ v_2 &= (-r_1 \cdot \text{val} + r_2 \cdot d)/\text{den}. \end{aligned} \tag{12}$$

Type 3. *single-pair* (E *is* 1×1, D *is* 2×2). The relevant equations are

$$-D\begin{pmatrix} u_1(j1) \\ u_1(j2) \end{pmatrix} + \begin{pmatrix} u_1(j1) \\ u_1(j2) \end{pmatrix}\lambda = \begin{pmatrix} r_1(j1) \\ r_1(j2) \end{pmatrix}$$

and the same equation for w_1 with D^{T} in place of D. Set $d = \lambda - \alpha$, den $= d^2 - \beta\gamma$. The solution is

$$\begin{aligned} v_1 &= (r_1(j1) \cdot d + r_1(j2) \cdot \tilde{\beta})/\text{den}, \\ v_2 &= (r_1(j1) \cdot \tilde{\gamma} + r_1(j2) \cdot d)/\text{den}, \end{aligned} \tag{13}$$

where $\tilde{\beta} = \begin{cases} \beta & \text{(for column)} \\ \gamma & \text{(for row} \end{cases}$ and $\tilde{\gamma} = \begin{cases} \gamma & \text{(for column)} \\ \beta & \text{(for row} \end{cases}$. In practice $\tilde{\beta} = T(JJ, J)$, $\tilde{\gamma} = T(J, JJ)$ and the indices J and JJ are given the values of $J1$ and $J2$ in the appropriate order.

Type 4. *single-single* (E *is* 1×1, D *is* 1×1). $v_1 = r_1(j)/\text{den}$, den $= \lambda - \alpha$.

Type 5. *formula breakdown.* If in any of the previous cases $D = E$ then the formulas for solution break down. There are two cases to consider.

(i) Linear Independence. Any element v_j for which the formula yields 0/0 can be set to any value, the most convenient is 0. This represents the existence of a whole space of eigenvectors associated with E.

(ii) Defective Case. Any element v_j for which the formula yields a value exceeding 1/TOL will cause the condition number to exceed 1/TOL. If this case is detected computation is interrupted, the condition number is set to 1/TOL, and the program proceeds to the next eigenvalue.

We propose that TOL $= 10^{-30}$ will be suitable for most applications and most computers.

These tests make the code simple and machine independent. However, it is possible to devise matrices for which the given value 1/TOL for the condition is very misleading. We know of no failsafe procedure which does not involve deciding the rank of $T - \xi$ for all ξ in a neighborhood of λ. This is a costly, difficult, and often unrewarding task.

3.3 *Closed Form Solution for Equations of Type* 1. The equations to be solved are of the form $-DV + V\hat{E} = R$, where

$$D = \begin{pmatrix} \alpha & \beta \\ \gamma & \alpha \end{pmatrix}, \quad \hat{E} = \begin{pmatrix} \lambda & \mu \\ -\mu & \lambda \end{pmatrix}, \quad R = \begin{pmatrix} r_{11} & r_{12} \\ r_{21} & r_{22} \end{pmatrix}.$$

The standardization of the block triangular matrix T forces the diagonal elements of D to be equal. This yields simple formulas for the elements of V.

Rewrite the equation as

$$(v_{11}\ v_{12}\ v_{21}\ v_{22})\begin{pmatrix} B & -\gamma I_2 \\ -\beta I_2 & B \end{pmatrix} = (r_{11}\ r_{12}\ r_{21}\ r_{22}) = r^{\mathrm{T}},$$

where

$$B = \begin{pmatrix} \lambda - \alpha & \mu \\ -\mu & \lambda - \alpha \end{pmatrix}.$$

Observe that

$$\begin{pmatrix} B & -\gamma I_2 \\ -\beta I_2 & B \end{pmatrix}\begin{pmatrix} B^{\mathrm{T}} & \gamma I_2 \\ \beta I_2 & B^{\mathrm{T}} \end{pmatrix} = \tau I_4 + 2\mu J_4,$$

where $\tau = (\lambda - \alpha)^2 + \mu^2 - \beta\gamma$, with $\beta\gamma < 0$,

$$J_4 = \begin{pmatrix} 0 & 0 & 0 & \gamma \\ 0 & 0 & -\gamma & 0 \\ 0 & \beta & 0 & 0 \\ -\beta & 0 & 0 & 0 \end{pmatrix},$$

and I_k is the $k \times k$ identity matrix. Further, $(\tau I_4 + 2\mu J_4)(\tau I_4 - 2\mu J_4) = [\tau^2 - 4\mu^2(-\beta\gamma)]I_4$. Hence

$$(v_{11}\ v_{12}\ v_{21}\ v_{22})(\tau^2 + 4\mu^2\beta\gamma) = r^{\mathrm{T}}\begin{pmatrix} B^{\mathrm{T}} & \gamma I_2 \\ \beta I_2 & B^{\mathrm{T}} \end{pmatrix}(\tau I_4 - 2\mu J_4)$$

$$= r^{\mathrm{T}}\begin{pmatrix} e & -f & \gamma g & -\gamma h \\ f & e & \gamma h & \gamma g \\ \beta g & -\beta h & e & -f \\ \beta h & \beta g & f & e \end{pmatrix}$$

where $d = \lambda - \alpha$, $e = d\tau$, $f = \mu(\tau + 2\beta\gamma)$, $g = \tau - 2\mu^2$, and $h = 2\,d\mu$. Note that

$$\tau^2 + 4\mu^2\beta\gamma = (d^2 + \mu^2 - \beta\gamma)^2 + 4\mu^2\beta\gamma$$

$$= g^2 + h^2$$

$$(= 0 \quad \text{if and only if} \quad \alpha = \lambda,\ \mu^2 = -\beta\gamma).$$

These same formulas will be valid for the row eigenvectors provided we exchange (β, γ) and $(\mu, -\mu)$.

The alternative to using this closed form solution is to code a special version of Gaussian elimination with pivoting. It is the pivoting which would lengthen the code considerably.

3.4 *The Condition Number of Conjugate Pairs of Eigenvalues.* Let $\lambda \pm i\mu$ be a complex pair of eigenvalues of the real Schur matrix T obtained by the QR algorithm. In the course of the algorithm the following real equations are solved for real n-vectors u_1, u_2, w_1, w_2:

$$T(u_1, u_2) = (u_1, u_2)\begin{pmatrix} \rho & \mu \\ -\mu & \rho \end{pmatrix}, \quad (w_1, w_2)^*T = \begin{pmatrix} \rho & \mu \\ -\mu & \rho \end{pmatrix}(w_1, w_2)^*. \tag{5}$$

Thus span (u_1, u_2) and span (w_1^*, w_2^*) are real invariant subspaces under T. However, $\{u_1, u_2\}$ and $\{w_1^*, w_2^*\}$ are very special bases of these spaces.

LEMMA. *With the notation given above, $u_1 \pm iu_2$ and $w_1^* \mp iw_2^*$ are the column and row eigenvectors belonging to $\lambda \pm i\mu$.*

PROOF. From (5),

$$Tu_1 = u_1\lambda - u_2\mu, \quad w_1^*T = \lambda w_1^* + \mu w_2^*,$$

$$Tu_2 = u_1\mu + u_2\lambda, \quad w_2^*T = -\mu w_1^* + \lambda w_2^*.$$

Hence

$$T(u_1 + iu_2) = u_1(\lambda + i\mu) + iu_2(i\mu + \lambda),$$

$$(w_1^* - iw_2^*)T = (\lambda + i\mu)w_1^* - (\lambda + i\mu)iw_2^*.$$

The eigenvectors for $\lambda - i\mu$ are obtained in the same way. □

Consequently,

$$\text{cond}\,(\lambda \pm i\mu) = \| u_1 + iu_2 \| \cdot \| w_1^* - iw_2^* \| / [w_1^* u_1 + w_2^* u_2 + i(w_1^* u_2 - w_2^* u_2)].$$

Use was made in the lemma of the quasi-triangular nature of T. A consequence of this form is that u_1 and w_1 can be packed into the same real n-vector with two overlapping elements as indicated:

$$\left.\begin{aligned} u_1^* &= (x, \ldots, x, p_i, q_i, 0, \ldots, 0) \\ w_i^* &= (0, \ldots, 0, \bar{p}_i, \bar{q}_i, x, \ldots, x) \end{aligned}\right\} \quad i = 1, 2.$$

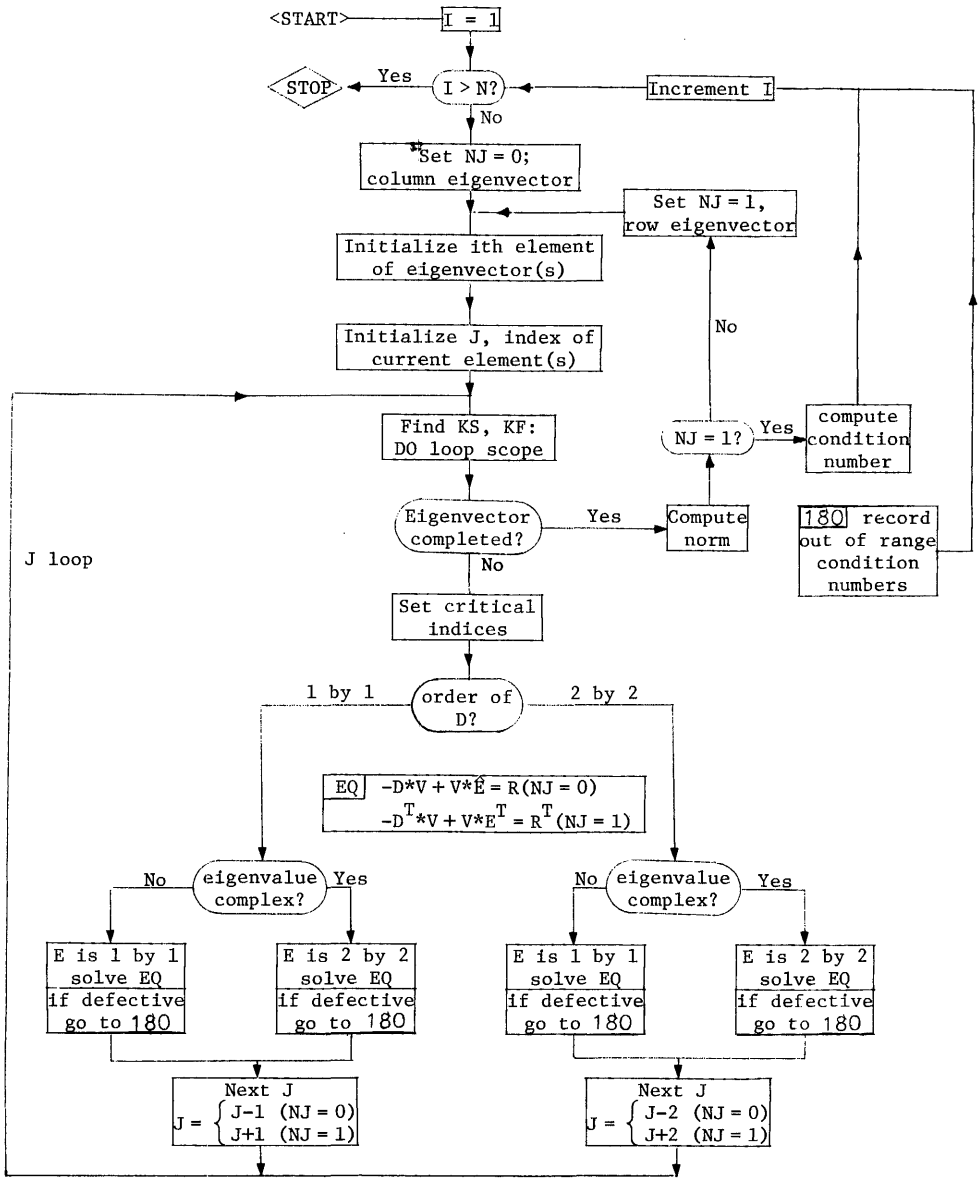

Fig. 1. Flowchart representing way in which column and row eigenvectors are computed allowing for haphazard ordering of 1×1 and 2×2 blocks on diagonal of real Schur form

