BRENTM, A Fortran Subroutine for the Numerical Solution of Systems of Nonlinear Equations [C5]

JORGE J. MORÉ
Argonne National Laboratory
and
MICHEL Y. COSNARD
Université Scientifique et Médicale de Grenoble

Key Words and Phrases: nonlinear equations, numerical solution, Brent's method
CR Categories: 4.6, 5.15
Language: Fortran

1. DESCRIPTION

BRENTM is a subroutine designed to solve a system of n nonlinear equations in n variables by using a modification of Brent's method [1]. This modification, and numerical results for our implementation, are discussed in [2].

Our subroutine does not use any techniques which attempt to obtain global convergence, and therefore convergence is only guaranteed if the initial estimate for the solution is close enough. On the other hand, our code does seem to have a large region of convergence; convergence only occurs at a zero of the function, and if the iteration is not making satisfactory progress, then BRENTM will attempt to diagnose this situation and stop the iteration with an appropriate message.

The user is only required to provide a subroutine which calculates components of the function. Note that because of the nature of Brent's method, it is advantageous to arrange the components of the function in increasing order of nonlinearity; in particular, any linear components should appear first.

The accuracy of BRENTM is controlled by the parameters FTOL and XTOL. Convergence occurs if all residuals are at most FTOL in magnitude. Thus FTOL should be chosen with care since an appropriate value depends on the scaling of the functions. Convergence also occurs if BRENTM estimates that

$$\| x - x^* \|_\infty \leq \mathrm{TOL} \| x^* \|_\infty$$

where x^* is a solution to the system of nonlinear equations and x is the current estimate of x^*. Note that if x^* has components of widely different magnitude,

Received 7 February 1978; revised 27 August 1979; accepted 11 December 1979.

This work was performed under the auspices of the U.S. Department of Energy.
Authors' addresses: J.J. Moré, Applied Mathematics Division, Argonne National Laboratory, Argonne, IL 60439; M.Y. Cosnard, Mathematiques Appliquées-Informatique, Université Scientifique et Médicale de Grenoble, Boite Postal 53, 38041 Grenoble Cédex, France.

then there is a danger that the smaller components of x will have large relative errors, but this usually does not happen because of the fast convergence of the iteration.

2. BRENT1

The complete generality provided by BRENTM is usually not required, and in these cases, the calling sequence can be shortened and simplified. We have incorporated the following simplifications into the easy-to-use driver BRENT1. Note that BRENT1 has 8 parameters in the calling sequence, while BRENTM has 15.

(1) Only allow one tolerance TOL by setting FTOL and XTOL equal to TOL. Unless there is information about the scaling of the function, this is a natural choice.

(2) Let MOPT maximize $\log(k + 1)/(n + 2k + 1)$ for $k = 1, 2, \ldots, n$. This is the value recommended in [1] and [2].

(3) Set MAXFEV to $50(n + 3)$. This limit permits 100 iterations of the algorithm, and in our experience BRENTM has either succeeded or reported unsatisfactory progress before this limit is reached.

(4) Eliminate NFEV from the calling sequence. Many users are not interested in the number of function evaluations required by BRENTM, and in any case NFEV can be computed by the user through FCN.

(5) Condense all arrays not required by FCN into one work array WA of length LWA. BRENTM would need LWA to be at least $n(n + 3)$.

and
DAN FENNER
Johns Hopkins Applied Physics Laboratory

Key Words and Phrases: fixed point, zero, nonlinear system, homotopy method, continuation method, parameterized nonlinear system, zero curve of a homotopy map, fixed points of nonlinear systems, zeros of nonlinear systems
CR Categories: 5.15
Language: Fortran

DESCRIPTION

Introduction

Homotopy methods (also known as continuation methods or methods of incremental loading) for computing zeros of nonlinear systems are well known [1, 4–11, 13]. In abstract terms a homotopy method is as follows: Let B be a Banach space and $f: B \to B$ the function whose zero is desired. Let $s: B \to B$ be a simple function with a known zero. Construct a continuous map (the homotopy) $\Phi: B \times [0, 1] \to B$ such that $\Phi(x, 0) = s(x)$ and $\Phi(x, 1) = f(x)$. Then by solving the equation $\Phi(x, \lambda) = 0$ in $B \times [0, 1]$, one attempts to move from the known zero of $s(x)$ (at $\lambda = 0$) to the unknown zero of $f(x)$ (at $\lambda = 1$). There is a considerable amount of theory concerning when this procedure will work [11], but, in general, moving from a zero of $s(x)$ to a zero of $f(x)$ may or may not be possible. Sometimes λ is treated as an independent variable [4, 11], and sometimes λ is a dependent variable with arc length or some other parameter as the independent variable [7, 9, 10, 13].

For the calculation of (Brouwer) fixed points, the supporting theory is much more satisfactory. Let B be the closed unit ball (or any compact, convex subset) in E^n, and let $f: B \to B$ be a C^2 map. Chow et al. [3] have proved the following powerful theorem: Define $\rho_a: [0, 1) \times B \to E^n$ by

$$\rho_a(\lambda, x) = \lambda(x - f(x)) + (1 - \lambda)(x - a)$$

where $f: B \to B$ is a C^2 map such that the Jacobian matrix of $x - f(x)$ is nonsingular at every fixed point of f. Then for almost all a in the interior of B, the

Authors' present addresses: L.T. Watson, Department of Computer Science, Virginia Polytechnic Institute, Blacksburg, VA. 24061; D. Fenner, Johns Hopkins Applied Physics Laboratory, Johns Hopkins Road, Laurel, MD 20810.

set $\{(\lambda, x) \mid 0 \le \lambda < 1, x \in B, \rho_a(\lambda, x) = 0\}$ of zeros of ρ_a consists of

(1) a finite number of closed loops (having finite length) in $(0, 1) \times B$;
(2) a finite number of arcs (having finite length) in $(0, 1) \times B$ with endpoints in $\{1\} \times B$;
(3) a curve of finite length starting at $(0, a)$ and ending at $(1, \bar{x})$, where $\bar{x} \in B$ is a fixed point of f.

The curves in (1), (2), and (3) are disjoint and continuously differentiable.

In other words, with probability 1 there is a zero curve of $\rho_a(\lambda, x)$ emanating from $(0, a)$ which reaches a fixed point $\bar{x}$ of f (at $\lambda = 1$). This zero curve is smooth and has finite length. Thus computing a fixed point of f merely amounts to tracking a (smooth) zero curve of $\rho_a(\lambda, x)$. Note that the asumptions on $f(C^2$ smoothness and nonsingularity of the Jacobian matrix of $x - f(x)$ at the fixed point) are quite mild considering that global convergence is guaranteed with probability 1.

A brief outline of how the zero curve is followed is given here. Complete details of the algorithm and convergence proofs are in [13]. The basic idea, which has been used by several authors [7, 9, 10], is to parameterize the zero curve of $\rho_a(\lambda, x)$ by arc length and then solve an initial value problem. The zero curve $(\lambda(s), x(s))$ emanating from $(0, a)$ satisfies

$$\rho_a(\lambda(s), x(s)) = 0, \qquad \lambda(0) = 0, \qquad x(0) = a \tag{1}$$

and thus is given by the solution of the initial value problem

$$\begin{aligned} &\frac{d}{ds}\rho_a(\lambda(s), x(s)) = 0, \\ &\left\|\left(\frac{d\lambda}{ds}, \frac{dx}{ds}\right)\right\| = 1, \qquad \lambda(0) = 0, \qquad x(0) = a. \end{aligned} \tag{2}$$

Computing $(d\lambda/ds, dx/ds)$ reduces to finding the kernel of the $n \times (n + 1)$ matrix $[a - f(x), I - \lambda Df(x)]$ which always has full rank [3, 13]. ($Df(x)$ is the Jacobian matrix of $f(x)$.) Therefore there are no "singular points" along the curve.

Of course the zero curve of $\rho_a(\lambda, x)$ could be followed by a general curve tracking program like that of Kubicek [10], but since the ultimate objective is a fixed point and not the zero curve of ρ_a, special tactics are called for. There are several other reasons for not using the program in [10]. That program produces a specified number of data points on the curve, and it would be difficult to make it stop exactly at $\lambda(s) = 1$. Furthermore, the numerical linear algebra and ordinary differential equation (ODE) techniques in that program are primitive compared with current technology (as, for example, [2] and [12]).

Computing Zeros. This algorithm for computing fixed points can be used to find zeros also, but then global convergence is not guaranteed. The homotopy map for zeros is

$$\Phi_a(\lambda, x) = \lambda f(x) + (1 - \lambda)(x - a),$$

and the rest of the details are similar to the fixed point case. Observe that in the fixed point case, the zero curve of ρ_a has finite length (in fact, fairly short for practical problems), and thus stiffness of the ODE is never a problem. However, the zero curve of ϕ_a can (and in practice frequently does) wander off to infinity, and the ODE can be stiff.

There are numerous conditions on f guaranteeing that the zero curve of Φ_a reaches a zero [3, 13], but these are frequently not satisfied for practical problems. One such sufficient condition is that for some $r > 0$,

$$x^t f(x) \ge 0 \qquad \text{on} \quad \|x\| = r.$$

Then $f(x)$ has a zero in the ball $\|x\| \le r$, and for almost all a in the interior of this ball, there is a zero curve of Φ_a connecting $(0, a)$ to $(1, \bar{x})$, and the Jacobian matrix $D\Phi_a$ has full rank along this zero curve [13].

In view of the preceding comments, the computer code should be used with caution on zero finding problems.

Organizational Details

There are seven subroutines: FIXPT, FODE, DCPOSE, INNER, STEP, INTRP, and ROOT. The user need only call FIXPT; all the others are directly or indirectly used by FIXPT.

The subroutines STEP, INTRP, and ROOT are from [12]. STEP is used to solve the initial value problem, and INTRP and ROOT are used to calculate the vector $x(s)$ corresponding to $\lambda(s) = 1$. FODE specifies the ordinary differential equation for STEP. FODE must determine the kernel of a matrix, and it uses DCPOSE and INNER for this purpose. DCPOSE was taken from [2] with minor modifications.

FIXPT and FODE contain dimension statements which limit N, and also use labeled common. These restrictions could have been avoided by considerably lengthening the call lists of STEP, FODE, and FIXPT. Instead we chose to use STEP verbatim, so that the user needs only one version of STEP, and future improvements in STEP can be easily incorporated into this fixed point package. The difficulty arises because FIXPT has parameters which must be passed to FODE via STEP, and DCPOSE must return information back up through FODE and STEP to FIXPT.

FIXPT limits the number of steps to 1000, but this can be changed in the DATA statement that sets the value of LIMITD.

FIXPT and FODE contain dimension statements which limit N to 100.

STEP and ROOT use machine dependent constants, for which appropriate DATA statements must be chosen, as explained in the listing. No other modifications are required by the user.

The user must supply two subroutines, F(X, V) and FJAC (X, V, K). Subroutine F evaluates f at X and returns the result in (the vector) V. Subroutine FJAC evaluates the Kth column of the Jacobian matrix of f at X and returns the result in V. FJAC may, of course, produce finite difference approximations to the Jacobian matrix. The effect of finite difference approximations on the overall efficiency and accuracy of the algorithm has not been explored so far.

Modifications for Large Sparse Problems. FIXPT was designed for low-dimensional ($n \leq 100$) problems where the Jacobian matrix of f is dense. It is not difficult to modify FIXPT for a problem where n is very large but the Jacobian matrix of f is sparse. Write the Jacobian matrix of the homotopy map as

$$D\rho_a(x, \lambda) = [I - \lambda Df(x), a - f(x)].$$

Note that the order of the variables has been switched. The subroutine DCPOSE essentially reduces $D\rho_a(x, \lambda)$ to upper triangular form. If $Df(x)$ is sparse, then $D\rho_a(x, \lambda)$ can be reduced to upper triangular form efficiently by, e.g., plane rotations. Probably DCPOSE should be tailored to the particular structure of $Df(x)$. FODE computes the kernel of the upper triangular matrix produced by DCPOSE. This calculation in FODE would have to be changed and again should probably be tailored to the particular form of $Df(x)$. Thus FODE and DCPOSE would require major changes, but all the other subroutines would remain the same (except, of course, for the DIMENSION statements in FIXPT). It might also be desirable to reduce the storage requirements of STEP as explained in [12].