The equations to be satisfied by p_i, q_i are of the form

$$\begin{pmatrix}\lambda & \beta\\ \gamma & \lambda\end{pmatrix}\begin{pmatrix}p_1 & p_2\\ q_1 & q_2\end{pmatrix} - \begin{pmatrix}p_1 & p_2\\ q_1 & q_2\end{pmatrix}\begin{pmatrix}\lambda & \mu\\ -\mu & \lambda\end{pmatrix} = 0,$$

$$\begin{pmatrix}\bar{p}_1 & \bar{q}_1\\ \bar{p}_2 & \bar{q}_2\end{pmatrix}\begin{pmatrix}\lambda & \beta\\ \gamma & \lambda\end{pmatrix} - \begin{pmatrix}\lambda & \mu\\ -\mu & \lambda\end{pmatrix}\begin{pmatrix}\bar{p}_1 & \bar{q}_1\\ \bar{p}_2 & \bar{q}_2\end{pmatrix} = 0,$$

where $\mu^2 = -\beta\gamma$. These equations reduce to

$$\beta q_2 = p_1\mu, \qquad \bar{p}_1\beta = \mu\bar{q}_2,$$

$$\beta q_1 = -\mu p_2, \qquad \beta\bar{p}_2 = -\mu\bar{q}_1.$$

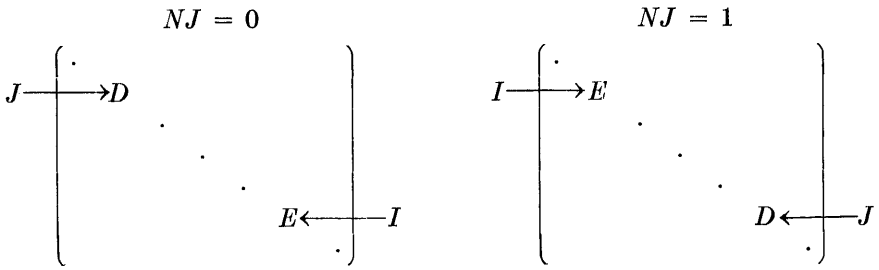
The simplest solution (which we adopt) takes $p_1 = \bar{p}_1 = 1$, $q_1 = p_2 = \bar{q}_1 = \bar{p}_2 = 0$, $q_2 = \mu/\beta$, $\bar{q}_2 = 1/q_2$. With this choice,

$$(w_1 - iw_2)^*(u_1 + iu_2) = (\bar{p}_1p_1 + \bar{p}_2p_2) + (\bar{q}_1q_1 + \bar{q}_2q_2) = 2 \text{ and}$$

$$\text{cond } (\lambda \pm i\mu) = [(\| u_1 \|^2 + \| u_2 \|^2)(\| w_1 \|^2 + \| w_2 \|^2)]^{1/2}/2. \tag{14}$$

4. The Structure of CONDIT

As indicated in Section 3.2 the same section of code (the J loop) computes the column and the row eigenvector of the Ith eigenvalue. It is the standardization of the Schur form which permits this economy. J, which always points to the block D, decreases for the column eigenvector ($NJ = 0$) and increases for the row eigenvector ($NJ = 1$), as indicated:



$$E = \begin{pmatrix}\lambda & \phi\\ \theta & \lambda\end{pmatrix} \text{ or } \lambda, \qquad \hat{E} = \begin{pmatrix}\lambda & \mu\\ -\mu & \lambda\end{pmatrix} \text{ or } \lambda,$$

where $\theta\phi = -\mu^2$.

Is the 0 diagonal element in $\mathbf{I}^0$ a keypunch error or did it really belong in the user's problem?

$$\mathbf{L}^0 = \begin{pmatrix}0 & \mathbf{X}\\ \mathbf{I}^0 & 0\end{pmatrix}; \quad \mathbf{I}^0 = \text{diag}(0, 1, 1, \ldots, 1);$$

$$\mathbf{X} = \begin{pmatrix}\mathbf{D} & \mathbf{T}_1 & 0\\ \mathbf{T}_2 & \mathbf{F}_1 & -\mathbf{F}_2\\ 0 & -\mathbf{F}_3 & \mathbf{F}_4\end{pmatrix}10^8; \quad \mathbf{F}\begin{pmatrix}a & b\\ c & d\end{pmatrix} = \begin{pmatrix}a & 0 & 0 & b\\ 0 & a & -b & 0\\ 0 & -c & d & 0\\ c & 0 & 0 & d\end{pmatrix};$$

$$\mathbf{D} = \text{diag}(.5221, .3563, .5552 \times 10^{-3}, .1328);$$

$$\mathbf{T}_1 = \begin{pmatrix}.5221 & 0 & 0 & -.8951\\ 0 & -.3563 & .6109 & 0\\ 0 & 0 & -.5552 \times 10^{-3} & 0\\ 0 & 0 & 0 & -.1328\end{pmatrix};$$

$$\mathbf{T}_2 = \begin{pmatrix}-.0976 & 0 & 0 & 0\\ 0 & -.0666 & 0 & 0\\ 0 & .02659 & -.4218 \times 10^{-4} & 0\\ -.03896 & 0 & 0 & -.1009 \times 10^{-1}\end{pmatrix}$$

$$\mathbf{F}_1 = \begin{pmatrix}2.859 & 0 & 0 & 1.079\\ 0 & 2.828 & -1.026 & 0\\ 0 & -.2389 & .4294 & 0\\ .2513 & 0 & 0 & .4607\end{pmatrix};$$

$$\mathbf{F}_2 = \mathbf{F}\begin{pmatrix}2.761 & .5891\\ .2123 & .3590\end{pmatrix}; \quad \mathbf{F}_3 = \mathbf{F}\begin{pmatrix}1.627 & .5373\\ .1096 & .2868\end{pmatrix}; \quad \mathbf{F}_4 = \mathbf{F}\begin{pmatrix}1.849 & .3731\\ .1178 & .4970\end{pmatrix};$$

$\| \mathbf{L}^0 \|_\infty \approx 5 \times 10^8$.

* The imaginary pair of eigenvalues had real parts less than 10^{-6} (a relative error of 10^{-11}).
V denotes a digit that changed when the matrix was balanced.
† The unbalanced matrix $\mathbf{L}^0$ had a negative eigenvalue -2×10^{-8} instead of -0.

At each major step in the J loop the equations EQ, given in the chart, are solved as D varies. Four cases are shown in the flowchart which is Figure 1.

5. Results

The matrix $\mathbf{L}^0$ described in Figure 2 came (in punched card form) from a large industrial company. It was causing their eigenvalue program to fail.

An inspection of the form of $\mathbf{L}^0$ suggests that the strange diagonal element in $\mathbf{I}^0$ and the discordant sign of the (1, 1) element of $\mathbf{T}_1$ were keypunch errors. Let us consider the matrices resulting from the removal of these anomalies:

$$\mathbf{L} = \begin{pmatrix} \mathbf{0} & \mathbf{X} \\ \mathbf{I} & \mathbf{0} \end{pmatrix}, \qquad \mathbf{M} = \begin{pmatrix} \mathbf{0} & \mathbf{Y} \\ \mathbf{I} & \mathbf{0} \end{pmatrix},$$

$$\mathbf{Y} = 10^8 \begin{pmatrix} \mathbf{D} & \mathbf{T}_1^- & \mathbf{0} \\ \mathbf{T}_2 & \mathbf{T}_1 & -\mathbf{F}_2 \\ \mathbf{0} & -\mathbf{F}_3 & \mathbf{F}_4 \end{pmatrix},$$

where $\mathbf{T}_1^-$ is obtained from $\mathbf{T}_1$ by reversing the sign of its (1, 1) element.

Notice that the eigenvalues of $\mathbf{L}$ are the square roots of those of $\mathbf{X}$:

$$\begin{pmatrix} \mathbf{0} & \mathbf{X} \\ \mathbf{I} & \mathbf{0} \end{pmatrix} \begin{pmatrix} \mathbf{u} \\ \mathbf{v} \end{pmatrix} = \lambda \begin{pmatrix} \mathbf{u} \\ \mathbf{v} \end{pmatrix} \leftrightarrow \mathbf{X}\mathbf{v} = \lambda^2\mathbf{v}, \quad \mathbf{u} = \lambda\mathbf{v}.$$

The eigenvalues of $\mathbf{L}^0$, $\mathbf{L}$, and $\mathbf{M}$ are given in Table I and we offer the following comments. Every eigenvalue of $\mathbf{L}^0$ is moderately ill conditioned and the zero pair appear to belong to a quadratic elementary divisor (only one eigenvector). Perhaps some of this is due to the unbalanced nature of $\mathbf{L}^0$. The thirteenth row of $\mathbf{L}^0$ is null and this must be permuted out of the way before the rest of the matrix can

be balanced. The result is that none of the computed eigenvalues changed, but half of them became almost perfectly conditioned.

In fact we can say that the ill condition of all six pairs is due to the zero element in position (13, 1). When this is replaced by one, we obtain the matrix **L** which has six pairs of eigenvalues almost identical to the well conditioned pairs of the balanced $\mathbf{L}^0$. Four of the other six pairs are changed completely, the remaining two ($\pm.186 \times 10^5$ and $\pm.11 \times 10^5 i$) are substantially altered. Interestingly the balanced versions of **L** and **M** are almost normal and we have not bothered to record the condition numbers. The six pairs of eigenvalues which were unchanged by the move from $\mathbf{L}^0$ to **L** were also invariant in the change from **L** to **M**. The other six pairs had relative errors less than 2.5 percent.

We can tell in advance what the balanced form of **L** and **M** will be:

$$\hat{\mathbf{L}} = \begin{pmatrix} 0 & 10^{-4}X \\ 10^4 I & 0 \end{pmatrix}, \quad \hat{\mathbf{M}} = \begin{pmatrix} 0 & 10^{-4}Y \\ 10^4 I & 0 \end{pmatrix}.$$

The change from $\mathbf{L}^0$ to **L** is tiny relative to $\| \mathbf{L}^0 \|$ ($\doteq 10^{-8} \| \mathbf{L}^0 \|$) but the change from $\hat{\mathbf{L}}^0$ to $\hat{\mathbf{L}}$ is approximately $\| \hat{\mathbf{L}} \|$.

We conclude that the suspicious element in $\mathbf{L}^0$ was probably a keypunch error. Concerning the (1, 1) element of $\mathbf{T}_1$ we cannot say, both **L** and **M** are reasonable matrices and indeed the change of sign does not affect the leading two decimals in any eigenvalue.

ALGORITHM 518
Incomplete Bessel Function I_0: The Von Mises Distribution [S14]

GEOFFREY W. HILL

Centre de Morphologie Mathématique, Fontainebleau, France

Key Words and Phrases: incomplete Bessel function, von Mises distribution, direction angles, circular statistics, asymptotic normal approximation
CR Categories: 5.5, 5.12
Language: Fortran

DESCRIPTION

The incomplete modified Bessel function $I_0(\Theta, \kappa)$ is formally equivalent to the cumulative distribution applied by von Mises [9] to study deviations of atomic weights from integer values, representable as points on the circumference of a circle or as circular directions. This distribution of points on a circle is analogous to the normal or Gaussian distribution of points on a line and has applications to the study of quantal or periodic data, directions of sedimentary bedding, surface fault lines, wildlife movements, etc. (cf. Batschelet [3] and Mardia [7]). The left tail area of this symmetrical distribution is evaluated by this Fortran FUNCTION of the angular deviation Θ and the concentration parameter κ, where

$$I_0(\Theta, \kappa) = P(x \leq \Theta; \kappa) = [2\pi I_0(\kappa)]^{-1} \int_{-\pi}^{\theta} \exp(\kappa \cos x)\, dx, \quad -\pi \leq \Theta < \pi.$$

A compromise between generality and efficiency is achieved by parameterizing the algorithm so that versions corresponding to different levels of accuracy are provided by selecting parameter sets as displayed in Table I.

The method of calculation for small κ involves backwards recursion through a series expansion in terms of modified Bessel functions, while for large κ an auxiliary FUNCTION for the normal probability integral or for the error function erf (x) is applied to an asymptotic normal approximation to order κ^{-4}.

In the case of small κ the series expansion given by Gumbel et al. [6] can be expressed as

$$\begin{aligned} F(\Theta; \kappa) &= \tfrac{1}{2} + \Theta/(2\pi) + \{\pi I_0(\kappa)\}^{-1} \sum_{n=1}^{\infty} n^{-1} I_n(\kappa) \sin(n\Theta) \\ &= \tfrac{1}{2} + \Theta/(2\pi) + \pi^{-1} V_1, \end{aligned}$$

where $V_1 = R_1(\kappa)\,[\sin\Theta + R_2(\kappa)\,[2^{-1}\sin 2\Theta + R_3(\kappa)\,[3^{-1}\sin 3\Theta + \cdots]]]$ represents a "nested" expression in terms of $R_n(\kappa) = I_n(\kappa)/I_{n-1}(\kappa)$, $n = 1, 2, 3, \ldots,$

Received 12 December 1975 and 8 June 1976.

This work was supported by a French Government Scientific Fellowship and a grant of computer time on the IRIS 80 of the École des Mines de Paris.
Author's present address: Division of Mineral Chemistry, CSIRO, Port Melbourne, Australia.

Table I. Parameter Values for Several Accuracy Levels

Accuracy in decimal digits	Recurrence over $[a_1 + a_2\kappa - a_3/(\kappa + a_4)]$ terms of nested series				Critical value of κ	Normalizing approximation
(D)	a_1	a_2	a_3	a_4	(CK)	(C_1)
6	8	1.0	3.0	1.0	6.5	62.0
7	9	1.0	3.5	0.7	8.0	60.5
8	12	0.8	8	1.0	10.5	56.0
9	15	0.75	16	1.5	15	53.0
10	18	0.7	24	2.0	21	51.7
11	22	0.6	48	3.5	32	50.8
12	28	0.5	100	5.0	50	50.1

the modified Bessel function ratio denoted as r_{n-1} by Amos [2]. Recursive evaluation of the Bessel function ratio is known to be numerically unstable in the direction of increasing n, but backwards recursion generates additional terms of the series expansions in powers of κ, so that numerical stability is achieved for $n = p - 1, \ldots, 3, 2, 1$, from the formulation:

$$\sin n\Theta = \sin (n + 1)\Theta \cos \Theta - \cos (n + 1)\Theta \sin \Theta$$

$$\cos n\Theta = \cos (n + 1)\Theta \cos \Theta + \sin (n + 1)\Theta \sin \Theta$$

$$R_n(\kappa) = [2n/\kappa + R_{n+1}(\kappa)]^{-1} \qquad \text{(cf. [2, eq. (2)])}$$

$$V_n = R_n(\kappa)\,[\sin (n\Theta)/n + V_{n+1}].$$

Starting values can be computed directly for $\sin (p\Theta)$ and $\cos (p\Theta)$, while $R_p(\kappa)$ and V_p may be assigned zero values, provided p is large enough, since $I_p(\kappa)/I_0(\kappa) \leq (\kappa/2)^p/p!$ implies that the truncation error of V_1 will be less than the corresponding truncation error of the convergent series expansion of $\exp (\kappa/2)$. An upper bound on the truncation error was calculated for various combinations of values of κ and p. Curves of $p(\kappa; D)$, interpolated for assigned accuracy levels of D decimal places, were found to be conservatively bounded by relations of the form $p = [a_1 + a_2\kappa - a_3/(\kappa + a_4)]$, where suitable values of coefficients $a_1, a_2, \ldots,$ are shown in Table I. Since larger values of κ entail larger values of p and thus more computing time and accumulated roundoff error, an alternative method is desired when κ is larger than some critical value, which we denote by CK.

For large values of κ the asymptotic normality of the von Mises distribution may be exploited in the following three steps. First, the angle Θ is transformed to the nearly normally distributed variate $z = b(\kappa) \sin (\Theta/2)$, where $b(\kappa) = (2/\pi)^{1/2} \exp (\kappa)/I_0(\kappa)$ is conveniently computed from a continued fraction approximation:

$$b^2(\kappa) \doteq (C - 6 - 54/(C - 26 - 347/(C - C_1)))/6, \quad C = 24\kappa.$$

Values for C_1, fitted for the minimum value of $\kappa = CK$ are included in Table I. The second step uses an approximation to order κ^{-4} for the asymptotic normalizing series in terms of z [4]:

$$\chi \doteq z - z^3\left\{(C - 2z^2 - 16)/3 - \left(z^4 + \frac{7}{4}z^2 + \frac{167}{2}\right) \Big/ (C - C_1 - z^2 + 3)\right\}^{-2}$$

in which the same value of C_1 is used in the divisor to reduce the remaining error of order κ^{-5}. The third step calls an auxiliary function, GAUSS (χ), to evaluate the normal integral

$$\Phi(\chi) = (2\pi)^{-1/2} \int_{-\infty}^{\chi} \exp (-t^2/2)\, dt$$

which, by virtue of the normalizing transforms, provides the required value of the von Mises integral, $F(\Theta; \kappa) = \Phi(\chi)$. Alternatively the normal integral may be

evaluated in terms of the error function, erf (x), by virtue of the relationship, $\Phi(x) = \frac{1}{2}[1 + \text{erf}\ (x/\sqrt{2})]$, where erf $(-x) = -\text{erf}\ (x)$.

The error of the asymptotic approximation decreases rapidly with increasing κ and can be calculated by comparison with sufficiently accurate results from the backwards recursion method. In this way critical values of CK in Table I were obtained such that for $\kappa > CK$ the asymptotic approximation is accurate to at least D decimal digits. Since the number of arithmetic operations for the recursive evaluation increases with increasing κ beyond that required for the asymptotic approximation and the auxiliary function, it is efficient to use backwards recursion for $\kappa \leq CK$ and asymptotic approximation for $\kappa > CK$.

Tests of the algorithm using values from Table I show that resultant probability values are accurate to at least D decimal digits for backward recurrence over $[a_1 + a_2\kappa - a_3/(\kappa + a_4)]$ terms when $\kappa \leq CK$ and for the normal approximations using the corresponding value of C_1 when $\kappa > CK$. For other accuracy levels interpolation should provide useful estimates which may need adjustment to improve efficiency without loss of desired accuracy. The level of accuracy achievable is limited by that of the standard functions for SIN, COS, and SQRT or of the auxiliary function, GAUSS or ERF. For lower-accuracy versions little is lost by use of a linear bound, $p = \kappa + \frac{4}{3}(D - \frac{1}{2})$, but for higher-accuracy versions the tighter bounding curve is more efficient. Should very high accuracy be required, it would be more efficient to utilize high order terms in the asymptotic series [4] to enable reduction of CK.

For real values of Θ outside the range $(-\pi, +\pi)$ the result from recursive evaluation lies outside the range (0,1), whereas the normalizing approximation yields results in the required range but lacks the monotonic increasing property appropriate for a cumulative distribution function. It is convenient to extend the domain of definition over all real Θ by treating the angle as reduced modulo 2π to the range $(-\pi, +\pi)$, so that results for both small κ and large κ remain consistent with the properties of a probability distribution. With this convention for angles in a circle, the probability over an interval (Θ_1, Θ_2), evaluated as $F(\Theta_2; \kappa) - F(\Theta_1; \kappa)$, can be negative if the interval includes $(2n + 1)\pi$, in which case the correct result is obtained by adding 1. Because accumulated roundoff error can produce results lying just outside (0,1) in extreme cases, such results are replaced by the limit values 0 or 1. It is also convenient to treat negative values of κ as zero so that the result (the cumulative uniform distribution if $\kappa \leq 0$) remains defined for all real κ as well as for all real Θ, and thus no error conditions can arise from invalid actual parameter values.

The algorithm is presented in the form of a real-valued FUNCTION VMISES (T, VK). T is the real value of the angle Θ in radians, VK is the real value of the concentration parameter κ. This form requires an auxiliary function GAUSS(X) having a single real argument and returning the left tail area of the normal distribution as a real value in the interval (0,1). A suitable function accurate to 10 decimal places can be provided by Algorithm CJ39 [1]. For higher-accuracy levels the somewhat slower algorithm, ACM Algorithm 304 [5] would return the required value with a precision matched to the processor used.

If an auxiliary real function, ERF(X), is supplied instead of GAUSS(X), columns 7 to 50 of each of the last three comment cards marked IF ERF must replace the statement preceding it, thus providing an appropriate alternative version of the function VMISES.

The backwards recurrence method in this algorithm is considerably faster and requires less storage than Algorithm AS 86 [8] which evaluates the von Mises distribution with accuracy up to 8D for Θ values extended to the whole real line. The approximation, accurate to 3D, offered for $\kappa > 30$ in the description of Algorithm AS 86, is considerably less effective than the asymptotic approximation in this algorithm.

The performance of this algorithm was tested on an IRIS 80 using a Fortran compiler with single precision to about 7 decimals and double precision to about

16 decimals. The numerical stability of backwards recursive evaluation of sin $n\Theta$ and cos $n\Theta$ was tested in single and double precision for $p \leq 50$, $n = 1$, indicating accuracy loss of at most 2 decimal digits. To check the backwards recurrence method, values of $1 - 2P(\Theta; \kappa)$ were computed by the algorithm for $\kappa = 0(0.2)4$ and $\Theta = 0°(5°)\ 180°$ and compared with Table 4 of Gumbel et al. [6]. Results corresponded within a unit in the last place, except for two misprints in the published tables; $\Phi_\alpha(\alpha = 10°, \kappa = 1.8) = 0.15740$ should be 0.16740 and $\Phi_\alpha(\alpha = 40°, \kappa = 4.0) = 0.71123$ should be 0.81123. The validity of the asymptotic approximation was tested by comparison with results of extensive recursion for a range of values of Θ and κ. Tests with negative and zero values of κ and Θ near 0 and 2π and in the range $(-5\pi, +5\pi)$ confirmed performance of the algorithm as specified.

ALGORITHM 519
Three Algorithms for Computing Kolmogorov-Smirnov Probabilities With Arbitrary Boundaries and a Certification of Algorithm 487 [S14]

RALPH KALLMAN
Ball State University

Key Words and Phrases: Kolmogorov-Smirnov probabilities, sample distribution function, boundary crossing probability
CR Categories: 5.5
Language: Fortran

DESCRIPTION

Introduction

Let $A(y)$, $B(y)$ be nondecreasing functions on [0, 1] where $B(0) < 0 < A(0)$, $B(1) < 1 < A(1)$. Let $G_n(y)$ be the sample distribution function for n independent random variables uniform on [0, 1]. We present three methods for computing $P = \Pr\{B(y) < G_n(y) < A(y), y \in [0, 1]\}$. The special case where $A(y) = y + D$, $B(y) = y - D$ has been treated by ACM Algorithm 487 [4].

Subroutine RAKK. A Generalization of Massey's Method

Massey has given a recursion formula [3; 5, p. 341, eq. (11.7.9)] for computing P when $A(y) = y + k/n$, $B(y) = y - k/n$. This can be generalized to arbitrary boundaries as follows. Let $y(1, j)$, $y(2, j)$ be the level points of $B(y)$, $A(y)$ for the ordinates $(j - 1)/n$ (e.g. $A(y(2, j)) = (j - 1)/n$). If the boundaries are not continuous and strictly increasing, let

$$y(2,j) = \sup\{y \in [0,1] \mid A(y) \leq (j-1)/n\}$$

$$y(1,j) = \inf(y \in [0,1] \mid B(y) \geq (j-1)/n\}$$

for those j such that the sup or inf is taken over a nonempty set. Arrange the $y(k, j)$ into a single ordered sequence $y(i)$, $i = 1, \ldots, m$, where $y(1) = 0$, $y(m) = 1$ are attached if not already present. Let $jt(i)$ = largest integer j such that $(j - 1)/n < A(y(i) -)$ and $jb(i)$ = smallest integer j such that $(j - 1)/n > B(y(i) +)$, $1 < i < m$. Note that if $jt(m) < n + 1$, then $P = 0$. Then define $j\text{top}(i) = \min(jt(i), n + 1)$, $j\text{bot}(i) = \max(jb(i), 1)$, $1 < i < m$; $j\text{bot}\ (1) = j\text{top}\ (1) = 1$; $j\text{bot}\ (m) = j\text{top}\ (m) = n + 1$. Then

$$P = \sum_j n! \prod_{k=2}^{m} \frac{[y(k) - y(k-1)]^{j(k)-j(k-1)}}{j(k)!}$$

Received 29 July 1975, 8 June 1976, and 14 September 1976.

Author's address: Department of Mathematical Sciences, Ball State University, Muncie, IN 47306.

where the summation is over the index set $\{j \equiv (j(1), \ldots, j(m)) \mid j\text{bot}(i) \leq j(i) \leq j\text{top}(i)\}$. Note that $j(1) \equiv 1$.

The computer program RAKK sums these multinomial probabilities recursively by computing $W(k, i)$ where

$$W(1, 1) = 1$$

$$W(k, i) = \sum W(j, i-1)\,[y(i) - y(i-1)]^{k-j}/(k-j)!,$$

$$k = j\text{bot}(i), \ldots, j\text{top}(i),\ i = 1, \ldots, m,$$

where the summation is over the index set $\{j \mid k - j \geq 0, j\text{bot}(i-1) \leq j \leq j\text{top}(i-1)\}$. Then $P = W(n+1, m)\,n!$.

Because machines with small exponent range on floating numbers cannot accommodate the array $W(\cdot, i)$ we have split the array into blocks. Each block contains the values of $W(\cdot, i)$ multiplied by a suitably large conversion factor. The reciprocals of these conversion factors are accumulated in TF by subroutine ACCUM; to keep the accumulated product TF within range it is multiplied by consecutive positive integers, as necessary, with the current value stored in NNN. At the conclusion of the program the value of TF is adjusted so that $NNN = N$ and then the multiplication by $n!$ in the formula $P = W(n+1, m)n!$ is accomplished by a multiplication by TF.

Subroutine DURB. Durbin's Method

The recursion is on $k!\,\alpha(k)$, $k!\,\beta(k)$ where α, β are defined in [1, eqs. (36), (37), (40)]. These variables are denoted by $ALPHA(k-1)$, $BETA(k-1)$ in our program, and the indexing runs through $k = 1, \ldots, n+1$. Durbin's algorithm computes the probability that $G_n(y)$ crosses a boundary so a subtraction from 1 is necessary. This instruction is flagged in the program listing.

Subroutine EPST. The Epanechnikov, Steck Method

This method [2, p. 15] is numerically unstable for larger values of n because of cancellation of digits in subtractions. Thus we do not include a listing of the computer program. However, we do include the test results for our implementation of this algorithm.

Organization of Programs

All three methods accept as inputs the boundary level points $y(k, j)$ and the sample size n. A preliminary computation of these boundary level points is necessary, and there must be $n+1$ of each. If $A(y) > (j-1)/n$ for all $y \in [0, 1]$, then a negative number must be given for $y(2, j)$ and if $B(y) < (j-1)/n$ for all $y \in [0, 1]$, then a number greater than 1 must be used for $y(1, j)$. As an example, we have included a listing of function PLN which computes P where A, B are (arbitrary) straight lines. As listed, PLN invokes method RAKK; the listing indicates the change necessary to invoke DURB or EPST.

Underflow occurs frequently in our programs and the underflow switch, if any, on the object machine should be set to return zero and the underflow diagnostic should be suppressed.

Test Results, Execution Times, and Precision

The three algorithms were programmed with single precision instructions only and were tested on the following machines: (a) DEC 10, (b) IBM 360-50, (c) CDC 6400. Single precision for these machines is, respectively, 8, 6, and 14 decimal digits and the range on decimal exponents is, respectively, -38 to 38, -75 to 75, and -293 to 321. The fortran compilers used were, respectively, FORTRAN 10/OPT, FORTRAN H(OPT = 2), and FUN. Table I lists the problems tested, where $A(y) = y + D$ and $B(y) = y - D$, and Table II gives the test results. If data is missing, the sample size n is too large for the machine and algorithm involved.