Testing. FIXPT has been tested on several hundred problems of mixed polynomial, exponential, and trigonometric types, with n ranging from 2 to 100. Some problems, for example, an exponential with a rapidly oscillating trigonometric exponent, give the method a great deal of difficulty. On the other hand, high-degree ($\geq$10) polynomials in 100 dimensions are handled easily. When used properly, the performance of FIXPT has been entirely satisfactory. The computed

* Did not converge.

† No convergence, reported "singular Jacobian."

fixed points are usually accurate to within the tolerance EPS and have never been in error by more than 10 EPS. Some typical computational results are given in [13]. Shown in Table I are the results for Brown's function

$$f_1(x) = x_1 - \left(\prod_{i=1}^{n} x_i - 1\right),$$

$$f_j(x) = x_j - \left(\sum_{i=1}^{n} x_i + x_j - (n+1)\right), \qquad j = 2, \ldots, n,$$

which was suggested by R. Saigal as a particularly difficult problem (because the Jacobian matrix is ill conditioned). ZSYSTM is from the IMSL library and uses a quasi-Newton method. ND is the number of Jacobian evaluations, and the CPU time is execution time (in seconds) on a CDC 6500. EPS = 1.E−8, ARCTOL = 1.0E−3 for N = 5, 10, 20, 25, and ARCTOL = 1.0E−5 for N = 15, 30, 35, 40, 45, 50. For this problem the zero curve does not turn back, although in the next example from [13] the zero curve turns back many times. Therefore, the use of the parameter λ as a *dependent* variable is crucial.

$$f_k(x) = \exp\left(\cos\left(k \sum_{i=1}^{5} x_i\right)\right), \qquad k = 1, \ldots, 5.$$

Starting from zero, both Steffensen's method and ZSYSTM failed to find a fixed point of $f(x)$. FIXPT required 6.39 seconds of CPU time, 513 Jacobian evaluations, with an arc length of 14.83, to compute a fixed point accurate to eight places.

Referee's Note. The single precision program given in the listing was run successfully in double precision on an IBM 3033, using the AUTODBL feature of the Fortran Extended H Compiler. However, the author reports that this worked on another system only after the final argument (0.0) in the two references to INNER in DCPOSE was changed to double precision.

C      X -- INITIAL VALUE OF THE INDEPENDENT VARIABLE                     497Ø
C      Y(*) -- VECTOR OF INITIAL VALUES OF DEPENDENT VARIABLES            498Ø
C      NEQN -- NUMBER OF EQUATIONS TO BE INTEGRATED                       499Ø
C      H -- NOMINAL STEP SIZE INDICATING DIRECTION OF INTEGRATION         5ØØØ
C           AND MAXIMUM SIZE OF STEP.  MUST BE VARIABLE                   5Ø1Ø
C      EPS -- LOCAL ERROR TOLERANCE PER STEP.  MUST BE VARIABLE           5Ø2Ø
C      WT(*) -- VECTOR OF NON-ZERO WEIGHTS FOR ERROR CRITERION            5Ø3Ø
C      START -- .TRUE.                                                    5Ø4Ø
C                                                                         5Ø5Ø
C   STEP REQUIRES THE L2 NORM OF THE VECTOR WITH COMPONENTS               5Ø6Ø
C   LOCAL ERROR(L)/WT(L)  BE LESS THAN EPS FOR A SUCCESSFUL STEP.  THE    5Ø7Ø
C   ARRAY WT ALLOWS THE USER TO SPECIFY AN ERROR TEST APPROPRIATE         5Ø8Ø
C   FOR HIS PROBLEM.  FOR EXAMPLE,                                        5Ø9Ø
C      WT(L) = 1.Ø  SPECIFIES ABSOLUTE ERROR,                             51ØØ
C            =ABS(Y(L))  ERROR RELATIVE TO THE MOST RECENT VALUE OF THE   511Ø
C                 L-TH COMPONENT OF THE DERIVATIVE,                       512Ø
C            = AMAX1(WT(L),ABS(Y(L)))  ERROR RELATIVE TO THE LARGEST      513Ø
C                 MAGNITUDE OF L-TH COMPONENT OBTAINED SO FAR,            514Ø
C            = ABS(Y(L))*RELERR/EPS + ABSERR/EPS SPECIFIES A MIXED        515Ø
C                 RELATIVE-ABSOLUTE TEST WHERE RELERR IS RELATIVE         516Ø
C                 ERROR, ABSERR IS ABSOLUTE ERROR AND EPS =               517Ø
C                 AMAX1(RELERR,ABSERR)                                    518Ø
C                                                                         519Ø
C      SUBSEQUENT CALLS --                                                52ØØ
C                                                                         521Ø
C   SUBROUTINE STEP IS DESIGNED SO THAT ALL INFORMATION NEEDED TO         522Ø
C   CONTINUE THE INTEGRATION, INCLUDING THE STEP SIZE H AND THE ORDER     523Ø
C   K, IS RETURNED WITH EACH STEP.  WITH THE EXCEPTION OF THE STEP        524Ø
C   SIZE, THE ERROR TOLERANCE, AND THE WEIGHTS, NONE OF THE PARAMETERS    525Ø
C   SHOULD BE ALTERED.  THE ARRAY WT MUST BE UPDATED AFTER EACH STEP      526Ø
C   TO MAINTAIN RELATIVE ERROR TESTS LIKE THOSE ABOVE.  NORMALLY THE      527Ø
C   INTEGRATION IS CONTINUED JUST BEYOND THE DESIRED ENDPOINT AND THE     528Ø
C   SOLUTION INTERPOLATED THERE WITH SUBROUTINE INTRP.  IF IT IS          529Ø
C   IMPOSSIBLE TO INTEGRATE BEYOND THE ENDPOINT, THE STEP SIZE MAY BE     53ØØ
C   REDUCED TO HIT THE ENDPOINT SINCE THE CODE WILL NOT TAKE A STEP       531Ø
C   LARGER THAN THE H INPUT.  CHANGING THE DIRECTION OF INTEGRATION,      532Ø
C   I.E., THE SIGN OF H, REQUIRES THE USER SET START = .TRUE. BEFORE      533Ø
C   CALLING STEP AGAIN.  THIS IS THE ONLY SITUATION IN WHICH START        534Ø
C   SHOULD BE ALTERED.                                                    535Ø
C                                                                         536Ø
C   OUTPUT FROM STEP                                                      537Ø
C                                                                         538Ø
C      SUCCESSFUL STEP --                                                 539Ø
C                                                                         54ØØ
C   THE SUBROUTINE RETURNS AFTER EACH SUCCESSFUL STEP WITH START AND      541Ø
C   CRASH SET .FALSE. .  X REPRESENTS THE INDEPENDENT VARIABLE            542Ø
C   ADVANCED ONE STEP OF LENGTH HOLD FROM ITS VALUE ON INPUT AND Y        543Ø
C   THE SOLUTION VECTOR AT THE NEW VALUE OF X .  ALL OTHER PARAMETERS     544Ø
C   REPRESENT INFORMATION CORRESPONDING TO THE NEW X NEEDED TO            545Ø
C   CONTINUE THE INTEGRATION.                                             546Ø
C                                                                         547Ø

ALGORITHM 556
Exponential Integrals [S13]

DONALD E. AMOS
Sandia National Laboratories

Key Words and Phrases: exponential integrals, Miller algorithm, confluent hypergeometric functions
CR Categories: 5.12
Language: Fortran

DESCRIPTION

The Fortran subroutine EXPINT given here is an implementation of [1]. EXPINT has four machine-dependent parameters XCUT, XLIM, ETOL, and EULER which are set into DATA statements. XCUT is a breakpoint such that for $x \leq$ XCUT, the series is evaluated and for $x >$ XCUT, the Miller algorithm is applied. XLIM is the approximate underflow limit for e^{-x}, $x \geq 0$, and ETOL is nominally set to 1.E$-D$ where D is the number of base 10 digits in a word. EULER is the negative Euler constant, $-\gamma$. Thus

```
DATA XCUT, XLIM, ETOL/2.0, 667.0, 1.E-12/
```

would be appropriate for CDC single-precision arithmetic, while

```
DATA XCUT, XLIM, ETOL/1.0, 172.0, 1.E-6/
```

would be appropriate for IBM single-precision arithmetic. The two choices for XCUT reflect the fact that there is a loss of up to two digits on $1 < x \leq 2$ with the series evaluation. This loss can be tolerated on longer word length machines, but not on shorter word length machines.

Maximum accuracy can always be achieved with XCUT = 1. However, for longer word lengths where $D = 14$, the reduction in computation by moving XCUT from 1 to 2, achieved at the expense of two digits of accuracy, seems to be a worthwhile trade-off, and $D = 12$ reflects this modification for CDC machines. $D = 12$ is also more consistent with the accuracy attainable from EXP($-X$) near the underflow limit $X = 667$.

While the subroutine EXPINT is almost portable, the function DIGAM, which computes the psi function at integer arguments, is supplied as a CDC 6600-7600 Fortran function. Modifications for other machines can be made easily from eq. (7) of [1].

The convergence of eq. (2) in [1] is so rapid that the $m = n - 1$ term, which requires $\psi(n)$, is reached for only small values of n. A table of 100 values suffices for virtually all single-precision implementations of EXPINT. An initialization step to generate a higher precision table might be appropriate if multiple precision is anticipated. For CDC single precision or IBM double precision, 36 values suffice for n as high as 10^{12} and relative errors of 10^{-14}

Testing of EXPINT

Extensive testing of EXPINT against a quadrature

$$E_n(x) = e^{-x}x^{n-1}\int_x^\infty \frac{e^{-(t-x)}}{t^n}\,dt$$

was used to check out the routine on parameter ranges

$$E_n(x) = e^{-x}x^{n-1}\int_x^\infty \frac{e^{-(t-x)}}{t^n}\,dt$$

was used to check out the routine on parameter ranges

$$10^{-11} \le \text{TOL} \le 0.1$$
$$0 \le X \le 100$$
$$1 \le N \le 100$$
$$1 \le M \le 100$$
$$\text{XCUT} = 1, 2$$
$$\text{KODE} = 1, 2$$

where KODE is used to scale $E_{N+k}(x)$, $k = 0, 1, \ldots, M-1$ by e^x, if desired. Some spot checks for x and N in the hundreds, as well as special values XCUT $\pm 10^{-13}$, were also made at tolerances TOL as low as 10^{-9}. The quadrature could be relied upon to give the requested accuracy down to TOL = 10^{-11} over the full exponent range of the CDC 6600. For large x, argument reduction in computing e^{-x} will result in decreased accuracy, up to three digits near the underflow limit $x \sim 667$. Hence tolerances smaller than 10^{-11} would require double-precision exponentials to obtain checks for large x.

Relative errors in long sequences, up to 100 terms, were checked for degradation of the recurrence by comparing members of a sequence with single evaluations ($M = 1$) at high accuracies. When $M = 1$, EXPINT uses one of the two basic methods for evaluation rather than recursion.

Relative errors in all of these tests were less than the relative error specified in EXPINT to generate the test values.

ALGORITHM 557
PAGP, A Partitioning Algorithm for (Linear) Goal Programming Problems [H]

JEFFREY L. ARTHUR
Oregon State University
and
A. RAVINDRAN
Purdue University

Key Words and Phrases: goal program, multiple objective optimization, constraint partitioning, simplex method
CR Categories: 5.41
Language: Fortran

DESCRIPTION

This algorithm is a Fortran implementation of the procedures developed in [1].

REFERENCE

1. ARTHUR, J.L., AND RAVINDRAN, A. PAGP, A partitioning algorithm for (linear) goal programming problems. *ACM Trans. Math. Softw. 6,* 3 (Sept. 1980), 378-386.