Table I. Problems Tested

Problem	n	D	P (approximate)
1	45	.0527	.001
2	200	.0257	.001
3	45	.1199	.500
4	120	.0742	.500
5	200	.0577	.500
6	45	.2849	.999
7	200	.1368	.999

Table II. Apparent Precision (in significant decimal digits) of Algorithms RAKK, DURB, and EPST

	RAKK			DURB			EPST		
	Machine			Machine			Machine		
Problem	(a)	(b)	(c)	(a)	(b)	(c)	(a)	(b)	(c)
1	7	5	12	4	2	9	7	5	12
2	6	4	11	—	2	9	4	—	10
3	6	4	12	6	5	12	3	2	10
4	6	3	11	—	4	12	—	—	7
5	6	3	11	—	4	11	—	—	4
6	6	3	11	8	6	12	—	—	3
7	6	2	10	2	5	12	—	—	—

Table III. Execution Times (in seconds) of Algorithms RAKK, DURB, and EPST

	RAKK			DURB			EPST		
	Machine			Machine			Machine		
Problem	(a)	(b)	(c)	(a)	(b)	(c)	(a)	(b)	(c)
1	.15	.53	.14	.56	3.08	.48	.03	.12	.02
2	1.73	5.53	1.44	—	71.10	11.21	.30	—	.24
3	.30	1.05	.29	.49	2.80	.41	.05	.32	.05
4	1.77	4.98	1.38	—	22.72	3.51	—	—	.24
5	4.53	11.40	3.22	—	64.52	10.54	—	—	.56
6	.73	1.80	.58	.38	1.92	.29	—	—	.10
7	10.54	28.72	7.24	19.62	53.70	8.84	—	—	—

The precision estimates for machines (a) and (b) are the number of digits which agree with the results of machine (c). The estimates for machine (c) were obtained by comparing the answers for the various methods. Since DURB computes the probability of the complementary event, the final subtraction from 1 accounts for the lesser precision of DURB in problems 1 and 2 and its greater precision in problems 6 and 7.

Execution times for arbitrary boundaries should be comparable to those given in Table III, plus the additional time needed to compute the level points $y(k, j)$.

Recommendations

Although EPST is numerically unstable for larger sample sizes, its execution times are very fast. Thus it would be suitable for numerous computations involving small sample sizes with occasional validations by one of the other routines. DURB is not suitable for large sample sizes on machines with small range on decimal exponents. Execution times for RAKK are faster. Thus RAKK appears to be the preferred choice. This is due largely to the extensive code with its controls against underflow, etc., rather than an intrinsic superiority of the algorithm.

Certification of Algorithm 487

Since Algorithm 487 [4], PKS2, treats a special case handled by Algorithms RAKK, DURB, and EPST, it may be validated by using the data presented in

Table IV. Apparent Precision (in significant decimal digits) of Algorithm PKS2

Machine	Problem Number 1	2	3	4	5	6
(a)	—	—	—	—	—	—
(b)	5	—	5	—	—	5
(c)	13+	—	12+	12+	—	13+

Table II. The results for the problems discussed are presented in Table IV. If data are missing the sample size is too large for the machine involved. (A computation of n^n is required by PKS2). Although Pomeranz claims precision of 8 decimal digits on the CDC 6400 [4], this seems rather modest. There is, apparently, a precision of at least 12 decimal digits on the CDC 6400 and a potentially greater precision if the double precision value generated by PKS2 is not returned as a single precision value.

ACKNOWLEDGMENT

These programs are an outgrowth of a seminar in computational probability given during 1974–1975 by Marcel Neuts of Purdue University, who also arranged for computer time on the Purdue machines.

ALGORITHM 520
An Automatic Revised Simplex Method for Constrained Resource Network Scheduling [H]

Language: Fortran

DESCRIPTION

Purpose

Subroutine ARSME solves a resource constrained, network scheduling problem for the case in which activities may be arbitrarily interrupted and restarted later with no increase in activity duration. The number of resource types is not a limiting factor in our procedure. The amount of any one resource available at any moment is constant. We shall use the "activity-on-arc" network representation, under the commonly imposed assumption that the network contains no directed cycles and has only one "beginning" and only one "terminal" node (event). It is further assumed that the network nodes (events) are ordered in such a way that node i precedes node j, if $i < j$. Such an ordering is always possible and it induces an ordering among the arcs (activities).

Optimal approaches to resource constrained, network scheduling problems where activities can require more than one resource type are presented in [1, 4]. Both methods assume integer durations of activities, and the method presented in [1] divides activity durations into unit intervals. Both methods can handle networks with up to about 30 activities and 3 resource types.

Subroutine ARSME is constructed in such a way that its storage requirements are minimal, a fact which permits the solution of problems for very large networks with many resource types. Moreover, an optimal solution can be obtained in a shorter time when relatively smaller amounts of the resources are available than when resources are less limited.

Let the number of activities be equal to M and the number of resource types be equal to RT. For activity j ($j = 1, 2, \ldots, M$) and resource k ($k = 1, 2, \ldots, RT$) the following variables are given: activity duration d_j; activity resource requirement R_{jk}, i.e. the amount of resource k required by activity j; resource limit RL_k, i.e. the amount of resource k available at any moment.

The solution of our problem consists of the assignment of time intervals to resource feasible sets of activities (i.e. activities which can be performed simul-

Received 18 December 1974, 5 June 1975, and 15 June 1976.

Authors' address: Institute of Control Engineering, Technical University of Poznan, Piotrowo 3a, 60 965 Poznan, Poland.

taneously and not violate resource limits), in order that the completion time of the project be minimal. For this reason, it is necessary to generate all such sets and to solve the ensuing linear programming (LP) representation of the problem. LP variables are the durations assigned to these activity sets. The optimal durations obtained are ordered according to the network structure. In similar fashion we obtain the time intervals making up the optimal schedule.

As input data for subroutine ARSME, it is necessary to provide the following data:

M	number of activities in the network;
$M1$	dimension limit equal to $M + 1$;
$M2$	dimension limit equal to $2M + 1$;
ME	dimension limit of vector E (see the discussion below);
ND	number of nodes;
RT	number of resource types;
NI	declared limit of the number of iterations, usually taken as $2M$ (the subroutine ends computations if the optimum solution is not found in NI iterations);
$NS(M2)$	network structure vector containing the consecutive activities as ordered pairs of nodes; no initial value is required for element $NS(M2)$;
$X(M1)$	vector of activity durations;
$RL(RT)$	vector of resource limits;
$R(M, RT)$	matrix of resource requirements.

The value of ME is taken to be $(M1 \times NI)$ if $M1 \times NI$ does not exceed the available amount of primary storage; otherwise, it is taken as the available limit of primary storage.

When the optimal solution is obtained, the optimal schedule (i.e. the sets of activities together with corresponding time intervals) are printed on the line printer. On the other hand, if the optimal solution is not reached in the declared number of iterations NI, then the message "number of iterations greater than NI" is printed. In this case, the computations should be repeated for a greater value of NI.

As an example let us consider the network shown in Figure 1. Input data are: $M = 5$; $M1 = 6$; $M2 = 11$; $ME = 60$; $ND = 4$; $RT = 3$; $NI = 10$; $NS = [1, 2, 1, 3, 2, 3, 2, 4, 3, 4]$; $X = [1.0, 2.0, 3.0, 2.0, 2.0]$; $RL = [5.0, 5.0, 3.0]$;

$$R = \begin{pmatrix} 2.0, & 2.0, & 1.0 \\ 0.0, & 2.0, & 1.0 \\ 2.0, & 1.0, & 3.0 \\ 3.0, & 3.0, & 3.0 \\ 1.0, & 1.0, & 0.0 \end{pmatrix}.$$

As an optimal schedule, ARSME yields

time intervals	activities				
	1	2	3	4	5
0.0–1.0	1	1	0	0	0
1.0–2.0	0	1	0	0	0
2.0–5.0	0	0	1	0	0
5.0–7.0	0	0	0	1	1
7.0–7.0	0	0	0	0	1

with $T_{\min} = 7$. This means that, in the optimal schedule, activities 1 and 2 should be performed simultaneously in the time interval $\langle 0.0, 1.0 \rangle$, activity 2 in the time interval $\langle 1.0, 2.0 \rangle$, etc.

Method

Subroutine ARSME solves an LP problem which is formulated as follows.

Let S_I denote the set of all activities which may be performed between the oc-

currence of node I and $I + 1$. Such sets will be called *main sets*. Let us number from 1 to N the resource feasible sets, i.e. those subsets of the main sets and those main sets for which the resource requirements do not exceed any resource limits.

Now, let Q_j denote the set of all numbers of resource feasible sets in which activity j may be performed, and let x_i denote the duration of set i. Thus the LP problem is obtained:

minimize

$$T = \sum_{i=1}^{N} x_i$$

subject to

$$\sum_{i \in Q_j} x_i = d_j \qquad (j = 1, 2, \ldots, M) \tag{1}$$

or in matrix notation,

$$\mathbf{A}\,\mathbf{x} = \mathbf{d} \tag{2}$$

where $\mathbf{A}$ is the matrix of coefficients

$$a_{ji} = \begin{cases} 1 & \text{if } i \in Q_j; \\ 0 & \text{otherwise.} \end{cases}$$

Obviously, columns of matrix $\mathbf{A}$ correspond to resource feasible sets.

When applying the simplex method directly to this problem, one must somehow store matrix $\mathbf{A}$, which is a very large matrix for even small problems. This greatly constrains the size of the problems which can be solved.

Subroutine ARSME eliminates the above storage problem by utilizing the revised simplex method [2] in which elements of matrix $\mathbf{A}$ are not transformed. This method is computationally profitable for sequencing problems, since in practical ones, the number of variables is greater than three times the number of constraints [5]. The specific version used is based upon the product form of the inverse [2].

The first basic feasible solution to the problem is known in advance. It consists of M, 1-element sets (consecutive performance of all activities).

Taking advantage of the special structure of the problem, a subroutine GEN has been developed which automatically generates the consecutive columns of matrix $\mathbf{A}$ (i.e. the resource feasible sets). An important feature of this subroutine is that at every moment only one main set and only one of its resource feasible subsets (which is actually needed in the simplex procedure) are stored. This allows one to solve problems of larger dimension than otherwise possible and of course radically simplifies the preparation of input data.

Subroutine GEN generates main sets $S_1, S_2, \ldots, S_{ND}$ using the network structure vector. When a single main set has been generated, the generation of its resource feasible subsets follows. For this purpose, so-called *primary subsets* are constructed, from which resource feasible subsets are created by adding activities from the main set. The first primary subset contains all the activities of the main set which also composed previously generated main sets, as well as one new activity. New primary subsets are created either when the last activity from the main set has been added, or when the generated subset is found to be unfeasible. In the first case, the last activity of the last generated subset is rejected and the penultimate one is replaced by the next from the main set. In the second case, the last activity of the unfeasible subset is replaced by the next from the main set. The number of sets in which resource feasibility is checked is always minimal and is usually much smaller than the total number of sets of activities which may be performed simultaneously. This follows from the construction of the primary subsets and from the fact that activities in the main sets are ordered by the subroutine ORDSNE in a unique fashion.

After generating each resource feasible set ARSME, together with subrou-

tine KFIND, checks, according to the simplex procedure, whether the set is good enough to be in the optimal solution. This procedure is repeated until the optimal solution is obtained. Then subroutine ORDSNE orders the sets composing the optimal solution, and subroutine PRISET prints out the results.

The parameters of ARSME, which are associated with the applied version of the simplex procedure, are as follows:

- *U, D* vector used for finding vectors introduced into, and eliminated from, the basis, respectively;
- *E* vector of the inverse;
- *LO* vector of the indices of vectors eliminated from the basis in successive iterations;
- *IBV* vector of indices of the basis vectors.

(Other parameters are subsidiary ones).

Timing Tests

A comparison of the computation time required by subroutine ARSME and other methods for solving the constrained resource network scheduling problem is not very helpful because of the different assumptions made in these methods. However, as an example, a comparison of computation times is shown in Table I for the two

Table I

Problem	Resource limits RL_k	Davis method		Patterson method		ARSME	
		Optimal schedule length	Time to optimal solution*	Optimal schedule length	Time to optimal solution‡	Optimal schedule length§	Time to optimal solution†
1. Davis and Heidorn	5, 5, 3	7		7	1.57	7	0.81
2. Moodie and Mandeville	5	8	2.00	8	1.35	8	1.20
3. Moodie and Mandeville	4	11		11	3.78	10.5	1.14

* IBM 7094 CPU time in seconds.
† IBM 360/67 CPU time in seconds.
‡ ICL 1900 CPU time in seconds.
§ Because of the provision for job splitting in our procedure, optimal schedule lengths may differ from those reported by Davis and by Patterson.

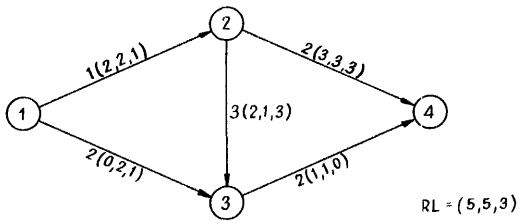

Fig. 1. Network used in problem formulated by Davis and Heidorn [1]

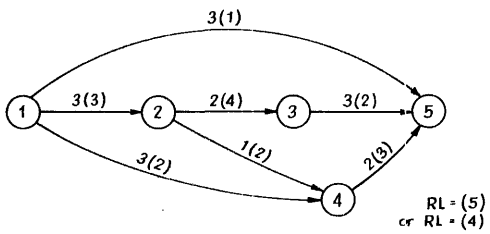

Fig. 2. Network used in problem formulated by Moodie and Mandeville [3]

simple networks described in [1, 3] and shown in Figures 1 and 2. One may notice that, for problem 3, ARSME finds a solution with a lower value of the objective function, because of the assumption of the arbitrary splitting of activities.

All tests have been made on an ODRA-1305 computer (license ICL-1900). Computation times for networks of about 20 activities vary from about 15 seconds to 3 minutes; for networks of about 50 activities, from 5 minutes to 25 minutes; and for networks of about 100 activities, from 20 minutes to 90 minutes. Variance in computation times for a given size of network appears to be primarily a function of the number of network nodes and the values of resource limits.

ACKNOWLEDGMENTS

The authors are indebted to Michael J. D. Powell and to James H. Patterson who made some valuable remarks for the overall improvement of this paper.

ALGORITHM 521
Repeated Integrals of the Coerror Function [S15]

WALTER GAUTSCHI
Purdue University

Key Words and Phrases: repeated integrals of the coerror function, Taylor's series, three-term recurrence relation, Miller's backward recurrence algorithm
CR Categories: 5.12
Language: Fortran

DESCRIPTION

This algorithm implements the procedures developed in [1].

ALGORITHM 522
ESOLVE, Congruence Techniques for the Exact Solution of Integer Systems of Linear Equations [F4]

S. CABAY and T. P. L. LAM
University of Alberta

Key Words and Phrases: symbolic and algebraic manipulation, systems of linear equations, congruence techniques, modular methods, Chinese remainder theorem
CR Categories: 5.14
Language: Fortran

DESCRIPTION

Descriptions of the main algorithm, ESOLVE, and accompanying subroutines SUBBND, MRADIX, and FRADIX, together with experimental results, are given in [1].

ALGORITHM 523
CONVEX, A New Convex Hull Algorithm for Planar Sets [Z]

WILLIAM F. EDDY
Carnegie-Mellon University

Key Words and Phrases: convex hull, QUICKERSORT, partitioning, sorting
CR Categories: 5.30, 5.31
Language: Fortran

DESCRIPTION

An algorithm, CONVEX, that determines which points of a planar set are vertices of the convex hull of the set is presented here. A detailed explanation of its operation and a report of a small sampling experiment are given in [1].

      SUBROUTINE CONVEX(N,X,M,IN,IA,IB,IH,NH,IL)
C THIS SUBROUTINE DETERMINES WHICH OF THE M POINTS OF ARRAY
C X WHOSE SUBSCRIPTS ARE IN ARRAY IN ARE VERTICES OF THE
C MINIMUM AREA CONVEX POLYGON CONTAINING THE M POINTS. THE
C SUBSCRIPTS OF THE VERTICES ARE PLACED IN ARRAY IH IN THE
C ORDER THEY ARE FOUND. NH IS THE NUMBER OF ELEMENTS IN
C ARRAY IH AND ARRAY IL. ARRAY IL IS A LINKED LIST GIVING
C THE ORDER OF THE ELEMENTS OF ARRAY IH IN A COUNTER
C CLOCKWISE DIRECTION. THIS ALGORITHM CORRESPONDS TO A
C PREORDER TRAVERSAL OF A CERTAIN BINARY TREE. EACH VERTEX
C OF THE BINARY TREE REPRESENTS A SUBSET OF THE M POINTS.
C AT EACH STEP THE SUBSET OF POINTS CORRESPONDING TO THE
C CURRENT VERTEX OF THE TREE IS PARTITIONED BY A LINE
C JOINING TWO VERTICES OF THE CONVEX POLYGON. THE LEFT SON
C VERTEX IN THE BINARY TREE REPRESENTS THE SUBSET OF POINTS
C ABOVE THE PARTITIONING LINE AND THE RIGHT SON VERTEX, THE
C SUBSET BELOW THE LINE. THE LEAVES OF THE TREE REPRESENT
C EITHER NULL SUBSETS OR SUBSETS INSIDE A TRIANGLE WHOSE
C VERTICES COINCIDE WITH VERTICES OF THE CONVEX POLYGON.

ALGORITHM 524
MP, A Fortran Multiple-Precision Arithmetic Package [A1]

RICHARD P. BRENT
Australian National University

Key Words and Phrases: arithmetic, multiple precision, extended precision, floating point, elementary function evaluation, Euler's constant, gamma function, polyalgorithm, software package, Fortran, machine-independent software, special function evaluation, Bessel functions, exponential integral, logarithmic intergral, Bernoulli numbers, zeta function, portable software
CR Categories: 3.15, 4.49, 5.11, 5.12, 5.15, 5.19, 5.25
Language: Fortran

DESCRIPTION

The design of the package and the theoretical background for the algorithms used are given in [1]. Details of calling sequences, etc., are given in the comments included here and in [2].

REMARK ON ALGORITHM 524

MP, A Fortran Multiple-Precision Arithmetic Package [A1]
[R.P. Brent, *ACM Trans. Math. Software 4*, 1 (March 1978), 71–81]

R.P. Brent [Recd 7 Aug. 1978 and 6 Dec. 1978]
Department of Computer Science, Australian National University, P.O. Box 4, Canberra, ACT 2600, Australia

A new version of the Fortran multiple-precision arithmetic package MP, which is described in [1] and given as ACM Algorithm 524, is now available from the ACM Algorithms Distribution Service. The new version may be used with the Augment preprocessor [4], and the necessary interface routines and description deck, described in [2], are supplied. The MP Users' Guide (also supplied with the package) has been revised to describe the Augment interface routines and the use of MP via Augment.

The new version incorporates faster algorithms for the exponential integral and Euler's constant [3]. Consequently, the TEST2 program described in [1] now runs about 10 percent faster.

In versions of MP dated June 7, 1978, and earlier (including Algorithm 524), there may be an error in the least significant digit when multiple-precision numbers with the same sign and exponent are added using subroutine MPADD. To correct this, change .LT. to .LE. in line MP007390 of MPADD3.

ACKNOWLEDGMENT

I am indebted to John P. Jeter of the University of South West Louisiana for finding both the error in MPADD3 and the required correction.

ALGORITHM 525
ADAPT, Adaptive Smooth Curve Fitting [E2]

JOHN R. RICE
Purdue University

Key Words and Phrases: piecewise polynomial approximation, adaptive curve fitting, adaptive approximation, Hermite interpolation, function approximation
CR Categories: 5.13
Language: Fortran

DESCRIPTION

1. Introduction and Background

The basic objectives of this function approximation algorithm are: speed, reliability, and smoothness. Algorithms already exist with any two of these three properties. Speed requires that the work be proportional to the length of the curve (for fixed accuracy and more or less uniform complexity of the function). Reliability requires that curves with singularities or near singularities, oscillations, and other complex behavior be handled. Smoothness (number of continuous derivatives) of the approximation obtained is input to the algorithm. The author believes that adaptive piecewise polynomial algorithms offer the best hope for such algorithms with nonadaptive piecewise polynomial schemes or rational function approximation as the only serious competitors. Nonadaptive schemes do not cope efficiently with functions having very nonuniform behavior (singularities in slopes, for example) and the work for rational approximation probably increases faster than linearly with the length of the curve.

The theoretical background for this algorithm is provided by Rice [1] and the references cited there. This may be summarized by saying that for given fixed degree n of the pieces the error of the best piecewise polynomial approximation behaves like k^{-n} where k is the number of pieces. This theoretical result applies to a broad class of functions which includes everything that conceivably could arise in applications. A class of adaptive algorithms has been found which chooses the knots so that the error behaves like k^{-n} even though the best approximation is not obtained. These algorithms apply to any piecewise smooth function with a finite number of "algebraic" singularities, i.e. to any function F(x) which behaves like $a + b(x - s)^{\alpha}$ near the singularity s. The exponent α must give a finite value for the norm of F(x) specified for ADAPT to use, i.e. $\alpha > -\frac{1}{2}$ for least squares, $\alpha > 0$ for uniform approximation.

Received 26 November 1975 and 1 November 1976.

This work was supported in part by the National Science Foundation under Grant GP 32940X.
Author's address: Department of Computer Science, Purdue University, Lafayette, IN 47907.

The key ingredients in these algorithms are a local approximation operator, a local error estimator, and a data structure for the subintervals generated. ADAPT uses Hermite interpolation at subinterval endpoints plus ordinary interpolation in between if needed. Error estimates are made by a simple Gauss quadrature formula and a stack is used for the intervals. This algorithm is probably the simplest choice from those currently known to give the optimal convergence rate. A more detailed description of ADAPT is given in Section 5. Note that the nature of ADAPT *requires* that F(x) and its derivatives be available for arbitrary x (see [2] for guidance on numerically estimating derivatives) and thus ADAPT is not directly applicable to discrete data sets.

Section 2 presents some remarks about the algorithm components; most of them incorporate rather standard methods. Section 3 discusses the use of ADAPT (input/output, role of the arguments CHARF = characteristic length of F(x) and EDIST = error distribution type, and portability). Section 4 describes the extensive testing performed and summarizes the algorithm properties observed in [2]. It also briefly describes the driver program and 20 functions with derivatives used for testing ADAPT which are applicable to similar algorithms. The final section has a very high level description of the algorithm; ADAPT itself is available through the ACM Algorithms Distribution Service.

2. The Principal Algorithm Components

The algorithm ADAPT is to approximate the function F(x) on the interval [A,B] to within an accuracy ACCUR by piecewise polynomials of degree DEGREE with a number SMOOTH of continuous derivatives. The error is measured in the L_p-norm with p set by NORM. Other input is the characteristic length CHARF of F, printed output level LEVEL, the error distribution type EDIST, and the number NBREAK of breakpoints (plus information about the breakpoints if NBREAK > 0). Breakpoints are points where there are breaks in the curve or its derivatives: knots are placed there and special calculations made. The output is the array XKNOTS of knots, the coefficients COEFS (relative to the knot locations) of the polynomial pieces, the estimated error ERROR, and number KNOTS of knots. The approximation obtained is automatically available as the FUNCTION subprogram PPOLY.

2.1 *Data Structure and Discard Procedure for Subintervals.* ADAPT generates a set of subintervals of [A,B] which are maintained in a stack with the leftmost on the top. Since subintervals are created by halving, the maximum size of the stack is limited by the machine word length.

Intervals are discarded whenever the estimated error on an interval is small enough. This decision made in the subprogram CHECK is somewhat subtle and three strategies are provided. This question is discussed later in some detail in connection with the argument EDIST which indicates the strategy selected by the user. Two subprograms, PUT and TAKE, are used for access to the interval stack.

2.2 *Hermite Interpolation.* The values of DEGREE and SMOOTH are specified by the user with DEGREE $\geq 2 *$ SMOOTH $+ 1$. The polynomial pieces are determined by interpolating F and SMOOTH derivatives of F at each endpoint of a subinterval plus the value of F at DEGREE $- 2 *$ SMOOTH $- 1$ other points. During the computation the polynomial pieces are represented by divided differences computed in NEWTON and used by POLYDD. Once a polynomial piece is accepted for the final approximation PTRANS transforms its representation into powers with origin at the left endpoint of the subinterval. The transformation is accomplished by repeated synthetic division. The subprogram COMPUT controls the computation of a polynomial piece as well as the error estimation.

2.3 *The Breakpoint Mechanism.* It is sometimes very useful for a user to be able to specify breaks in some derivative at certain points. Most commonly one has a known or desired jump in the slope at a given point and ADAPT allows this via NBREAK and associated arguments XBREAK, DBREAK, BLEFT, BRIGHT which specify the exact nature of the breakpoint. This rather straightforward facility is implemented primarily in TAKE with some impact on COMPUT.

2.4 *Error Estimation.* The L_P-norm of the local error is estimated in ERRINT by a 4-point Gauss quadrature for (F − POLYDD)**P on the subinterval under consideration. Special code is used for P = infinity (minimax approximation). The global error estimate is built up in PUT by appropriately combining the local error estimates.

2.5 *Fatal Errors.* The algorithm normally terminates when the stack is empty. The stack should not overflow but might do so at very strong singularities which cause the algorithm to want to operate at accuracies inconsistent with the machine word length. This overflow has not occurred in the testing so far, but if it does a message such as the following is printed:

```
INTERVAL DIVIDED TOO MUCH, EXCEEDED LIMIT 50 ON INTERVAL STACK
AT
17923.12345678     17923.12345687
INTERVAL DISCARDED AND COMPUTATION CONTINUED
```

This message may be suppressed by setting LEVEL = −1, but note that the computation is allowed to proceed on the conjecture that this situation is not truly fatal.

A strong singularity has been observed to cause another situation indicated by a message like

```
GOT SHORT INTERVAL **** 3210.12345678   3210.12345679 **** DISCARD IT
```

which may also be suppressed by setting LEVEL = −1. Experiments indicate that the algorithm will recover and produce satisfactory results provided it can discard (and ignore) enough short intervals to get out of the region where the machine word length is inadequate. It often cannot get out of this region before exceeding run time limits or, more likely, the limit on the number of knots. The variable BUFFER in PUT governs short interval detection.

The arrays XKNOTS and COEFS are passed to ADAPT with variable dimensions KDIMEN and NDIMEN. If the number of knots computed exceeds KDIMEN then a fatal error message is printed and the computation aborted. This message cannot be suppressed. Checks are made on various input parameters by SETUP and inconsistent or impossible input leads to fatal error messages and a RETURN without any computation.