ALGORITHM

```
C      PROGRAM MAIN (INPUT,OUTPUT,TAPE5=INPUT,TAPE6=OUTPUT)                A   1Ø
C ***********************************************************************
C ****
C ****
C **** PAGP (THE PARTITIONING ALGORITHM FOR GOAL PROGRAMMING) IS
C **** DESIGNED TO SOLVE THE LINEAR GOAL PROGRAMMING PROBLEM.  THE
C **** ALGORITHM PARTITIONS THE GOAL CONSTRAINTS OF THE PROBLEM
C **** ACCORDING TO THE HIGHEST PRIORITY ASSIGNED TO EITHER DEVIATIONAL
C **** VARIABLE (D- OR D+) IN EACH GOAL.  THE ALGORITHM IS THUS ABLE TO
C **** SOLVE A SEQUENCE OF SMALLER PROBLEMS IN ORDER TO FIND A SOLUTION
C **** TO THE ORIGINAL PROBLEM.
C ****
C ****
C ***********************************************************************
C ****
C ****
C **** MUCH OF THE NOTATION AND STRUCTURE OF THE PAGP CODE IS TAKEN
C **** (WITH THE AUTHOR'S PERMISSION) FROM THE LINEAR GOAL PROGRAMMING
```

Received 24 April 1978; revised 21 June 1979; accepted 12 December 1979.

Authors' addresses: J.L. Arthur, Department of Statistics, Oregon State University, Corvallis, OR 97331; A. Ravindran, School of Industrial Engineering, Purdue University, West Lafayette, IN 47907.

ALGORITHM 558

A Program for the Multifacility Location Problem with Rectilinear Distance by the Minimum-Cut Approach [H]

TO-YAT CHEUNG
University of Ottawa

Key Words and Phrases: multifacility, optimal location, rectilinear distance, minimum cut
CR Categories: 3.57, 5.41
Language: Fortran

DESCRIPTION

This algorithm complements [1], where more details are given. The coding of the algorithm consists of two subroutines, LOCATE and NETFLO. A user's program calls LOCATE, which contains the major coding, and calls NETFLO for solving the minimum-cut network flow subproblems.

ACKNOWLEDGMENTS

This author wishes to thank Prof. A. Nijenhuis, Prof. H. Wilf, and Academic Press for their permission to use and modify their subroutine NETFLO. The referees' efforts in testing the program are very much appreciated.

ALGORITHM 559
The Stationary Point of a Quadratic Function Subject to Linear Constraints [E4]

J. T. BETTS
The Aerospace Corporation

Key Words and Phrases: quadratic programming, orthogonal decomposition
CR Categories: 5.14, 5.15, 5.4, 5.40, 5.41
Language: Fortran

DESCRIPTION

This algorithm implements the method developed in [1].

REFERENCE

1. BETTS, J.T. A compact algorithm for computing the stationary point of a quadratic function subject to linear constraints. *ACM Trans. Math. Softw. 6*, 3 (Sept. 1980), 391-397.

ALGORITHM 560
JNF, An Algorithm for Numerical Computation of the Jordan Normal Form of a Complex Matrix [F2]

BO KÅGSTRÖM and AXEL RUHE
University of Umeå, Sweden

Key Words and Phrases: Jordan normal form, canonical form, eigenvalues, eigenvectors, principal vectors, block diagonal form
CR Categories: 5.14
Language: Fortran

DESCRIPTION

1. Introduction

The routines given here are the actual Fortran implementation of the algorithm presented and discussed in [2]. We describe in detail how to use the Fortran subroutines and how to reach the results from a call. We also give some comments on the code that might be of value when implementing the subroutines on a particular machine. The subroutines have been checked with the PFORT verifier [4] and the notation from [2] is used.

2. The User-Written Routine DECIDE

DECIDE is a user-written subroutine which makes it possible for the user to change the grouping and/or the values of the numerical multiple eigenvalues.

This routine is useful when we have some information on the eigenvalues and their multiplicities in advance, and want the eigenvectors and the principal vectors for the given matrix. For instance, if we know of physical reasons why zero should be the only possible multiple eigenvalue and all others simple, then the contents of the parameters should be changed as indicated in Table I.

If the user does not want to influence the grouping or the values of the eigenvalues, it is enough to define a dummy subroutine, i.e.,

```
SUBROUTINE DECIDE (NM, N, NDEL, CSHTR, CSHTI, NBLOCK, HR, HI)
RETURN
END
```

3. The Rank Determination Process and the RDEFL Routine

The rank determination process is described in [2, Section 2.2 and Section 3, Step 6 of the algorithm]. According to these two alternatives we have two subroutines

Received 21 May 1975 and August 1977.

This work was supported by the Swedish Natural Science Research Council.
Authors' address: Institute of Information Processing, University of Umeå, S-901 87 Umeå, Sweden.

Table I. Example of Use of the Subroutine DECIDE

On entry N = 10 NBLOCK = 6		On exit NBLOCK = 7	
NDEL	CSHT	NDEL	CSHT
0	−1.5	0	−1.5
1	0.002	1	0.0
5	2.4	5	H(6, 6)
7	3.5	6	H(7, 7)
8	8.6	7	3.5
9	9.5	8	8.6
10		9	9.5
		10	

RDEFL—one for the singular value decomposition strategy and one for the Kublanovskaya (RQ) decomposition strategy. Only the routine based on singular value decomposition is presented here.

In the RDEFL routine we use the CSVD algorithm [1] with one change; namely, we sort the singular values in increasing instead of decreasing order as in the original program.

4. How to Reach Any of the Vectors

The eigenvectors and principal vectors are stored in the arrays ZR, ZI(NM, N). To find the vectors, we use the information stored in NBLOCK, NDEL, NDB, NDEFL, and NXT (see the parameter list of subroutine JNF).

The column indices K in ZR and ZI for eigenvectors, principal vectors, and principal chains of an eigenvalue are listed below in Algol for-statement notation.

(a) Find the eigenvectors of the multiple eigenvalue
I = 1, . . . , NBLOCK.
J := NDB[I];
for K := NDEL[I] + 1 **step** 1 **until** NDEFL[J + 1] − 1 **do**;

(b) Find the principal vectors of grade P to the eigenvalue I = 1, . . . , NBLOCK.
J := NDB[I] + P − 1;
for K := NDEFL[J] **step** 1 **until** NDEFL[J + 1] − 1 **do**;

(c) Find the principal chain which ends with the eigenvector in column L.

```
First:
(A − EV[L]*I)*Z[L] = 0   (eigenvector)
Then:
K1 := L;
for K := NXT[K1] while K > 0 do
begin
Here:
(A − EV[K]*I)*Z[K] = SUPD[K1]*Z[K1];   (principal vector)
K1 := K
end;
```

(Here we use the fact that the diagonal elements may be different as in [2, eq. (4.2)]. To get chains of the nilpotent B, EV[K] should be replaced by EV[L].)

In Table II we list the values of NDEL, NDEFL, NXT, NDB, and SUPD for the first test matrix in [2, Section 5].

5. Comments on the Fortran Code

Since we use the EISPACK routines CBAL, COMHES, COMLR2, and CBABK2 [5], we have their representation of complex arrays, i.e., the real parts are represented in one array with the name ending in R (e.g., HR, ZR) and the imaginary parts are represented in one array with the name ending in I (e.g., HI, ZI). This representation makes it possible to execute most of the computations in real arithmetic.

We use real arithmetic in all steps of the algorithm except Steps 4 and 7, i.e., the elimination processes, where we use some complex arithmetic.

Table II. Example of Output of Index Vectors

I	NDEL	NDB	NDEFL	NXT	SUPD
1	0	1	1	3	1.9903
2	4	3	3	4	48.080
3	9	6	5	0	0
4	10	0	7	0	0
5	0	0	9	7	3.1314
6	0	0	10	8	5.5354
7	0	0	11	0	0
8	0	0	0	9	1.3994
9	0	0	0	0	0
10	0	0	0	0	0

Note. Output for the first test matrix in [2] is displayed.

Because of this complex arithmetic we also have to use the complex standard functions REAL(X), AIMAG(X), and CMPLX(X, Y).

If the actual Fortran compiler does not accept complex arithmetic, we can implement the functions CMUL, CDIV, CADD, and CSUB from [6] and substitute the actual statements with new statements.

A new parameter (NOBACK) has been added to the EISPACK routine COMLR2. We use this parameter (NOBACK = 0) as a control so that we do not get the eigenvectors from COMLR2. We get the transformations which transform the matrix to upper triangular form.

In the RDEFL routine we use complex arrays and arithmetic since the routine CSVD1 [1] is made for complex arithmetic.

6. Numerical Experiments

We have performed several numerical tests, both on matrices with a well-defined Jordan normal form, and on cases specially constructed in order to provide the routine with difficulties. Results from full Jordan normal form reduction are reported and discussed in [2]. In [2, Section 4] we describe how to choose tolerance parameters in the grouping procedure and in the procedure for determining the structures inside the invariant subspaces corresponding to different numerical multiple eigenvalues. We also describe how to analyze the results from the program, given a combination of the tolerance parameters.

A large number of results from block diagonal reductions (ISTEP = 5 and 6) are reported and discussed in [3].

Key Words and Phrases: heap, table maintenance
CR Categories: 3.74, 5.31
Language: Fortran

DESCRIPTION

1. Introduction

In many computational problems one has a collection of entities whose time history is being studied. The calculation proceeds by creating, destroying, and generally processing these entities, henceforth called nodes. Often the node to be processed is that one which is "most important" in some problem-dependent sense. Examples of such calculations occur in particle following for accelerator problems and adaptive quadrature, to name but two [3, 4, 6]. In such problems the time spent maintaining the nodes is significant, and it is important to implement this efficiently.

An organization of nodes based on "most important in, first out" (i.e., where every deletion removes the most important node) is called a priority queue [5]. The computer implementation of such queues can vary considerably. An unordered table of nodes is the simplest arrangement but requires an expensive search for the most important node. Maintaining an ordered table allows easy access to the most important node, but then insertions become slow. A "heap" [1] is a data structure that implements a priority queue in an efficient way, being equally fast for both insertions and deletions. Here we present a suite of Fortran programs of library quality for heaps. These programs are of modest length and can easily be included in other packages. Similar programs were used in [6] but they were not found to be general enough for library use.

In this paper we do not describe any of the detailed properties of heaps since these have been well documented [1, 7]. Rather we give only enough information about them so that the use of the programs can be quickly understood. The last section contains two simple examples.

In our implementation the work required to form the heap from N given nodes is $O(N)$, and the work required either to remove the most important and update or to insert and update is $O(\log_2 N)$. This data structure is appropriate if the current most important node might be processed and destroyed before other

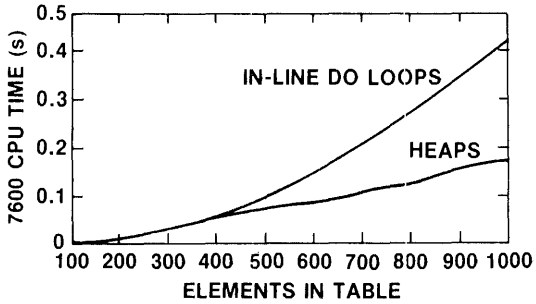

Fig. 1. Example of table management with heaps versus in-line DO loops.

nodes are created; the data structure is less appropriate if all the nodes are created before any are processed and destroyed.

The advantages of the programs presented in this paper over more familiar searching techniques are illustrated in Figure 1. Here we compare calls to the heap subroutines with in-line DO loops for the management of variously sized tables. This computation was selected to maximize the advantage of the in-line programming. (Specifically, example 1 of Section 3 was reprogrammed to use a DO loop at each stage to find the maximum element in an unordered table.) More typical problems should produce even more favorable time comparisons. For example, the production program MARLOWE, available from the Argonne Code Center, can have its execution time reduced 95 percent by using heaps instead of linear searches.

2. Using the Programs

We take a node to be one or more consecutive words of computer memory, with the data in these words defining the node. To investigate particle interactions (e.g., in an accelerator beam), each node could represent one particle, the nodal fields being position in phase space, energy, etc. For adaptive quadrature a node represents a portion of the region of integration; the fields in the node give the physical description of the region as well as local quadrature and error estimates. The most important node could be associated with the particle of largest energy or, for quadrature, the subregion with largest or smallest error, error per unit volume, that region nearest the origin, etc. To implement this variety, we require a Boolean function, HPFUN, on the nodes. Given two nodes A and B, this function returns .TRUE. if node A is "more important" than node B. The most important node is called TOP (i.e., it is the one for which HPFUN (TOP, X) = .TRUE. for any other node X).