3. Algorithm Usage

3.1 *User Interface.* The input to ADAPT is via the COMMON block INPUTZ except for the function F. This is the most convenient for extensive use of ADAPT but not for occasional use. A subroutine PPFIT4 is provided which has all input as arguments. Entry points PPFIT1, PPFIT2, and PPFIT3 in PPFIT4 have fewer (10, 12, 15, respectively) arguments than PPFIT4 (21 arguments). Due to the variable nature of entry point implementations, these are only indicated by COMMENT cards and local modifications are needed to activate these features.

The basic output is the arrays XKNOTS and COEFS which are arguments to ADAPT (and also the PPFIT subroutines) and the numbers KNOTS and ERROR in the COMMON block RESULZ. The PPFIT routines have KNOTS and ERROR as arguments. In addition the FUNCTION subprogram PPOLY (T, XKNOTS, COEFS, KDIMEN, NDIMEN) returns the value at the point T of the most recently computed approximation. It is automatically available to the user.

There are six levels (−1, 0, 1, 2, 3, 4) of printed output available. LEVEL = −1 only provides fatal error messages; LEVEL = 0 also provides "semifatal" error messages plus 1 line of output; LEVEL = 1 provides a printout of the input and the approximation obtained; LEVEL = 2 provides a condensed trace of the computation and the last two levels are only useful for debugging program modifications.

3.2 *The Characteristic Length of F, CHARF.* The correct operation of ADAPT depends on certain estimates being accurate which, in turn, depend on the relevant subintervals being small enough. Specifically, the sampling that ADAPT does of

F must reveal the nature of F and not allow any significant features to go undetected. The nature of ADAPT is such that for reasonable functions it is very unlikely to miss significant features without using CHARF at all. However, knowing how ADAPT works, one can readily construct examples where it will fail unless CHARF is set properly. The value of CHARF is an *upper* limit on the size of the subintervals for polynomial pieces and it is to be set so that the 4-point Gauss quadrature formulas are reasonably (but not highly) accurate. This means that if F has some complex behavior on a very short segment, then setting CHARF to, say, half the length of this segment will force ADAPT to detect this behavior.

The argument CHARF is essential to proving ADAPT correct (which has not been attempted) but its practical value is debatable. If F is more or less uniformly complicated then short intervals are needed everywhere. It is extremely unlikely, but not impossible, that ADAPT would be fooled in such a case. If F is very smooth except on a very short segment, then ADAPT may well be fooled and setting CHARF small will avoid this. However, it will also force very small intervals where F is smooth and where they are not needed. Thus high reliability is obtained here at the cost of great inefficiency.

The nature of the approximations computed by ADAPT are such that there is a simple and efficient alternative to setting CHARF small. Let [C,D] be the subinterval of [A,B] where F is rough and let F be smooth elsewhere. One can then approximate F on [A,C], [C,D], and [D,B] independently, and the approximations fit together smoothly at C and D to give a single smooth approximation for the entire interval [A,B].

3.3 *The Error Distribution Type, EDIST.* The least squares error for the approximation S(x) to F(x) is

$$E(A,B) = [\int_A^B (F(x) - S(x))^2 \, dx]^{1/2}.$$

To make $E(A,B) < .01$ is equivalent to making $E(A,B)^2 < .0001$, and for any L_p-norm the program actually operates with $ACCUR^p$. Suppose $A=0, B=1$, then we can achieve $E(0,1)^2 < .0001$ by achieving $E(0,1/2)^2 < .0001/2$ and $E(1/2, 1)^2 < .0001/2$ since $E(A,B)^2$ is simply additive over intervals. This approach is called *proportional error distribution*, i.e. the total error requirement is distributed over the subintervals of [A,B] in proportion to the lengths of the subintervals. This choice is selected by EDIST=0 and automatically results in the total error $E(A,B)^2$ less than the specified error $ACCUR^2$.

An alternative approach is to make the errors approximately equal on each of the subintervals independent of their lengths. This is called *fixed error distribution* and is selected by EDIST=2. The argument ACCUR is used for each subinterval and if k subintervals are finally used we see that the total error is then

$$[k * ACCUR^p]^{1/p} = \sqrt[p]{(k)}\ ACCUR$$

and thus ACCUR is not the specified total error when EDIST=2. This alternative is awkward to use because the final approximation error depends on the number of subintervals required which, of course, is unknown until after the approximation is computed. However, for rough or singular F(x) this disadvantage is more than compensated by the superior performance of this error distribution type. This is seen in the theory and verified in actual use.

A compromise approach called *approximate fixed error distribution* is selected by EDIST=1. Basically the algorithm keeps a running estimate of the final number of intervals it will use and adjusts the error requirement for subintervals accordingly. This approach is obviously not foolproof, but the testing reported below shows it to be 98 to 99 percent reliable. In any case, the total error actually obtained is available for the user to see and to test. For smooth, uniformly varying F(x) the proportional error distribution gives perfectly satisfactory efficiency.

We observe that for p = infinity (NORM=3) there is no difference between the fixed and proportional error distributions.

3.4 *Portability Considerations.* Considerable pains have been taken to make the Fortran program portable. It is written in a subset of ANSI Fortran specified by PFORT (see [5]) except that four characters are packed per word rather than one as specified by PFORT. The current version is in single precision and specifically tailored to a machine with a long word length (CDC 6000–7000 series computers). Specific directions are given in the comments for changing the precision or to use it on machines with a shorter word length. In particular, all REAL variables are explicitly declared to facilitate the change to DOUBLE PRECISION. The program has been generated by an experimental Fortran converter which automatically produces versions tailored for different machines and precisions. Several of these versions have been produced and run successfully.

4. Algorithm Testing and Verification

This algorithm is based on a method with theoretically known properties. Care was taken to adhere to the requirements of that theory and considerable analysis has been made of various features and parts of the algorithm. However, no formal proof has been attempted since, as with many numerical algorithms, one cannot say a priori what is to be computed. A somewhat related algorithm has been proved correct with a few idealizing assumptions (infinite precision arithmetic and infinite memory, for example); see [3, 4].

Very extensive testing of the algorithm has been performed to see if the theoretical expectations are, in fact, realized by this algorithm. There are some approximation methods where this has not been the case. These tests are discussed at some length in [2] and we summarize them by saying that this algorithm performs as expected from the theory. The results in [2] give many insights into the practical use of this algorithm. About 2500 to 3000 different approximations have been computed in these tests and all have been examined for signs of incorrect performance. A few hundred of these runs were specifically designed to test the validity and correctness of the program.

The code with the ADAPT includes a set of 20 test functions (10 of them parame-

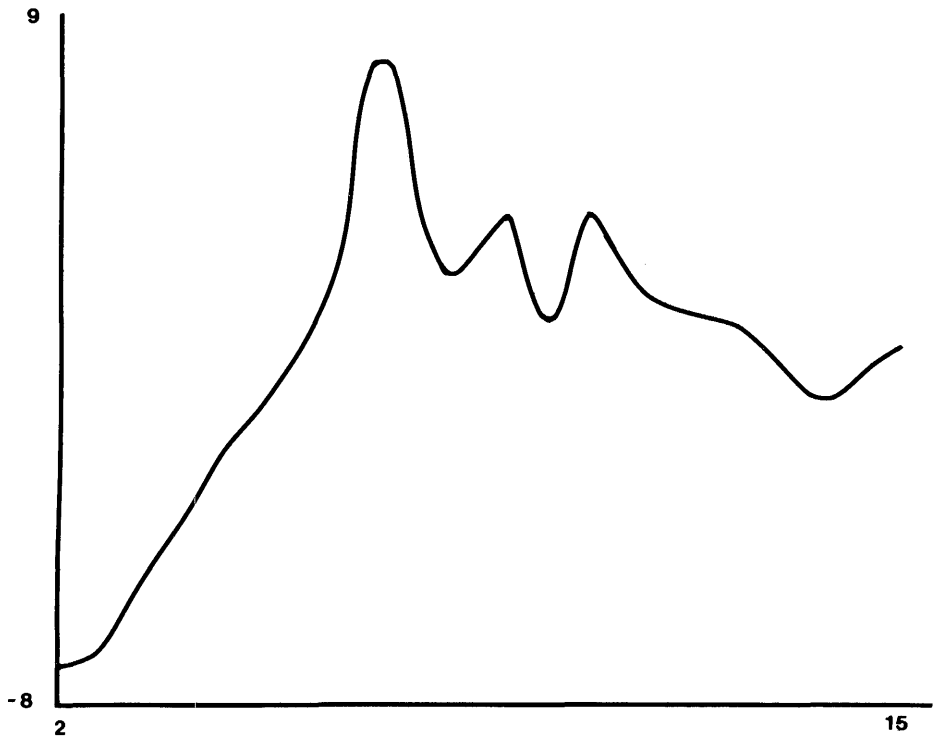

Fig. 1. The complicated function with seven pieces approximated in the second example

terized in various ways) and a driver to exercise ADAPT and measure its performance in various ways. These are included because it is felt they will be useful for testing other function approximation programs. We note that the 20 test functions are chosen to present various features of the approximation problem and we found it amazingly difficult to get the first few derivatives of these functions computed correctly.

We give sample output for two functions, one easy and one difficult. The first is $F(x) = 1./(1+(x-2.5)^4)$ with LEVEL=2 output given. The second function is shown in Figure 1 with LEVEL = 0 output given. In the first example the first and last three lines of output are from the test driver and the specific information about the problem is printed by ADAPT. For the second example the approximation is on [2,15] for polynomial degree 6 with 1 continuous derivative; the requested and estimated accuracies are .001 and .00057 in the minimax norm; proportional error distribution was used with CHARF=4. This example is function 18 of the set of test functions and one of its parameters, P8F, has been set to 1.6 here instead of 0.6 as given in the DATA for F(x). The output has been reformatted to accommodate the narrowed page width here.

ALGORITHM 526
Bivariate Interpolation and Smooth Surface Fitting for Irregularly Distributed Data Points [E1]

HIROSHI AKIMA
Institute for Telecommunication Sciences

Key Words and Phrases: bivariate interpolation, interpolation, partial derivative, polynomial, smooth surface fitting
CR Categories: 5.13
Language: ANSI Standard Fortran

DESCRIPTION

This algorithm describes the IDBVIP/IDSFFT subprogram package that implements the method of bivariate interpolation and smooth surface fitting for irregularly distributed data points [1]. The package is written in ANSI Standard Fortran [2].

The package consists of nine subprograms, i.e. eight subroutines and a function. Two subroutines, IDBVIP and IDSFFT, are the master subroutines of the package, and each interfaces with the user. The IDBVIP subroutine performs bivariate interpolation; it estimates the z values at the specified points in the x-y plane. The IDSFFT subroutine performs smooth surface fitting; it estimates the z values at the specified rectangular grid points in the x-y plane and generates a doubly-dimensioned array containing these estimated values.

The remaining six subroutines are supporting subroutines called by either IDBVIP or IDSFFT or by both: IDCLDP determines several data points closest to each of the data points; IDGRID organizes output grid points for IDSFFT by sorting them in ascending order of triangle numbers; IDLCTN locates a point (i.e. determines a triangle in which the point lies) for IDBVIP; IDPDRV estimates partial derivatives at the data points; IDPTIP performs punctual interpolation (i.e. interpolation at a point); and IDTANG triangulates (or divides into a number of triangles) the x-y plane. A function, IDXCHG, is called by IDTANG and determines whether or not an exchange of triangles is necessary.

The package includes two common blocks, IDLC and IDPI. Including these common areas, the package occupies approximately 3500 locations on the CDC-6600 computer.

When the user wishes to call either the IDBVIP or the IDSFFT subroutine repeatedly with identical data as parts of input data in two consecutive calls, he can save computation times considerably by specifying an appropriate mode of computation. (This mode is specified with the MD parameter in the call statements.)

Tables I and II show the approximate computation times required for the IDBVIP and IDSFFT subroutines, respectively, on the CDC-6600 computer when

Received 28 December 1976; revised 6 June 1977.

TABLE I. Approximate Computation Times Required for the IDBVIP Subroutine on the CDC-6600 Computer

NDP	NIP	Time (seconds)		
		MD = 1	MD = 2	MD = 3
10	10	.03	.02	.02
	100	.13	.12	.08
	1000	1.1	1.1	.70
100	10	.75	.10	.07
	100	.86	.22	.14
	1000	2.1	1.5	.84
1000	10	47.	.84	.60
	100	47.	1.1	.68
	1000	50.	3.8	1.4

TABLE II. Approximate Computation Times Required for the IDSFFT Subroutine on the CDC-6600 Computer

NDP	NXI * NYI	Time (seconds)		
		MD = 1	MD = 2	MD = 3
10	11 * 11	.08	.07	.04
	33 * 33	.41	.40	.22
	101 * 101	3.5	3.4	1.8
100	11 * 11	.86	.20	.14
	33 * 33	1.3	.66	.37
	101 * 101	4.6	4.0	2.0
1000	11 * 11	47.	1.1	.70
	33 * 33	49.	2.6	1.3
	101 * 101	54.	8.2	3.5

four additional data points are used for estimating partial derivatives at each data point (i.e. NCP = 4). In these tables, NDP is the number of data points, NIP is the number of output points at which interpolation is to be performed, and NXI and NYI are the numbers of output grid points in the x and y coordinates. MD is the mode of computation; MD = 1 for a new NCP value and/or a new set of x-y coordinates of data points, MD = 2 for an old NCP value, an old set of x-y coordinates of data points, and a new set of x-y coordinates of output points, and MD = 3 for an old NCP value, an old set of x-y coordinates of data points, and an old set of x-y coordinates of output points.

REMARK ON ALGORITHM 526

Bivariate Interpolation and Smooth Surface Fitting for Irregularly Distributed Data Points [E1]
[H. Akima, *ACM Trans. Math. Software 4,* 2 (June 1978), 160-164]

Hiroshi Akima [Recd 19 December 1978]
U.S. Department of Commerce, National Telecommunications and Information Administration, Institute for Telecommunication Sciences, Boulder, CO 80303

In Section 10.2.6, ANSI Standard Fortran provides that the completion of execution of a RETURN statement in a subprogram causes all local variables in that subprogram to become undefined. Some of the subprograms in Algorithm 526, however, are dependent on the retention of values by local variables. The algorithm, therefore, will fail to work properly if the above provision is strictly enforced as in the case where the "reset own" option is used on the Burroughs B6700 computer.

Illegal use of undefined local variables will take place in the following cases:
(1) in IDBVIP when called with MD = 2 or 3;
(2) in IDSFFT when called with MD = 2 or 3;
(3) in IDLCTN when IDBVIP is called with NIP > 1;
(4) in IDPTIP when IDBVIP is called with NIP > 1;
(5) in IDPTIP when IDSFFT is called with NXI > 1 and/or NYI > 1.

Cases (1) and (2) can be corrected by resetting two integer variables in IDBVIP and IDSFFT, respectively. Case (3) can be corrected by combining a local integer variable with another integer variable in a COMMON area shared by IDBVIP and IDLCTN, and by placing 13 real variables in the same COMMON area. Cases (4) and (5) can be corrected by placing 27 real variables in a COMMON area shared by IDBVIP, IDPTIP, and IDSFFT. (Corresponding to the last correction, some additional minor changes are required in IDPTIP.) These corrections require no changes for the program that calls IDBVIP and/or IDSFFT.

Specifically, the following replacement, insertion, and deletion should be made:

```

ALGORITHM 527
A Fortran Implementation of the Generalized Marching Algorithm [D3]

RANDOLPH E. BANK
The University of Chicago

Key Words and Phrases: marching algorithms, block tridiagonal, elliptic partial differential equations
CR Categories: 5.14, 5.17
Language: Fortran

1. DESCRIPTION

Subroutines GMA and GMAS are implementations of the generalized marching algorithm [1, 2], which may be used to solve linear systems arising from 5-point discretizations of separable or constant coefficient elliptic boundary-value problems on rectangular domains. A Dirichlet, Neumann, or mixed boundary condition may be independently specified on each side of the rectangle; periodic boundary conditions may be specified on opposing sides. An appropriate linear system is block tridiagonal, or nearly block tridiagonal, real, symmetric, positive or negative definite (for GMA) or semidefinite (for GMAS), and of the form $Ax = b$:

$$\begin{bmatrix} T+\alpha_1 I & -\beta_2 I & & & -\beta_1 I \\ -\beta_2 I & T+\alpha_2 I & -\beta_3 I & & \\ & \ddots & \ddots & \ddots & \\ & & -\beta_{N-1} I & T+\alpha_{N-1} & -\beta_N I \\ -\beta_1 I & & & -\beta_N I & T+\alpha_N I \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \\ \vdots \\ x_{N-1} \\ x_N \end{bmatrix} = \begin{bmatrix} b_1 \\ b_2 \\ \vdots \\ b_{N-1} \\ b_N \end{bmatrix} \tag{1}$$

Here $T = TM$ is the (nearly) tridiagonal $M \times M$ matrix

$$TM = \begin{bmatrix} \gamma_1 & -\sigma_2 & & & -\sigma_r \\ -\sigma_2 & \gamma_2 & -\sigma_3 & & \\ & \ddots & \ddots & \ddots & \\ & & -\sigma_{M-1} & \gamma_{M-1} & -\sigma_M \\ -\sigma_1 & & & -\sigma_M & \gamma_M \end{bmatrix} \tag{2}$$

Received 1 April 1976 and 15 February 1977.

This program was written while the author was a summer visitor at Argonne National Laboratory, Argonne, IL.
Authors' present address: Department of Mathematics, University of Texas, Austin, TX 78712.

The α_i, β_i, γ_i, and σ_i are scalars, and x_i and b_i are M-vectors. Many common discretizations which do not automatically yield symmetric matrices A (for example, in the case of Neumann or mixed boundary conditions) can be transformed into the form of eq. (1) using diagonal similarity transformations [4, 11]. No restrictions on N and M, other than N, M $\geq$ 3 are imposed.

The eigenvalues of certain principal submatrices of the N×N matrix TN, given by

$$\mathrm{TN} = \begin{bmatrix} \alpha_1 & -\beta & & & -\beta_1 \\ -\beta_2 & \alpha_{22} & -\beta_3 & & \\ & \ddots & \ddots & \ddots & \\ & & -\beta_{N-1} & \alpha_{N-1} & -\beta_N \\ -\beta_1 & & & -\beta_N & \alpha_N \end{bmatrix} \tag{3}$$

are required by the generalized marching algorithm and must be computed in a separate preprocessing phase. To solve a problem, the user must call GMA or GMAS twice, first to carry out the preprocessing, and then to solve the linear system. (If the same linear system is to be solved with many right-hand sides, the preprocessing need be done only once if the contents of the array R are saved.) Nineteen other subroutines are called internally as required.

PARTN, ROOTSC, ROOTSG, SORT, QL, and BANDR are entered during the preprocessing phase. In PARTN, the matrix A is partitioned into ND + 1 blocks by ND = [N/K] separating lines (the M unknowns in the vector x_J comprise the J-th line). Each block has K or fewer lines, where K is the marching parameter specified by the user or supplied by default. The integer NE, which satisfies $2^{NE-1} \leq$ ND $\leq 2^{NE} - 1$ if ND > 0, NE = 0 if ND = 0, is also computed.

ROOTSC and ROOTSG perform eigenvalue calculations for constant coefficient and general separable problems, respectively. SORT orders the eigenvalues according to size, both to insure numerical stability and to allow certain reductions in computation to occur in the constant coefficient case. QL and BANDR are called by ROOTSC and ROOTSG in connection with solving the eigenvalue problems; they are adaptations of TQLRAT and BANDR from the EISPACK subroutine library [7, 12].

In the backsolution phase, subroutines STEP1, STEP2, STEP3, STEP4, TRI1, TRI2, MARCH1, MARCH2, and MARCH3 are entered. In STEP1 the ND + 1 problems associated with the partitioned matrix A are partially solved using the marching algorithm. Next, in STEP2, NE − 1 "2-reductions" are applied to a reduced set of equations involving the separating lines. In STEP3, the solution vectors x_J corresponding to the separating lines are calculated in NE recursive substeps, effectively decomposing the N line problem into ND + 1 smaller problems. In STEP4, these smaller problems are solved via the marching algorithm. If periodic boundary conditions are specified for the matrix TN, certain adjustments are made in the backsolution process.

In the backsolution phase, O(N·NE) linear systems of the form $(\mathrm{T} - r\mathrm{I})x = y$ are solved; this is done in TRI1 and TRI2. Additionally, the backsolution requires O(N) matrix multiplications of the form $x = \mathrm{T}y$, which are carried out in MARCH1, MARCH2, and MARCH3.

Subroutine GMA is entered using

```
CALL GMA(NPC, N, NTYPE, TN1, TN2, M, MTYPE, TM1, TM2, IBDIM, B, K, R, A)
```

The parameter list is:

NPC is an integer. If NPC = 0, GMA does preprocessing calculations; if NPC = 1 GMA solves the linear system.
N is the dimension of the matrix TN; N > 2.
NTYPE is an integer describing the matrix TN.

NTYPE = 1: General separable; Dirichlet, Neumann, or mixed boundary conditions.
$\beta_1 = 0$; $\beta_i \neq 0$, $2 \leq i \leq N$;
α_i arbitrary, $1 \leq i \leq N$.
NTYPE = 2: Constant coefficient; Dirichlet, Neumann, or mixed boundary conditions.
$\beta_1 = 0$; $\beta_i = \beta \neq 0$, $3 \leq i \leq N - 1$;
$\alpha_i = \alpha$, α arbitrary, $2 \leq i \leq N - 1$.

Top boundary condition: One of

$\beta_2 = \beta$; $\alpha_1 = \alpha$	(Dirichlet)
$\beta_2 = (\sqrt{2})\beta$; $\alpha_1 = \alpha$	(Neumann centered)
$\beta_2 = \beta$; $\alpha_1 = \alpha - \beta$	(Neumann noncentered)
$\beta_2 = \psi \neq 0$; $\alpha_1 = \rho$, ρ arbitrary	(mixed).

Bottom boundary condition: One of

$\beta_N = \beta$; $\alpha_N = \alpha$	(Dirichlet)
$\beta_N = (\sqrt{2})\beta$; $\alpha_N = \alpha$	(Neumann centered)
$\beta_N = \beta$; $\alpha_N = \alpha - \beta$	(Neumann noncentered)
$\beta_N = \chi \neq 0$; $\alpha_N = \eta$, η arbitrary	(mixed).

NTYPE = 3: General separable; periodic boundary conditions.
$\beta_i \neq 0$, $1 \leq i \leq N$;
α_i arbitrary, $1 \leq i \leq N$.
NTYPE = 4: Constant coefficient; periodic boundary conditions.
$\beta_i = \beta \neq 0$, $1 \leq i \leq N$;
$\alpha_i = \alpha$, α arbitrary, $1 \leq i \leq N$.
If N = 3, GMA may respecify NTYPE.

TN1 is a real array of length N + 1, with TN1(I) = α_I, $1 \leq I \leq N$.
TN2 is a real array of length N + 1, with TN2(I) = β_I, $1 \leq I \leq N$.
Input values of TN2(N + 1), and TN2(1) if NTYPE $\leq$ 2, may be overwritten by GMA.
M is the dimension of the matrix TM; M > 2.
MTYPE is an integer describing the matrix TM.
MTYPE = 1: General separable; Dirichlet, Neumann, or mixed boundary conditions.
MTYPE = 2: Constant coefficient; Dirichlet, Neumann, or mixed boundary conditions.
MTYPE = 3: General separable; periodic boundary conditions.
MTYPE = 4: Constant coefficient; periodic boundary conditions.
Restrictions on γ_i and σ_i are analogous to those for α_i and β_i, respectively, for each given type. If M $\leq$ 5, GMA may respecify MTYPE.
TM1 is a real array of length M + 1, with TM1(I) = γ_I, $1 \leq I \leq M$.
TM2 is a real array of length M + 1, with TM2(I) = σ_I, $1 \leq I \leq M$.
IBDIM is the row dimension of the array B, as it appears in the calling program.
B is a two-dimensional array with at least M rows and N columns. On input, B contains the right-hand side, with the vector b_I residing in the I-th column; B(J, I) = $(b_I)_J$, $1 \leq J \leq M$, $1 \leq I \leq N$. On output B contains the solution, with the vector x_I residing in the I-th column; B(J, I) = $(x_I)_J$, $1 \leq J \leq M$, $1 \leq I \leq N$.
K is the marching parameter. If K < 2, then K assumes the default value K = 2.
R is a real array of length N·P + 3·N + 2, where $\log_2 (N/K) \leq P$, P an integer, K $\geq$ 2. The array R contains the output of a call to GMA with NPC = 0 (preprocessing calculations).
A is a real array of length 4·Q, where Q = max(N + 1, M + 1). This array is used as a scratchpad array by GMA.

Subroutine GMA has one labeled common block, /MACHEP/, containing one

variable, TOL. TOL is a machine-dependent constant, which is equal to the machine epsilon. It is initialized in GMA in the first executable statement.

When the matrix A of eq. (1) is positive or negative *semi*definite, with zero an eigenvalue of multiplicity one, then subroutine GMAS should be used in place of GMA to compute a least-squares solution. The usage of GMAS is nearly identical to that of GMA, though the two differ internally in several respects.

First, in the preprocessing phase (NPC = 0), the eigenvector v corresponding to the zero eigenvalue is determined by computing appropriate eigenvectors of the matrices TN and TM. The particular root S, for which TM − SI is singular, is perturbed to guard against possible divide checks.

Second, in the backsolution phase (NPC = 1), the right-hand side b is projected into the orthogonal complement of the vector v. The right-hand sides for the reduced equations after STEP1 and STEP2 are also projected into their appropriate orthogonal complements, since the original orthogonalities may be diminished by roundoff growth during these steps of the backsolution. Finally, the solution x is projected into the orthogonal complement of v. This completes the least-squares solution.

Subroutine GMAS calls internally the 15 subroutines employed by GMA. Additionally, GMAS calls subroutines TINVIT, PINVIT, SVALUE, and PROJ as required. TINVIT and PINVIT are used to compute eigenvectors of symmetric tridiagonal matrices and symmetric matrices with periodic boundary conditions, respectively, using the method of inverse iteration [11]. TINVIT is a modified version of EISPACK subroutine of the same name [7, 12]. Subroutine SVALUE computes the perturbation of the root S. PROJ computes the projections described above.

Subroutine GMAS is entered using