Operations that can be performed on the heap, corresponding subroutines, and calling sequence parameters are shown in Table I. We also show (for completeness) the form of the Boolean HPFUN as well as an internally used subroutine HPGRO. A description of the parameters is given later.

The usual sequence of calls begins with HPINIT, perhaps followed by HPBLD. The main calculations usually require numerous calls to HPINS, HPACC, and HPDEL in various orders and combinations.

The package stores nodes into and removes them from a scratch area (DATA) provided by the user. The function HPFUN is an argument to the subroutines and thus may be changed from run to run or even during a single run. The latter situation might be useful during a calculation in which too many nodes are being generated.

The subroutine parameters are as follows:

NMAX Maximum number of nodes permitted, set by user.
NWDS Number of words per node, set by user.
DATA Real work array, at least NMAX * NWDS words, dimensioned by the user for node storage.

Table I. Heap Functions, Subroutines, and Calling Sequence Parameters

Function	Subroutine	Calling sequence parameters
Initialize package at start of each calculation	HPINIT	NMAX, N, T
Build a heap	HPBLD	NMAX, NWDS, DATA, N, T, HPFUN
Insert a node	HPINS	NMAX, NWDS, DATA, N, T, XNODE, HPFUN
Delete top node	HPDEL	NMAX, NWDS, DATA, N, T, HPFUN
Access a node (K = 1 gives top)	HPACC	NMAX, NWDS, DATA, N, T, XNODE, K
Determine the "more important" of two given nodes	HPFUN[a]	A, B, NWDS
Internally used subroutine	HPGRO	NMAX, NWDS, DATA, N, T, HPFUN, I

[a] Generic name—user may supply his own, but name must be EXTERNALed.

N Current number of nodes in the heap, set by the package.

T Integer work array dimensioned at least NMAX by the user, defined and used internally as a pointer.

XNODE Real array of NWDS words dimensioned by the user and used to store a single node. Thus to insert a node via HPINS, the user forms XNODE, i.e., defines its NWDS words and calls HPINS to copy these into the heap. To access a node with HPACC, the package copies the nodal data into XNODE (see examples).

HPFUN Name of a logical function with two real parameters and one integer parameter, of the form

```
LOGICAL FUNCTION HPFUN (A, B, NWDS)
INTEGER NWDS
REAL A(NWDS), B(NWDS)
```

The name of this function must be included in an EXTERNAL statement in the user calling program. When this function is called by the package, the arguments A and B will be two different nodes. The package provides two Boolean functions, LESS and GREATR, defined by

```
LESS = A(1) .LT. B(1)
GREATR = A(1) .GT. B(1)
```

These functions may be used when the characteristic on which the heap is organized appears in the first word of each node. The LESS and GREATR functions make the TOP smallest or largest, respectively. If the user wants more complicated functions, he must write them himself. For example, to select the node that is closest to the origin in the sense of the sum of squares of components, we can write

```
      LOGICAL FUNCTION L2 (A, B, NWDS)
      INTEGER NWDS, I
      REAL A (NWDS), B (NWDS), DA, DB
      DA = 0.0
      DB = 0.0
      DO 1 I = 1, NWDS
    1   DA = DA + A (I)**2
        DB = DB + B (I)**2
      L2 = DA .LT. DB
      RETURN
      END
```

K (In SUBROUTINE HPACC) the index of the node to be accessed; set by user. K = 1 corresponds to the TOP, and K must be in the range $1 \leq K \leq N \leq NMAX$. (Since the heap is only partially ordered, there is no way to predict the node produced by using this subroutine with $K > 1$. It is allowed as a convenience to those users who may wish to examine all the nodes without altering the heap structure.)

Note. If subroutines in the package are called with incorrect arguments, e.g., N > NMAX, the programs return without performing any calculations. No error diagnostics are given.

Operation Counts. The initialization program HPINIT and the infrequently used HPBLD require $O(N)$ operations. Inserting or deleting a node, HPINS or HPDEL, requires $O(\log_2 N)$ operations; accessing a node with HPACC requires $O(1)$ operations and has no effect upon the heap.

3. Examples of Use

Our first example is trivial. It has no application except to illustrate the use of the package. Nevertheless it forms the framework for the second example, adaptive quadrature, an important algorithm.

Example 1. A Simple Example of Heap Subroutines

A node is a single real number, between 0 and 1, generated at random. The TOP node in the heap is that one with largest numerical value. The calculation is as follows. Start with an initial node. While the number of nodes is less than 1000, print the value of the TOP node, remove it from the heap, and replace it by two others also selected at random. The complete Fortran program is as follows:

```
      REAL DATA (1000), XNODE
      INTEGER T(1000)
      EXTERNAL GREATR
      LOGICAL GREATR
C
      NMAX = 1000
      CALL HPINIT (NMAX, N, T)
      XNODE = RANNUM (0.)
      CALL HPINS (NMAX, 1, DATA, N, T, XNODE, GREATR)
C
    1 IF (N .GE. NMAX) STOP
        CALL HPACC (NMAX, 1, DATA, N, T, XNODE, 1)
        WRITE (6,100) XNODE
        CALL HPDEL (NMAX, 1, DATA, N, T, GREATR)
        XNODE = RANNUM (0.)
        CALL HPINS (NMAX, 1, DATA, N, T, XNODE, GREATR)
        XNODE = RANNUM (0.)
        CALL HPINS (NMAX, 1, DATA, N, T, XNODE, GREATR)
        GO TO 1
  100 FORMAT (E16.8)
      END
```

Example 2. Global Adaptive Quadrature

We start with an initial interval, a user-provided subroutine for evaluating the integrand, and $\epsilon > 0$. The algorithm generates subintervals by bisection and produces an integral estimate and error estimate for each. The subinterval subdivided next is that one having largest error estimate. The algorithm terminates where the sum of subinterval error estimates is less than ϵ. This is the prototype algorithm on which heaps were successfully used in [6]. A node is a real four-word array corresponding to an interval and has the form

$NODE_1$ = error estimate ≥ 0
$NODE_2$ = integral estimate

$NODE_3$ = left endpoint
$NODE_4$ = right endpoint

The heap is organized so that the TOP is the node with the largest error estimate. Thus the function GREATR provided in the package is used.

The main user subroutine is AGQ. Auxiliary calculations use the user-written programs:

QINIT	Initializes the first interval to a node.
QSDVD	Produces two half-interval nodes from each full interval.
QUAD	Provides integral estimate and error estimate for the user function on a given node.

In our sample program integral/error estimates are calculated by 2- and 3-point Gauss quadrature. This is, however, independent of any other aspect of the algorithm, and readers may substitute Newton–Cotes, Kronrod, etc. Our program has not taken advantage of the fact that for this problem a deletion is always followed by an insertion; the gain by doing this is very small. Furthermore the favorable timings of the heap programs relative to a simple list only appear after about 100 nodes, a situation which does not occur for the two problems in the example. On the other hand, for automatic integrators small gains in efficiency are not a major issue for problems generating such a small number of nodes. This same simple program organization can be used, however, for multidimensional adaptive quadrature after obvious changes in the definition and storage requirements for a node. For these problems large numbers of nodes can easily be generated. The program of Example 2 is a prototype of the library software that is now being developed in this area. For more complex applications of these ideas see [2] and [4].

ALGORITHM 562
Shortest Path Lengths [H]

U. PAPE
Technische Universität Berlin

Key Words and Phrases: shortest path, shortest route problem
CR Categories: 5.32
Language: Fortran IV

DESCRIPTION

This algorithm finds the shortest path lengths from a specific node to all other nodes in a network. It is a modification of Moore's algorithm [4], originally due to d'Esopo as reported by Pollack and Wiebenson [7] and refined by Pape [5, 6]. The algorithm does not determine the shortest paths. If a shortest path is to be determined, this algorithm may be combined with any algorithm that traces the shortest path from the root node to any other node from the list of predecessors of nodes. As the calculation of the path lengths is the most time-consuming part of the whole process, we confine our attention to this problem.

The main idea of the given algorithm centers around the "status" of a newfound successor node j. If j has not yet been reached by the process, it is entered at the end of the successor list; if it is currently in the list, no new entry is made, but if it has already been processed and removed from the list, it is entered at the top of the list so that it will be processed next. The current status of each node is recorded by the values of the list which are stored as linked deque (double-ended queue). The steps involved are as follows:

```
top element of the deque := j;
mj := ∞; mj_j := 0;
while deque ≠ ∅ do
begin i := top element of the deque;
  remove top element;
  for all successors k of i do
  begin mjk := mj_i + d_ik
    if mjk < mj_k then
    begin mj_k := mjk; wj_k := i;
      if k has not yet been reached then enter k at the end of the deque;
      if k has already been processed then enter k at the top of the deque
    end
  end
end;
```

The great advantage of the above-mentioned technique is that errors in minimal distances are often corrected as soon as they are detected and not

Received 15 May 1976; revised 17 December 1979; accepted 26 February 1980.

allowed to progress further. In practice this leads to a considerable reduction in CPU time, particularly for grid networks.

The additional bookkeeping work required costs less than the savings from the early processing of the nodes. This follows from a comparison of this technique with a more obvious strategy, where the deque is handled as a FIFO list (see [6]).

The network N is represented by its forward star structure (see [3]) which is also used as input to the subroutine. This input consists of three arrays: the array KF, containing information about where the data for each node begin in the other two arrays; the array FList, containing the numbers of the nodes which can be reached directly from each node; and the integer array DFList, containing the distances to each of these nodes.

The algorithm has been coded and tested in Algol 60, Algol-W, and Fortran IV for an IBM 370/158 (Berlin), an ICL 1907 (Braunschweig), and a CDC 6600 (Austin). It has been tested on different networks, real transportation/road networks and random road networks, constructed by network generators developed at Berlin and Austin. Independently, a variant of this algorithm has been tested at the Institute for Transportation Studies at the University of Leeds [8]. It has been compared with several versions of Dijkstra's algorithm [2] (with different binary tree structures for the nodes to be discussed), particularly Dial's algorithm [1]. The investigations have shown that the algorithm, based on d'Esopo's idea, is generally the most efficient in terms of CPU times (and core storage) for a large variety of networks. The code is highly insensitive to the magnitude of the distance measures.

ALGORITHM 563
A Program for Linearly Constrained Discrete l_1 Problems

RICHARD H. BARTELS and ANDREW R. CONN
The University of Waterloo

Key Words and Phrases: numerical analysis, overdetermined linear systems, linear constraints, discrete l_1 approximation
CR Categories: 5.13, 5.41
Language: Fortran

DESCRIPTION

The subroutine CL1 given here is a complement of [1], where the theoretical development appears.

Editor's Note

Owing to the increasing length of algorithms accepted for publication in ACM Transactions, it has become impractical to supply lengths of individual procedures. Instead, lengths of entire algorithms are given on the Algorithms order form.

ALGORITHM 564
A Test Problem Generator for Discrete Linear L_1 Approximation Problems

K.L. HOFFMAN and D.R. SHIER
National Bureau of Standards

Key Words and Phrases: L_1 approximation, least absolute deviation, problem generator, test data
CR Categories: 5.13, 5.41, 5.5
Language: Fortran

DESCRIPTION

The algorithm given here is a complement to [1], where its theoretical development and implementation are described.

ALGORITHM 565 PDETWO/PSETM/GEARB: Solution of Systems of Two-Dimensional Nonlinear Partial Differential Equations [D3]

DAVID K. MELGAARD
Kansas State University
and
RICHARD F. SINCOVEC
Boeing Computer Services Company

Key Words and Phrases: partial differential equations, method of lines, finite differences, ordinary differential equations
CR Categories: 5.17
Language: FORTRAN

DESCRIPTION

The algorithm presented here combines PDETWO, PSETM[1], and a modified version of GEARB[2] to form a complete partial differential equations package for systems of time-dependent nonlinear partial differential equations defined over a two-dimensional rectangular region. The descriptions of PDETWO and PSETM, test results, references, and the use of this algorithm are contained in the authors' paper [2]. The ordinary differential equations package, GEARB, is described by Hindmarsh [1], so we only comment on those modifications that we made to GEARB for this algorithm. The principal modification is the addition of a new subroutine to set pointers for dynamic dimensioning of arrays and to check the validity of some of the user input parameters. The interpolation routine in GEARB was also modified so that it would return correctly interpolated solution values at the user-specified output time for time-dependent boundary conditions.

Machine-readable documentation within the package serves as a complete user's guide. The comments in subroutine PDETWO give the essential details on the use of this package, including descriptions of the user-required subroutines. Additional user information is contained in subroutine DRIVEP, the driver routine for the package.

C
C***********************************************************************
C
C       PDETWO IS AN INTERFACE DESIGNED TO SOLVE A SYSTEM OF SECOND
C  ORDER TIME DEPENDENT PARTIAL DIFFERENTIAL EQUATIONS (PDE*S)
C  DEFINED OVER A RECTANGLE IN CONJUNCTION WITH AN ORDINARY
C  DIFFERENTIAL EQUATION (ODE) INTEGRATOR PACKAGE (PRIMARILY A MODI-
C  FIED VERSION OF GEARB(1)).  IT IS AN EXTENSION OF PDEONE (2,3), AN
C  INTERFACE DEVELOPED FOR THE SOLUTION OF ONE-DIMENSIONAL SYSTEMS OF
C  PDE*S.  THIS EXTENSION CONSISTS OF CHANGING FROM THREE POINT
C  DIFFERENCING TO FIVE POINT DIFFERENCING IN ORDER TO APPROXIMATE
C  THE SPATIAL DERIVATIVES IN THE TWO DIMENSIONAL PDE SYSTEM.  TO
C  SOLVE A PDE SYSTEM USING THIS SOFTWARE INTERFACE IN CONJUNCTION
C  WITH AN ODE INTEGRATOR, THE USER IS REQUIRED ONLY TO PROVIDE
C  THE SPATIAL MESH AND DEFINE THE PROBLEM TO BE EVALUATED.  THE
C  INTERFACE WILL THEN FORM AND EVALUATE A SEMIDISCRETE APPROXI-
C  MATION OF THIS SYSTEM OF PDE*S AND THUS PERMIT ONE TO SOLVE
C  THE ORIGINAL PDE SYSTEM AS A SYSTEM OF TIME DEPENDENT ODE*S
C  USING AN ODE INTEGRATOR.
C
C       TO CREATE A DOUBLE PRECISION VERSION OF PDETWO..
C  CHANGE THE REAL STATEMENT BELOW.
C
C***********************************************************************
C  PROBLEM DEFINITION
C***********************************************************************
C
C       PDETWO IS DESIGNED TO BE USED TO SOLVE A COUPLED SYSTEM OF
C  NPDE PDE*S.  THE L-TH PDE OF THIS SYSTEM IS OF THE FORM ..
C
C     DUDT(L) = F (T, X, Y, U, UX, UY, DUXX, DUYY )
C
C  WHERE
C
C       DUDT(L) REPRESENTS THE FIRST PARTIAL OF THE L-TH COMPONENT
C               OF U WITH RESPECT TO T,
C       T       IS THE CURRENT TIME,
C       X,Y     DEFINE THE POSITION IN THE HORIZONTAL AND VERTICAL
C               DIRECTIONS RESPECTIVELY,
C
C       U    =  (  U(1), ... ,  U(NPDE) ),
C       UX   =  ( UX(1), ... , UX(NPDE) ),
C       UY   =  ( UY(1), ... , UY(NPDE) ),
C
C       DUXX    IS AN NPDE BY NPDE ARRAY SUCH THAT
C                          D
C               DUXX(L,K) = -- (DH(L,K)*UX(K)),
C                          DX
C               THE L-TH ROW OF DUXX CORRESPONDS TO THE L-TH PDE,
C
C       DUYY    IS AN NPDE BY NPDE ARRAY SUCH THAT
C                          D
C               DUYY(L,K) = -- (DV(L,K)*UY(K)),
C                          DY
C               THE L-TH ROW OF DUYY CORRESPONDS TO THE L-TH PDE,
.
C
```

```
C  AND
C
C       U(K)     IS THE VALUE OF THE SOLUTION FOR THE K-TH PDE AT
C                (T, X, Y),
C       UX(K)    IS THE FIRST PARTIAL DERIVATIVE OF U(K) WITH RESPECT
C                TO X,
C       UY(K)    IS THE FIRST PARTIAL DERIVATIVE OF U(K) WITH RESPECT
C                TO Y,
C       DH(L,K) IS THE DIFFUSION COEFFICIENT IN THE HORIZONTAL
C                DIRECTION FOR THE L-TH PDE ASSOCIATED WITH U(K),
C       DV(L,K) IS THE DIFFUSION COEFFICIENT IN THE VERTICAL
C                DIRECTION FOR THE L-TH PDE ASSOCIATED WITH U(K).
C
C       DH(L,K) AND DV(L,K) MAY BE FUNCTIONS OF T, X, Y AND U.
C
C  HORIZONTAL BOUNDARY CONDITIONS
C
C     AH(L)*U(L) + BH(L)*UY(L) = CH(L)
C
C  VERTICAL BOUNDARY CONDITIONS
C
C     AV(L)*U(L) + BV(L)*UX(L) = CV(L)
C
C       AH(L), BH(L) AND CH(L) (AV(L), BV(L) AND CV(L)) ARE AT LEAST
C     PIECEWISE CONTINUOUS FUNCTIONS OF THEIR RESPECTIVE VARIABLES.
C     IF BH(L) .NE. Ø (BV(L) .NE. Ø) THEN AH(L), BH(L) AND CH(L)
C     (AV(L), BV(L) AND CV(L)) MAY BE FUNCTIONS OF T, X, Y AND U
C     BUT OTHERWISE THEY MAY ONLY BE FUNCTIONS OF T, X AND Y. NULL
C     BOUNDARY CONDITIONS ARE NOT ALLOWED SINCE PDETWO WAS NOT
C     DESIGNED TO SOLVE HYPERBOLIC PDE*S. A ZERO DIVIDE WILL OCCUR
C     IF A NULL BOUNDARY CONDITION IS SPECIFIED.
C
C  INITIAL CONDITIONS
C
C       THE INITIAL SOLUTION IS DEFINED FOR EACH U(K) TO BE A
C     KNOWN FUNCTION OF X AND Y FOR THE INITIAL TIME T = TØ.
C     THE INITIAL CONDITIONS NEED NOT BE CONSISTENT WITH THE
C     BOUNDARY CONDITIONS AND MAY CONTAIN DISCONTINUITIES.
C
C*************************************************************************
C  USER SUPPLIED ROUTINES
C*************************************************************************
C
C       THE USER MUST PROVIDE A MAIN PROGRAM AND FIVE SUBROUTINES
C  BNDRYH, BNDRYV, DIFFV, DIFFH AND F.  THESE ROUTINES ARE ALL THAT
C  IS REQUIRED TO DEFINE COMPLETELY THE PROBLEM GIVEN ABOVE.
C
C  1)     THE MAIN PROGRAM DEFINES THE SPATIAL MESH, THE INITIAL
C     CONDITIONS AND THE PARAMETERS FOR THE ODE INTEGRATOR, CALLS
C     THE INTEGRATOR AND PRINTS OR PLOTS THE RESULTS.  THE MAIN
C     PROGRAM SHOULD BE CONSTRUCTED AS FOLLOWS ..
C
C     DIMENSION U(***,*,**),X(*),Y(**)
C     DIMENSION WORK(*****),IWORK(****)
C
C         FOR THE DIMENSIONS ABOVE ENTER THE ACTUAL NUMERICAL
C       VALUES FOR * = NX, ** = NY, *** = NPDE , **** = NODE, AND
C       ***** = NPDE * ( NPDE*(NX*2+3) + 13 + NX ) + NX*4 + 4*NODE
C       + LPW + LU
C       WHERE
C           NODE = NPDE*NX*NY
C           LPW  = 1                          IF MITER = Ø
C                = (3*(NX+1)*NPDE-2)*NODE     IF MITER = 1,2
C                = NODE                       IF MITER = 3
C           LU   = NODE*(MORDER+1)
C        SEE MF AND MORDER BELOW FOR THE DEFINITION OF MITER AND
C        MORDER.
C
C        DEFINE ..
C
C        1) THE NUMBER OF MESH POINTS IN THE X (HORIZONTAL) DIRECTION,
C           NX .GE. 3 AND THE NUMBER OF MESH POINTS IN THE Y (VERTICAL)
C           DIRECTION, NY .GE. 3  ( TO CONSERVE STORAGE ORIENT THE
C           PROBLEM SO THAT NX .LE. NY ),
C        2) THE MESH POINTS (I.E. X(1) .LT. X(2) .LT. ... .LT. X(NX)
```

```
C          AND Y(1) .LT. Y(2) .LT. ... .LT. Y(NY)),
C       3) NPDE, THE NUMBER OF PARTIAL DIFFERENTIAL EQUATIONS,
C       4) INITIAL VALUES FOR ALL OF U,
C       5) MORDER, THE MAXIMUM ORDER OF THE METHOD USED IN THE
C          MODIFIED GEARB.  MORDER MUST BE LESS THAN OR EQUAL TO 12
C          IF METH = 1 OR IF METH = 2, IT MUST BE LESS THAN OR EQUAL
C          TO 5.  SEE MF BELOW FOR THE DEFINITION OF METH.
C       6) THE PARAMETERS FOR THE CALL TO THE INTEGRATOR, AND
C       7) THE FIRST SIX LOCATIONS OF THE ARRAY IWORK AS FOLLOWS.
C          IWORK(1) = NPDE
C          IWORK(2) = NX
C          IWORK(3) = NY
C          IWORK(4) = MORDER
C          IWORK(5) = NRWK
C          IWORK(6) = NRIWK
C          WHERE NRWK AND NRIWK ARE THE LENGTHS OF THE ARRAYS WORK
C          AND IWORK RESPECTIVELY.  THEY SHOULD BE AT LEAST EQUAL
C          TO ***** AND **** AS DEFINED IN THE DESCRIPTION OF THE
C          DIMENSIONS.
C
C         IN DETERMINING THE MESH SPACING, THE USER SHOULD BE AWARE
C       THAT THE DIFFERENCE APPROXIMATIONS AT THE INTERIOR POINTS
C       ARE SECOND ORDER ONLY FOR UNIFORM MESHES.  FOR NONUNIFORM
C       MESHES, ONLY FIRST ORDER APPROXIMATIONS SHOULD BE EXPECTED.
C       IN UNUSUAL SITUATIONS (SEE REMARK IN SECTION 3 OF THE
C       ACCOMPANYING PAPER) INVOLVING COUPLED SYSTEMS OF EQUATIONS,
C       CERTAIN APPROXIMATIONS AT THE BOUNDARY ARE ONLY FIRST ORDER.
C       IN THESE UNUSUAL SITUATIONS THE ERROR CAN BE MINIMIZED BY
C       CHOOSING SMALL MESH SPACINGS NEXT TO THE BOUNDARY.  IN ANY
C       CASE THE USER IS ADVISED TO CHOOSE A MESH WHICH IS LOCALLY
C       NEARLY UNIFORM.
C
C         FOR THE MODIFIED GEARB THE PARAMETERS INCLUDE THE DESIRED
C       OUTPUT TIME (TOUT), THE DESIRED LOCAL ACCURACY (EPS), THE
C       NUMBER OF ODE*S (NODE = NPDE*NX*NY), THE INITIAL TIME (TØ),
C       THE INITIAL TIME STEP SIZE (H),THE TYPE OF CALL BEING MADE
C       (INDEX) AND THE TYPE OF INTEGRATION METHOD DESIRED (MF).
C       MF HAS TWO DECIMAL DIGITS, METH AND MITER (MF = 1Ø*METH +
C       MITER).  METH IS THE BASIC METHOD INDICATOR..
C         METH  = 1 MEANS THE ADAMS METHODS.
C         METH  = 2 MEANS THE BACKWARD DIFFERENTIATION FORMULAS
C                   (BDF), OR STIFF METHODS OF GEAR.
C       MITER IS THE ITERATION METHOD INDICATOR..
C         MITER = Ø MEANS FUNCTIONAL ITERATION (NO PARTIAL
C                   DERIVATIVES NEEDED).
C         MITER = 1 MEANS THE CHORD METHOD WITH AN ANALYTIC
C                   JACOBIAN SUPPLIED IN THE USER DEFINED
C                   ROUTINE PDB.  THIS METHOD IS IN GEARB,
C                   BUT IT SHOULD BE AVOIDED.
C         MITER = 2 MEANS THE CHORD METHOD WITH THE JACO-
C                   BIAN CALCULATED IN PSETM.  THIS IS THE
C                   ONLY METHOD WHERE PSETM IS USEFUL.
C         MITER = 3 MEANS THE CHORD METHOD WITH THE JACO-
C                   BIAN REPLACED BY A DIAGONAL APPROXI-
C                   MATION BASED ON A DIRECTIONAL DERIV-
C                   ATIVE.  THIS METHOD IS IN GEARB, BUT
C                   IS NOT GENERALLY USEFUL IN SOLVING PDE*S.
C       SEE COMMENTS IN DRIVEP FOR ADDITIONAL INFORMATION ON THESE
C       PARAMETERS.  NATURALLY THESE PARAMETERS ARE DEPENDENT ON THE
C       INTEGRATOR BEING USED.  FINALLY THE USER SHOULD CALL THE
C       INTEGRATOR.
C
C     CALL DRIVEP (NODE,TØ,H,U,TOUT,EPS,MF,INDEX,WORK,IWORK,X,Y)
C
C       THE INTEGRATOR WILL RETURN THE SOLUTIONS (U) AT T = TOUT
C       TO THE MAIN PROGRAM TO BE PRINTED OR PLOTTED.  IF A CONTINUA-
C       TION TO ANOTHER TOUT IS DESIRED, SIMPLY RESET TOUT AND CALL
C       DRIVEP AGAIN.
C
C     STOP
C     END
```