```
CALL GMAS(NPC, N, NTYPE, TN1, TN2, M, MTYPE, TM1, TM2, IBDIM, B, VN, VM
  K, R, A).
```

All parameters except VN, VM, and A are identical to the corresponding parameters in the calling sequence for GMA.

VN is a real array of length N + 1. On output from a call to GMAS with NPC = 0, VN contains the eigenvector of TN associated with the zero eigenvalue.

VM is a real array of length M + 1. On output from a call to GMAS with NPC = 0, VM contains the eigenvector of TM associated with the zero eigenvalue.

A is a real array of length 5·Q, where Q = max(N + 1, M + 1). This array is used as a scratchpad array by GMAS.

2. TESTS

The operation count for subroutine GMA (GMAS) is $O(N \cdot M \cdot NE) = O(N \cdot M \cdot \log_2 (N/K))$, with the constant depending on the problem specification and the boundary conditions. (If NE = 0 this becomes $O(N \cdot M)$). Constant coefficient problems are important special cases of general separable problems in which the operation count can be reduced, often dramatically, by taking advantage of the additional restrictions on the coefficients. In Table I we have assembled execution times (in milliseconds) for GMA on an IBM 370-195 computer for some benchmark values of N = M and K. Both constant coefficient and general separable problems were solved to illustrate the savings which can accrue in the special cases. The programs were compiled using the Fortran-H compiler, option = 2. Overall execution time is given as a sum of preprocessing time (NPC = 0) and backsolution time (NPC = 1).

The constant coefficient problems were all Helmholtz equations in the unit

square, with the Helmholtz constant a pseudorandom number between zero and one. Dirichlet boundary conditions were imposed on all boundaries. For the general separable problems, the β_i and σ_i, $1 \leq i \leq N + 1$, were all pseudorandom numbers between one and two. Then $\alpha_i = \beta_i + \beta_{i+1} + \rho_i$ and $\gamma_i = \sigma_i + \sigma_{i+1} + \eta_i$, $1 \leq i \leq N$, were calculated, with ρ_i and η_i pseudorandom numbers between zero and N^{-2}; this insured that the resulting matrices were diagonally dominant, hence positive definite.

The savings which result in the constant coefficient case depend to some extent

Table I. Execution Times for Subroutine GMA on the IBM 370-195

(P = preprocessing time (NPC = 0) in milliseconds, B = backsolution time (NPC = 1) in milliseconds, T = total execution time in milliseconds. NTYPE = MTYPE = 1 in general separable problems, NTYPE = MTYPE = 2 in constant coefficient problems, N = M in all problems.)

		Constant coefficient problems			General separable problems		
		N = 31	N = 63	N = 127	N = 31	N = 63	N = 127
K = 2							
	P	3	7	17	22	73	245
	B	24	103	449	44	215	1033
	T	27	110	446	66	288	1278

	T	9	52	294	18	118	651

on the boundary conditions, the Dirichlet problem illustrated being the optimal case. For both constant coefficient and general separable problems, the execution times increase if periodic boundary conditions are imposed.

In Table II we present some results illustrating the numerical stability of the generalized marching algorithm as a function of N = M and K for each problem type. An exact solution x_e of pseudorandom numbers on $[-1, 1]$ was generated and substituted into the difference equation in order to generate a right-hand side. The linear system was then solved, and the computed solution x_c was compared with the exact solution. The number of correct digits was computed using digits $= -\log_{10}((e^T e / x_e^T x_e)^{1/2})$, $e = x_e - x_c$. REAL*8 arithmetic was used (approximately 16 decimal digits).

For K = 2, 4, the error primarily reflects the condition number of the matrix A. When K = 8, 16, 32, however, an exponential "marching" term becomes the dominant term in the error [1].

Note that both execution time and numerical stability decrease with increasing K; thus one must seek to strike a balance between rapid execution times and accuracy requirements.

Table II. Numerical Stability of Subroutine GMA on the IBM 370-195

(NTYPE = MTYPE = 1 in general separable problems, NTYPE = MTYPE = 2 in constant coefficient problems, N = M in all problems.)

	constant coefficient problems			general separable problems		
	N = 31	N = 63	N = 127	N = 31	N = 63	N = 127
K = 2	14.8	14.3	13.9	13.3	12.5	12.6
K = 4	14.2	14.0	13.9	13.3	12.5	12.6
K = 8	11.1	11.1	11.0	11.1	11.0	11.6
K = 16	4.9	4.9	4.9	4.6	4.1	4.0
K = 32	0.0	0.0	0.0	0.0	0.0	0.0

Subroutine KPICK is designed to aid the user in making appropriate choices of the marching parameter K and to provide other information useful in determining if a linear system is appropriate for GMA or GMAS.

KPICK can be used in two ways: first, to find an optimal value of K for a user-specified accuracy demand, or, second, to estimate the accuracy for a user-selected value of K.

KPICK is based on a heuristic which supposes that subroutine GMA (or GMAS) yields solutions satisfying error estimates of the form (COND + EMARCH)*TOL, where COND is the condition number of the linear system EMARCH is the marching error, and TOL is the machine epsilon. In [1], error bounds of this form are proved for constant coefficient Dirichlet problems when $N = K2^L - 1$ for a non-negative integer L.

Subroutine KPICK is entered using

CALL KPICK(NPC, N, NTYPE, TN1, TN2, M, MTYPE, TM1, TM2, DEMAND, K, COND, EMARCH, DIGITS, IFLAG)

The parameter list is:

NPC is an integer. If NPC = 0, KPICK determines K such that the solutions computed using subroutine GMA or GMAS will have approximately DEMAND significant digits. If NPC = 1, subroutine will test the input value of K.

N, NTYPE, TN1, TN2, M, MTYPE, TM1, TM2 are identical to the corresponding parameters in the calling sequence for subroutine GMA.

DEMAND is the real number, stating the number of significant digits desired in the computed solution. It must be specified if NPC = 0.

K is an integer. If NPC = 0, on output K is equal to the marching parameter determined by KPICK. If NPC = 1, the user must specify the value of K to be tested as an input parameter.

COND is a real number, normally returning the condition number of the linear system.

EMARCH is a real number, normally returning an estimate of the marching error for the output value of K.

DIGITS is a real number, normally returning a value of max(0.0, −log((COND + EMARCH)*TOL). This is an estimate of the number of significant digits, in the 2-norm, one may expect in the computed solution.

IFLAG is an integer, describing error returns.

IFLAG = 0: Normal return.

IFLAG = 1: KPICK failed to successfully compute COND. The linear system is not positive or negative definite. If the linear system is positive or negative semidefinite with a zero eigenvalue of multiplicity one, the condition is computed

relative to the orthogonal complement of the eigenvector associated with the zero eigenvalue. Otherwise the default values COND = EMARCH = DIGITS = 0.0 are returned.

IFLAG = 2: The marching error may not satisfy the assumptions underlying the algorithm used to compute EMARCH. (The marching error appears to grow more slowly than $(2 \cdot 5)^K$.) If NPC = 0, KPICK returns estimates for K = 2; if NPC = 1, KPICK returns estimates for the input value of K.

IFLAG = 3: Conditions 1 and 2 exist.

IFLAG = 4: The linear system cannot be solved to DEMAND significant digits for any $K \geq 2$. KPICK returns estimates for K = 2. This return can occur only if NPC = 0.

IFLAG = 5: Conditions 1 and 4 exist.

IFLAG = 6: Conditions 2 and 4 exist.

IFLAG = 7: Conditions 1, 2, and 4 exist.

IFLAG = 8: The input values of N, NTYPE, TN1, and/or TN2 are incorrectly specified.

IFLAG = 9: The input values of M, MTYPE, TM1, and/or TM2 are incorrectly specified.

IFLAG = 10: Conditions 8 and 9 exist.

If IFLAG = 0, 2, 4, 6, then the problem is appropriate for subroutine GMA with the qualifications noted above. If IFLAG = 1, 3, 5, 7, with other than default values for COND, EMARCH, and DIGITS, then the problem is appropriate for GMAS.

Subroutine KPICK calls subroutines TCHECK, EIGEN, TRIEIG, PEREIG, and ERROR as required. TCHECK is used to determine if the matrices TN and TM have been correctly specified. Then COND is determined by computing the extremal eigenvalues of TN and TM; this is done in EIGEN. For some matrix types, the eigenvalues are well known; otherwise TRIEIG or PEREIG are used. These routines compute eigenvalues of symmetric tridiagonal and periodic matrices, respectively, using bisection and the Sturm sequence property [4, 11].

For a fixed value of K, EMARCH is defined to be the largest 2-norm over the set of marching polynomials arising in STEP1 or STEP4 of the generalized marching algorithm [1, 2]. For a fixed value of K, subroutine ERROR is used to compute the marching error; the three-term recurrence relation for generating the marching polynomials is employed [1, 2]. If NPC = 1 computation of EMARCH is straightforward; if NPC = 0, the method of bisection is used to determine the optimal value of K, and hence EMARCH.

To test the effectiveness of KPICK, 3000 random problems (1000 nonsingular, 1000 singular, and 1000 where singularity was randomly determined) were solved on an IBM 370-195 using REAL*8 arithmetic. All required input values for KPICK, GMA, and GMAS were generated using random number generators of the type used in testing the EISPACK codes [7].

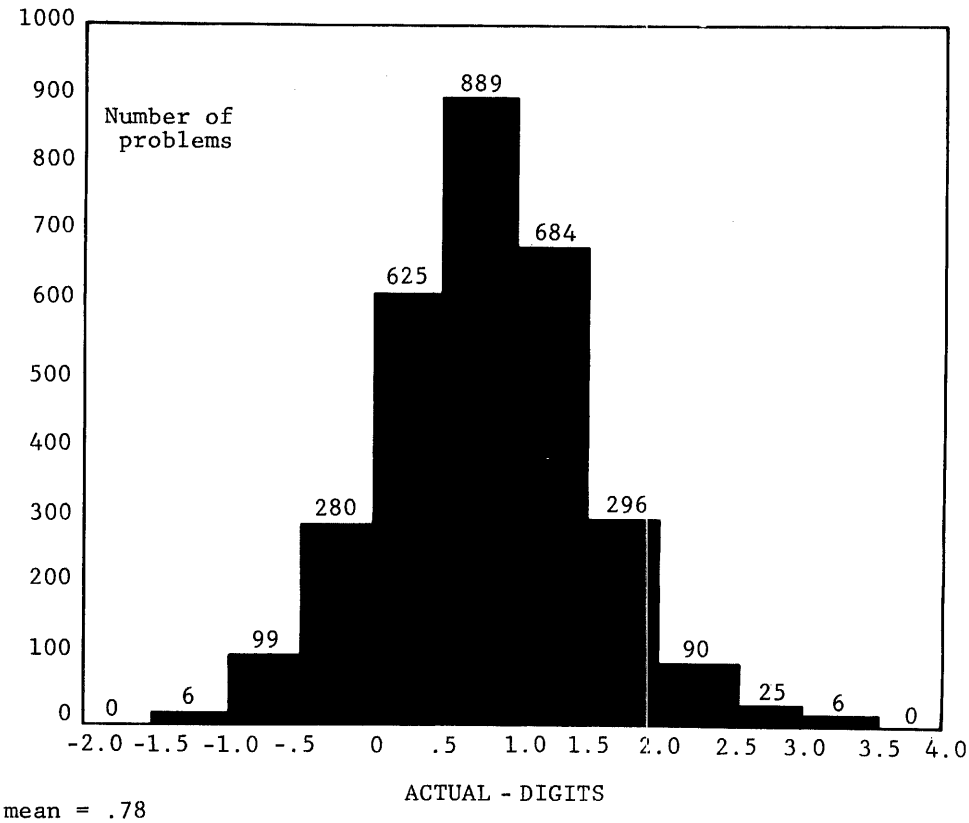
The values of N and M were random integers between 3 and 63; NTYPE and MTYPE were random integers between 1 and 4 (for type-2 matrices, the boundary condition combination was determined randomly). The matrix entries themselves were generated using random real numbers on $[10^{-3}, 1.0]$. Positive or negative definiteness (semidefiniteness) was determined randomly.

The parameter DEMAND was a random real number on $[1.0, -\log(\text{TOL}) - 1.0]$. Exact solutions were generated using random numbers on $[-1.0, 1.0]$ and were substituted into the difference equations to generate right-hand sides.

The random problems were analyzed by KPICK, with NPC = 0; the values of K produced in this fashion ranged between 2 and 29. The problems were then solved, using GMA or GMAS, and the computed solutions compared with the exact solutions. The number of correct digits, in the 2-norm, of the computed solution ACTUAL was determined and compared with the estimate of DIGITS provided by KPICK. The results are summarized in Table III, where we have

Table III. Effectiveness of Subroutine KPICK in Predicting the Error for 3000 Random Problems

(ACTUAL = actual number of correct digits in the computed solution in the 2-norm using GMA or GMAS, DIGITS = number of correct digits predicted by KPICK.)



mean = .78

variance = .48

graphed the value of ACTUAL–DIGITS versus the number of problems. The results indicate the effectiveness of KPICK in predicting the accuracy of computed solutions using GMA and GMAS. The results for singular and nonsingular problems considered separately are essentially the same as those given in Table III.

Other Fortran programs for solving eq. (1) or certain special cases using fast direct methods can be found in [3, 8]; theoretical discussions of the algorithms are given in [5, 6, 9, 10].

ACKNOWLEDGMENT

The author is indebted to Paul Concus of Lawrence Berkeley Laboratory, whose tests and critiques of preliminary versions of the program led to many improvements in the final version, and to Jack Dongarra of Argonne National Laboratory for many helpful discussions.