```
C
C  2)     THE BOUNDARY SUBROUTINES, BNDRYH AND BNDRYV PROVIDE
C     PDETWO WITH THE COEFFICIENTS FOR THE HORIZONTAL AND
C     VERTICAL BOUNDARY CONDITIONS RESPECTIVELY.  THE CONSTRUCTION
C     OF BNDRYV IS ANALOGOUS TO THE CONSTRUCTION OF BNDRYH.  THE
C     USER SHOULD CONSTRUCT BNDRYH AS FOLLOWS ..
C
C     SUBROUTINE BNDRYH (T,X,Y,U,AH,BH,CH,NPDE)
C     DIMENSION U(NPDE), AH(NPDE), BH(NPDE), CH(NPDE)
C
C        THE INCOMING PARAMETERS X AND Y REPRESENT ANY POINT
C       OF X(J) (J = 1,2,...,NX) AND EITHER Y(1) OR Y(NY) RESPECTIVELY.
C       DEFINE THE FUNCTIONS AH(K), BH(K) AND CH(K) (K = 1,2,...,NPDE)
C       FOR THE LOWER (Y=Y(1)) AND UPPER (Y=Y(NY)) BOUNDARIES. NULL
C       BOUNDARY CONDITIONS ARE NOT ALLOWED AND IF SPECIFIED WILL
C       RESULT IN A ZERO DIVIDE.
C
C         TO INSURE A COMPLETELY ACCURATE DEFINITION OF THE BOUNDARY
C       CONDITIONS AT THE CORNER MESH POINTS, THE USER SHOULD
C       CONSULT THE APPROPRIATE DIFFERENCE APPROXIMATIONS (SEE
C       SECTION 3 OF THE ACCOMPANYING PAPER).
C
C     RETURN
C     END
C
C  3)     DIFFH AND DIFFV DEFINE FOR PDETWO THE HORIZONTAL AND VERTICAL
C     DIFFUSION COEFFICIENTS RESPECTIVELY.  THE CONSTRUCTION OF
C     DIFFV IS ANALOGOUS TO THE CONSTRUCTION OF DIFFH.  THE
C     USER SHOULD CONSTRUCT DIFFH AS FOLLOWS ..
C
C     SUBROUTINE DIFFH (T,X,Y,U,DH,NPDE)
C     DIMENSION U(NPDE),DH(NPDE,NPDE)
C
C        IN THIS ROUTINE DEFINE THE DH(L,K) COEFFICIENTS (L,K =
C       1,2,...,NPDE).  THE INCOMING PARAMTERS X AND Y DENOTE EITHER
C       A BOUNDARY POINT OR A MESH MIDPOINT.
C
C     RETURN
C     END
C
C  4)     THE RIGHT HAND SIDE OF THE PDE IS DEFINED FOR PDETWO IN
C     THE SUBROUTINE F.  THIS ROUTINE IS CONSTRUCTED AS FOLLOWS..
C
C     SUBROUTINE F (T,X,Y,U,UX,UY,DUXX,DUYY,DUDT,NPDE)
C     DIMENSION U(NPDE), UX(NPDE), UY(NPDE), DUXX(NPDE,NPDE),
C    * DUYY(NPDE,NPDE), DUDT(NPDE)
C
C        IN THIS ROUTINE, THE INCOMING VALUES X AND Y REPRESENT
C       THE MESH POINT BEING EVALUATED AND UX, UY, DUXX AND DUYY
C       ARE THE VALUES DENOTED IN THE PROBLEM DEFINITION ABOVE.
C       USING THESE VALUES, DEFINE IN DUDT(L) (L = 1,2,...,NPDE)
C       THE RIGHT HAND SIDE OF THE PDE*S.
C
C     RETURN
C     END
C
C*************************************************************************
C  THE INPUT PARAMETERS
C*************************************************************************
C
C  NPDE         IS THE NUMBER OF PARTIAL DIFFERENTIAL EQUATIONS.
C  NX           IS THE NUMBER OF MESH POINTS IN THE HORIZONTAL
C               DIRECTION.
C  NY           IS THE NUMBER OF MESH POINTS IN THE VERTICAL
C               DIRECTION.
C  X            ARE THE MESH POINTS IN THE HORIZONTAL DIRECTION.
C  Y            ARE THE MESH POINTS IN THE VERTICAL DIRECTION.
C  T            IS THE CURRENT TIME.
C  U            CONTAINS THE CURRENT SOLUTION VALUES FOR ALL THE
C               MESH POINTS.
```

```
C  DVS           SAVES THE VERTICAL DIFFUSION COEFFICIENTS FOR
C                FUTURE EVALUATIONS.
C  DVST          SAVES THE VERTICAL DIFFUSION COEFFICIENTS FOR THE
C                FUTURE EVALUATIONS OF THE TOP ROW OF MESH POINTS.
C  DH            RETURNS FROM DIFFH THE HORIZONTAL DIFFUSION COEFFI-
C                CIENTS AND CONTAINS DUXX, THE APPROXIMATIONS TO THE
C                HORIZONTAL DIVERGENCE TERMS, ON CALLS TO F AND STORES
C                THE PREVIOUS VALUE OF DUXX.
C  DV            RETURNS FROM DIFFV THE VERTICAL DIFFUSION COEFFI-
C                CIENTS AND CONTAINS DUYY, THE APPROXIMATIONS TO THE
C                VERTICAL DIVERGENCE TERMS, ON CALLS TO F.
C  AH, BH, CH    CONTAIN THE HORIZONTAL BOUNDARY COEFFICIENTS
C                PASSED TO PDETWO FROM BNDRYH.
C  AV, BV, CV    CONTAIN THE VERTICAL BOUNDARY COEFFICIENTS
C                PASSED TO PDETWO FROM BNDRYV.
C  UX,UY         STORE THE DIFFERENCE APPROXIMATIONS FOR THE FIRST
C                PARTIAL OF U WITH RESPECT TO X AND Y RESPECTIVELY.
C  DXI,DXIR,
C    DXIC        STORE INFORMATION ABOUT THE HORIZONTAL MESH SPACING.
C  XAVG          STORES INFORMATION ABOUT THE AVERAGE BETWEEN TWO MESH
C                POINTS ON THE HORIZONTAL AXIS.
C  UDVA,UDVB,
C    UDHR,UDHL   STORE INFORMATION FOR APPROXIMATING DUXX AND DUYY.
C  UAVGH,UAVGV   CONTAIN U AVERAGES FOR APPROXIMATING THE DIFFUSION
                 COEFFICIENTS AT THE MESH MID-POINTS.
C
C*********************************************************************
C  THE OUTPUT PARAMETERS
C*********************************************************************
C
C  U             CONTAINS SOLUTIONS UPDATED TO TIME T FOR THE
C                BOUNDARY MESH POINTS DEFINED BY DIRICHLET BOUNDARY
C                CONDITIONS.
C  DUDT          IS THE RIGHT HAND SIDE OF THE SYSTEM OF ODE*S PASSED
C                TO THE INTEGRATOR.  THESE VALUES ARE CALCULATED
C                FROM THE CENTERED DIFFERENCE APPROXIMATIONS OF
C                THE SPATIAL VARIABLES.
C
C*********************************************************************

C             SOLUTIONS OF SYSTEMS OF PARTIAL DIFFERENTIAL EQUATIONS,
C             ACM TRANSACTIONS ON MATHEMATICAL SOFTWARE, SEPT.
C             1975, PP. 262-263.
C
C*********************************************************************
      SUBROUTINE PSETM (NPDE,NX,NY,X,Y,U,UMAX,USAVE,DUDTR,DUDT,PW,CON,
     *                  MITER,IER,NEBAND,WORK,IWORK)
C
C*********************************************************************
C
C       PSETM IS INTENDED TO BE USED IN CONJUNCTION WITH THE
C  INTERFACE PDETWO FOR THE SOLUTION OF SECOND ORDER TIME DEP-
C  ENDENT PARTIAL DIFFERENTIAL EQUATIONS (PDE*S) DEFINED OVER A
C  RECTANGULAR REGION.  PSETM IS SPECIFICALLY DESIGNED TO REPLACE
C  THE ROUTINE PSETB USED IN THE ORDINARY DIFFERENTIAL EQUATION
C  INTEGRATOR GEARB (1) IN ORDER TO MINIMIZE THE COMPUTATIONS
C  REQUIRED TO GENERATE THE JACOBIAN MATRIX.
C
```

```
C       PSETM IS CALLED BY STIFFP, A ROUTINE IN THE MODIFIED GEARB,
C  WHEN THE INTEGRATION METHOD (MITER=1 OR 2) REQUIRES A JACOBIAN
C  MATRIX.  WHEN MITER=1, THE JACOBIAN IS DETERMINED BY A USER
C  DEFINED ROUTINE, PDB.  THIS METHOD SHOULD BE AVOIDED SINCE IT RE-
C  QUIRES THE USER TO COMPLETELY UNDERSTAND PDETWO.  IF THIS
C  METHOD IS USED, PSETM OFFERS NO ADVANTAGE OVER PSETB.  IF
C  MITER=2, THE JACOBIAN IS APPROXIMATED BY FINITE DIFFERENCES,
C  USING THE APPROXIMATION  J = (DUDT(U+R) - DUDT(U)) / R,
C  WHERE DUDT(U+R) AND DUDT(U) ARE THE VALUES OF THE RIGHT HAND
C  SIDE OF THE PDE*S EVALUATED AT U+R AND U RESPECTIVELY, AND R
C  IS SOME SMALL NUMBER.  PSETM TAKES ADVANTAGE OF THE STRUCTURE
C  OF THE JACOBIAN MATRIX REQUIRED BY PDETWO TO REDUCE THE COMPU-
C  TATIONS NEEDED TO GENERATE THE MATRIX (REQUIRING ONLY 5 * NPDE
C  CALLS TO PDETWO).  WITH EACH CALL TO PDETWO, PSETM DETERMINES
C
C  THE ENTRIES IN THE JACOBIAN FOR THE MESH POINTS IN THE FOLLOWING
C  PATTERN ..
C
C                  X 0 0 0 0 X 0 0 0 0
C                  0 0 0 X 0 0 0 0 X 0
C                  0 X 0 0 0 0 X 0 0 0
C                  0 0 0 0 X 0 0 0 0 X
C                  0 0 X 0 0 0 0 X 0 0
C                  X 0 0 0 0 X 0 0 0 0
C
C  WHERE X REPRESENTS THE POINTS FOR WHICH THE JACOBIAN IS
C  APPROXIMATED.  MITER=2 IS THE RECOMMENDED METHOD.
C
C       TO CREATE A DOUBLE PRECISION VERSION OF PSETM..
C  CHANGE THE REAL STATEMENT BELOW AND CHANGE THE SINGLE PRECISION
C  FUNCTIONS ABS, SQRT, AND AMAX1.
C
C***********************************************************************
C  THE  PARAMETERS
C***********************************************************************
C
C  NPDE          IS THE NUMBER OF PARTIAL DIFFERENTIAL EQUATIONS.
C  NX            IS THE NUMBER OF MESH POINTS IN THE HORIZONTAL
C                DIRECTION.
C  NY            IS THE NUMBER OF MESH POINTS IN THE VERTICAL
C                DIRECTION.
C  X             ARE THE MESH POINTS IN THE HORIZONTAL DIRECTION.
C  Y             ARE THE MESH POINTS IN THE VERTICAL DIRECTION.
C  U             CONTAINS THE CURRENT SOLUTIONS OF THE PARTIAL
C                DIFFERENTIAL EQUATIONS.
C  UMAX          IS THE MAXIMUM U VALUES, WHICH ARE USED TO SCALE
C                THE VALUE IN R AND FOR ERROR CONTROL IN GEARB.
C  USAVE         IS A TEMPORY STORE FOR U VALUES.
C  DUDTR         IS THE VALUE OF DUDT(U+R) RETURNED FROM PDETWO.
C  DUDT          IS THE VALUE OF DUDT(U), WHICH IS PASSED TO PSETM
C                FROM STIFFP.
C  PW            STORES THE APPROXIMATION FOR THE JACOBIAN.
C  CON           IS THE CONSTANT (-H*EL(1)).
C  MITER         INDICATES THE TYPE OF ITERATION METHOD BEING USED
C                BY THE INTEGRATOR.
C                MITER = Ø MEANS FUNCTIONAL ITERATION.
C                MITER = 1 MEANS THE CHORD METHOD WITH AN ANALYTIC
C                          JACOBIAN SUPPLIED IN THE USER DEFINED
C                          ROUTINE PDB.  THIS METHOD IS IN GEARB,
C                          BUT IT SHOULD BE AVOIDED.
C                MITER = 2 MEANS THE CHORD METHOD WITH THE JACO-
C                          BIAN CALCULATED IN PSETM.  THIS IS THE
C                          ONLY METHOD WHERE PSETM IS USEFUL.
C                MITER = 3 MEANS THE CHORD METHOD WITH THE JACO-
C                          BIAN REPLACED BY A DIAGONAL APPROXI-
C                          MATION BASED ON A DIRECTIONAL DERIV-
C                          ATIVE.  THIS METHOD IS IN GEARB, BUT
C                          IS NOT GENERALLY USEFUL IN SOLVING PDE*S.
C  IER           IS AN ERROR INDICATOR USED IN THE ROUTINE DECBR.
C  NEBAND        = 3 * ML + 1
```

```
C  WORK          PROVIDES WORKING STORAGE FOR DYNAMIC DIMENSIONING
C                OF THE ARRAYS IN PDETWO AND THE MODIFIED GEARB.
C  IWORK         IS THE PIVOT VECTOR USED IN THE LU DECOMPOSITION.
C
C***********************************************************************
C  THE VARIABLES
C***********************************************************************
C
C  R             IS A SMALL INCREMENT USED IN EVALUATING THE
C                FUNCTION NEAR THE CURRENT SOLUTION U ( I.E.
C                DUDT (U+R)).
C  RØ            IS A LOWER BOUND ON THE SIZE OF R.
C  D             IS A SMALL NUMBER USED TO APPROXIMATE THE
C                DERIVATIVE.
C  NXNPDE        = NX * NPDE
C
C  T             IS THE TIME BEING USED FOR THE INTEGRATION.
C  H             IS THE CURRENT TIME STEP SIZE BEING USED IN THE
C                INTEGRATION.
C  UROUND        IS THE UNIT ROUNDOFF OF THE MACHINE.
C  EPSJ          IS SQRT(UROUND).
C  ML            IS THE WIDTH OF THE LOWER (AND UPPER) HALF OF THE
C                BAND OF THE JACOBIAN.  ML = (NX + 1) * NPDE - 1.
C  IW1 - IW27    ARE THE SUBSCRIPT POINTERS USED TO INDICATE THE
C                STORAGE LOCATIONS IN WORK OF ARRAYS IN PDETWO AND
C                THE MODIFIED GEARB.
C
C***********************************************************************
C  THE ROUTINES CALLED BY PSETM
C***********************************************************************
C
C  PDB(NODE,T,U,PW,NODE,ML,ML) IS A USER DEFINED ROUTINE WHICH DEFINES
C                THE JACOBIAN IN PW IF MITER=1.  SINCE THIS METHOD IS
C                NOT RECOMMENDED, A DUMMY ROUTINE IS PROVIDED.
C  DECBR(NEBAND,NODE,ML,ML,PW,IWORK,IER) COMPUTES THE LU DECOMPOSITION
C                OF THE JACOBIAN FOR THE DIRECT SOLUTION OF THE
C                JACOBIAN.
C  PDETWO(NPDE,NX,NY,X,Y,T,U,...) IS THE INTERFACE WHICH DESCRETIZES
C                THE SPATIAL VARIABLES OF THE TWO DIMENSIONAL SYSTEM OF
C                PDE*S, THEREBY EVALUATING THE RIGHT HAND SIDE OF
C                THE SYSTEM OF ODE*S.

Language: FORTRAN

DESCRIPTION

This is the FORTRAN package of subroutines described in [1] for testing unconstrained optimization software. The following three problem areas are considered.

(1) Zeros of systems of N nonlinear functions in N variables.
(2) Least squares minimization of M nonlinear functions in N variables.
(3) Unconstrained minimization of an objective function with N variables.

The subroutines that define the test functions and starting points depend on the dimension parameters M and N and on the problem number NPROB. We first describe the subroutines for the test functions.

For systems of nonlinear functions,

VECFCN(N, X, FVEC, NPROB)

returns the function values in the N-vector FVEC, and

VECJAC(N, X, FJAC, LDFJAC, NPROB)

returns the Jacobian matrix in the N by N array FJAC. (The parameter LDFJAC is the leading dimension of the array FJAC as defined in the main program.) In order to prevent gross inefficiencies with solvers that only require one function value at a time,

COMFCN(N, K, X, FCNK, NPROB)

returns the Kth function value in FCNK.

For nonlinear least squares,

SSQFCN(M, N, X, FVEC, NPROB)

returns the function values in the M-vector FVEC, and

SSQJAC(M, N, X, FJAC, LDFJAC, NPROB)

returns the Jacobian matrix in the M by N array FJAC.

Received 19 September 1978, 16 May 1979, and 27 July 1979.
This work was performed under the auspices of the U.S. Department of Energy.
Authors' address: Argonne National Laboratory, 9700 South Cass Avenue, Argonne, IL 60439.

For unconstrained minimization,

OBJFCN(N, X, F, NPROB)

returns the objective function value in F, and

GRDFCN(N, X, G, NPROB)

returns the gradient components in the N-vector G.

For each problem area, the starting points are generated by

INITPT(N, X, NPROB, FACTOR)

which returns in X the starting point corresponding to the parameters NPROB and FACTOR. If XS denotes the standard starting point, then X will contain FACTOR*XS, except that if XS is the zero vector and FACTOR is not unity, then all the components of X will be set to FACTOR.

To test a code in any of the three problem areas, the user must provide a driver and interface routine. The driver reads in the data that define the dimensions, the problem number, and FACTOR, calls INITPT, and then calls the code of interest and prints out results. The interface routine provides a link between the code with its particular function routine calling sequences and the subroutines for the test functions.

The package includes example drivers and interface routines for each of the problem areas. Sample data are also provided.

ALGORITHM 567
Extended-Range Arithmetic and Normalized Legendre Polynomials [A1], [C1]

D. W. LOZIER
National Bureau of Standards
and
J. M. SMITH
George Mason University and National Bureau of Standards

Key Words and Phrases: angular momentum, extended-range arithmetic, Legendre polynomials, overflow, underflow
CR Categories: 3.17, 4.9, 5.12
Language: FORTRAN

DESCRIPTION

This algorithm consists of two logically distinct parts: (1) a package of six FORTRAN subroutines to facilitate the use of a special form of computer floating-point arithmetic that we call extended-range arithmetic; and (2) a FORTRAN subroutine that computes values of normalized Legendre polynomials according to an algorithm that generates (for some inputs) floating-point numbers that are outside the range of any computer. Our desire to produce a robust FORTRAN subroutine to compute these polynomials stimulated the development of the extended-range software package. This package may prove to be useful for many other computations.

Normalized Legendre polynomials are defined by the formula

$$\bar{P}_\nu^\mu(x) = \left\{\left(\nu + \frac{1}{2}\right)\frac{(\nu-\mu)!}{(\nu+\mu)!}\right\}^{1/2} (1-x^2)^{\mu/2}\frac{d^\mu}{dx^\mu}P_\nu(x),$$

where μ and ν are nonnegative integers, x is a real variable lying in the closed interval $[-1, 1]$, and $P_\nu(x)$ is the ordinary Legendre polynomial. These functions satisfy a three-term recurrence relation in μ that is useful in computing $\bar{P}_\nu^\mu(x)$ for fixed ν and x, and sequences $\mu_1, \mu_1 + 1, \ldots, \mu_2$ of values of μ. For stability reasons, the recurrence is applied in the backward direction, starting at $\mu = \nu + 1$ and $\mu = \nu$ and proceeding through $\nu - 1, \nu - 2, \ldots, \mu_1$. The starting value of $\bar{P}_\nu^\nu(x)$ is determined from a first-order recurrence relation, and $\bar{P}_\nu^{\nu+1}(x) = 0$ for all ν, x. When x is close to ± 1 and ν is moderately large, this method fails because of underflow of early values in the recurrence sequence. Nevertheless, the method is attractive because of its inherent stability and simplicity.

A simple extension of floating-point arithmetic, called extended-range arithmetic, overcomes this difficulty. A real number ξ is represented in three storage locations. Two of these hold a number x in ordinary double-precision form; the third holds a signed integer k. The value of ξ is given by

$$\xi = x \times r^k,$$

Received 30 March 1977; 3 January 1979; and 28 February 1979.
Authors' address: National Bureau of Standards, Washington, DC 20234.

where r is the base (or radix) of double-precision numbers. In this (nonunique) representation x is called the *principal part* and k is called the *auxiliary index.* Addition, subtraction, multiplication, and division of extended-range numbers are, of course, trivial to define. The main challenge was to design subroutines that are portable and, at the same time, as efficient as possible. Addition and conversion of extended-range numbers to a decimal form suitable for printing proved to be the most complicated. The subroutine for addition uses nine cases to preclude underflow and overflow of the principal part of the result. The algorithm used in conversion to decimal form requires triple-precision calculation to achieve double-precision accuracy in the converted value of r^k, because of the possible large size of the auxiliary index k.

ACKNOWLEDGMENT

The authors are pleased to acknowledge the aid of R. N. Freemire of the National Bureau of Standards in testing the software and critically reviewing the FORTRAN coding.

ALGORITHM

[Usage of the extended-range software is described in the comments in the initializing subroutine SETUP. These are reproduced below. Similarly, usage of NORMP (the subroutine for computing normalized Legendre polynomials) is described below. The complete listings are available from the ACM Algorithms Distribution Service].

```
C *** SUBROUTINE NORMP ***
      SUBROUTINE NORMP(NU, MU1, MU2, ARG, MODE, PN, IPN, ISIG)
      INTEGER NU, MU1, MU2, MODE, IPN, ISIG
      DOUBLE PRECISION ARG, PN
C
C        SUBROUTINE TO CALCULATE NORMALIZED LEGENDRE POLYNOMIALS
C        OF VARYING ORDER AND OF FIXED ARGUMENT AND DEGREE.
C        THE ORDER MU AND DEGREE NU ARE NONNEGATIVE INTEGERS AND THE
C        ARGUMENT IS REAL. THE ALGORITHM REQUIRES THE USE OF
C        NUMBERS OUTSIDE THE NORMAL MACHINE RANGE. THEREFORE,
C        THIS SUBROUTINE EMPLOYS A SPECIAL ARITHMETIC CALLED
C        EXTENDED-RANGE ARITHMETIC.  (SEE SMITH, J.M., OLVER,
C        F.W.J., AND LOZIER, D.W., EXTENDED-RANGE ARITHMETIC
C        AND NORMALIZED LEGENDRE POLYNOMIALS, ACM TRANSACTIONS
C        ON MATHEMATICAL SOFTWARE, 1981).
C
C        IN EXTENDED-RANGE ARITHMETIC EACH NUMBER IS REPRESENTED
C        AS A PAIR (X,IX) WHICH HAS THE VALUE  X*RADIX**IX, WHERE
C        RADIX IS THE BASE IN WHICH CALCULATIONS ARE PERFORMED.  FOR
C        A FULL DESCRIPTION OF EXTENDED-RANGE ARITHMETIC, SEE THE
C        COMMENTS AT THE BEGINNING OF SUBROUTINE SETUP.
C
C        THE NORMALIZED LEGENDRE POLYNOMIAL IS A MULTIPLE OF THE
C        ASSOCIATED LEGENDRE POLYNOMIAL OF THE FIRST KIND
C        WHERE THE NORMALIZING COEFFICIENT IS CHOSEN SO THAT
C        THE INTEGRAL OF THE SQUARE OF THE FUNCTION FROM -1
C        TO +1 IS EQUAL TO 1 (SEE JAHNKE,E. EMDE,F. AND LOSCH,F.,
C        TABLES OF HIGHER FUNCTIONS, MCGRAW HILL, NEW YORK,
C        196Ø, P. 121).
C
C        THE INPUT VALUES TO NORMP ARE NU, MU1, MU2, ARG, AND MODE.
C        THESE MUST SATISFY:
C          1. NU IS A NON-NEGATIVE INTEGER SPECIFYING THE DEGREE.
C          2. MU1 AND MU2 ARE NON-NEGATIVE INTEGERS, WITH
C             MU1.LE.MU2, SPECIFYING THE RANGE OF ORDERS.
C          3. MODE IS AN INTEGER, RESTRICTED TO 1 OR 2,
C             WHICH INDICATES WHICH OF TWO FORMS OF THE
```

```
C             DOUBLE-PRECISION VARIABLE ARG IS INTENDED:
C              A. IF MODE=1 THEN NORMALIZED LEGENDRE(NU,MU,ARG) IS
C                 COMPUTED FOR ALL MU SUCH THAT MU1 .LE. MU .LE. MU2 ,
C                 IN THIS CASE, -1 .LE. ARG .LE. 1  MUST BE SATISFIED.
C              B. IF MODE=2 THEN NORMALIZED LEGENDRE(NU,MU,COS ARG) IS
C                 COMPUTED FOR ALL MU SUCH THAT MU1 .LE. MU .LE. MU2 ,
C                 IN THIS CASE, -PI .LT. ARG .LT. PI  MUST BE SATISFIED.
C
C        THE OUTPUT OF SUBROUTINE NORMP CONSISTS OF THE TWO
C        ARRAYS PN AND IPN AND THE ERROR ESTIMATE ISIG. THE
C        NORMALIZED LEGENDRE POLYNOMIALS ARE STORED AS EXTENDED-
C        RANGE NUMBERS WITH DOUBLE-PRECISION PRINCIPAL PARTS
C        IN ARRAY PN AND AUXILIARY INDICES IN ARRAY IPN. THUS
C             (PN(1),IPN(1))=NORMALIZED LEGENDRE(NU,MU1,X)
C             (PN(2),IPN(2))=NORMALIZED LEGENDRE(NU,MU1+1,X)
C                .
C                .
C             (PN(K),IPN(K))=NORMALIZED LEGENDRE(NU,MU2,X)
C        WHERE K=MU2-MU1+1 AND X=ARG IF MODE=1, OR X=COS ARG IF MODE=2.
C        FINALLY, ISIG IS AN ESTIMATE OF THE NUMBER OF  DECIMAL DIGITS
C        LOST THROUGH ROUNDING ERRORS IN THE COMPUTATION. IF ARG IS
C        ACCURATE TO N SIGNIFICANT DECIMALS, THEN THE COMPUTED FUNCTION
C        VALUES ARE ACCCURATE TO N-ISIG SIGNIFICANT DECIMALS (EXCEPT IN
C        NEIGHBORHOODS OF ZEROS OF THE FUNCTIONS).
C *** SUBROUTINE SETUP ***
C USAGE
C                    CALL SETUP(IRAD,NRADPL,DZERO,NBITS)
C DESCRIPTION
C
C   SUBROUTINE  SETUP  MUST BE CALLED PRIOR TO CALLING ANY OTHER
C EXTENDED-RANGE SUBROUTINE. IT CALCULATES AND STORES SEVERAL
C MACHINE-DEPENDENT CONSTANTS IN COMMON BLOCKS. THE USER MUST
C SUPPLY FOUR CONSTANTS THAT PERTAIN TO HIS PARTICULAR COMPUTER.
C THE CONSTANTS ARE
C
C          IRAD = THE INTERNAL BASE OF DOUBLE-PRECISION
C                 ARITHMETIC IN THE COMPUTER.
C        NRADPL = THE NUMBER OF RADIX PLACES CARRIED IN
C                 THE DOUBLE-PRECISION REPRESENTATION.
C         DZERO = THE SMALLEST OF 1/DMIN, DMAX, DMAXLN WHERE
C                 DMIN = THE SMALLEST POSITIVE DOUBLE-PRECISION
C                 NUMBER OR AN UPPER BOUND TO THIS NUMBER,
C                 DMAX = THE LARGEST DOUBLE-PRECISION NUMBER
C                 OR A LOWER BOUND TO THIS NUMBER,
C                 DMAXLN = THE LARGEST DOUBLE-PRECISION NUMBER
C                 SUCH THAT DLOG(DMAXLN) CAN BE COMPUTED BY THE
C                 FORTRAN SYSTEM (ON MOST SYSTEMS DMAXLN = DMAX).
C         NBITS = THE NUMBER OF BITS (EXCLUSIVE OF SIGN) IN
C                 AN INTEGER WORD.
C
      SUBROUTINE SETUP(IRAD, NRADPL, DZERO, NBITS)
      INTEGER IRAD, NRADPL, NBITS
      DOUBLE PRECISION DZERO
C
C   THIS IS THE SETTING-UP SUBROUTINE FOR A PACKAGE OF SUBROUTINES
C THAT FACILITATE THE USE OF EXTENDED-RANGE ARITHMETIC. EXTENDED-RANGE
C ARITHMETIC ON A PARTICULAR COMPUTER IS DEFINED ON THE SET OF NUMBERS
C OF THE FORM
C
C               (X,IX) = X*RADIX**IX
C
C WHERE X IS A DOUBLE-PRECISION NUMBER CALLED THE PRINCIPAL PART,
C IX IS AN INTEGER CALLED THE AUXILIARY INDEX, AND RADIX IS THE
C INTERNAL BASE OF THE DOUBLE-PRECISION ARITHMETIC.  OBVIOUSLY,
C EACH REAL NUMBER IS REPRESENTABLE WITHOUT ERROR BY MORE THAN ONE
C EXTENDED-RANGE FORM.  CONVERSIONS BETWEEN  DIFFERENT FORMS ARE
C ESSENTIAL IN CARRYING OUT ARITHMETIC OPERATIONS.  WITH THE CHOICE
C OF RADIX WE HAVE MADE, AND THE SUBROUTINES WE HAVE WRITTEN, THESE
C CONVERSIONS ARE PERFORMED WITHOUT ERROR (AT LEAST ON MOST COMPUTERS).
C (SEE SMITH, J.M., OLVER, F.W.J., AND LOZIER, D.W., EXTENDED-RANGE
C ARITHMETIC AND NORMALIZED LEGENDRE POLYNOMIALS, ACM TRANSACTIONS ON
C MATHEMATICAL SOFTWARE, 1981).
C
C   AN EXTENDED-RANGE NUMBER  (X,IX)  IS SAID TO BE IN ADJUSTED FORM IF
C X AND IX ARE ZERO OR
C
C           RADIX**(-L) .LE. DABS(X) .LT. RADIX**L
C
```

```
C IS SATISFIED, WHERE L IS A COMPUTER-DEPENDENT INTEGER DEFINED IN THIS
C SUBROUTINE. TWO EXTENDED-RANGE NUMBERS IN ADJUSTED FORM CAN BE ADDED,
C SUBTRACTED, MULTIPLIED OR DIVIDED (IF THE DIVISOR IS NONZERO) WITHOUT
C CAUSING OVERFLOW OR UNDERFLOW IN THE PRINCIPAL PART OF THE RESULT.
C WITH PROPER USE OF THE EXTENDED-RANGE SUBROUTINES, THE ONLY OVERFLOW
C THAT CAN OCCUR IS INTEGER OVERFLOW IN THE AUXILIARY INDEX. IF THIS
C IS DETECTED, THE EXTENDED-RANGE SOFTWARE PRINTS A MESSAGE AND STOPS.
C
C   MULTIPLICATION AND DIVISION IS PERFORMED BY SETTING
C
C                  (X,IX)*(Y,IY) = (X*Y,IX+IY)
C OR
C                  (X,IX)/(Y,IY) = (X/Y,IX-IY).
C
C PRE-ADJUSTMENT OF THE OPERANDS IS ESSENTIAL TO AVOID
C OVERFLOW OR  UNDERFLOW OF THE PRINCIPAL PART. SUBROUTINE
C ADJUST (SEE BELOW) MAY BE CALLED TO TRANSFORM ANY EXTENDED-
C RANGE NUMBER INTO ADJUSTED FORM.
C
C   ADDITION AND SUBTRACTION REQUIRE THE USE OF SUBROUTINE ADD
C (SEE BELOW).  THE INPUT OPERANDS NEED NOT BE IN ADJUSTED FORM.
C HOWEVER, THE RESULT OF ADDITION OR SUBTRACTION IS RETURNED
C IN ADJUSTED FORM.  THUS, FOR EXAMPLE, IF (X,IX),(Y,IY),
C (U,IU),  AND (V,IV) ARE IN ADJUSTED FORM, THEN
C
C                  (X,IX)*(Y,IY) + (U,IU)*(V,IV)
C
C CAN BE COMPUTED AND STORED IN ADJUSTED FORM WITH NO EXPLICIT
C CALLS TO ADJUST.
C
C   WHEN AN EXTENDED-RANGE NUMBER IS TO BE PRINTED, IT MUST BE
C CONVERTED TO AN EXTENDED-RANGE FORM WITH DECIMAL RADIX.  SUBROUTINE
C CONVRT IS PROVIDED FOR THIS PURPOSE.
C
C   THE SUBROUTINES CONTAINED IN THIS PACKAGE ARE
C
C *** SUBROUTINE ADD ***
C USAGE
C                   CALL ADD(X,IX,Y,IY,Z,IZ)
C DESCRIPTION
C                   FORMS THE EXTENDED-RANGE SUM  (Z,IZ) =
C                   (X.IX) + (Y,IY).  (Z,IZ) IS ADJUSTED
C                   BEFORE RETURNING. THE INPUT OPERANDS
C                   NEED NOT BE IN ADJUSTED FORM, BUT THEIR
C                   PRINCIPAL PARTS MUST SATISFY
C                   RADIX**(-2L).LE.DABS(X).LE.RADIX**(2L),
C                   RADIX**(-2L).LE.DABS(Y).LE.RADIX**(2L).
C
C *** SUBROUTINE ADJUST ***
C USAGE
C                   CALL ADJUST(X,IX)
C DESCRIPTION
C                   TRANSFORMS (X,IX) SO THAT
C                   RADIX**(-L) .LE. DABS(X) .LT. RADIX**L.
C                   ON MOST COMPUTERS THIS TRANSFORMATION DOES
C                   NOT CHANGE THE MANTISSA OF X PROVIDED RADIX IS
C                   THE NUMBER BASE OF DOUBLE-PRECISION ARITHMETIC.
C
C *** SUBROUTINE CNV21Ø ***
C USAGE
C                   CALL CNV21Ø(K,Z,J)
C DESCRIPTION
C                   GIVEN K THIS SUBROUTINE COMPUTES J AND Z
C                   SUCH THAT  RADIX**K = Z*1Ø**J, WHERE Z IS IN
C                   THE RANGE 1/1Ø .LE. Z .LT. 1.
C                   THE VALUE OF Z WILL BE ACCURATE TO FULL
C                   DOUBLE PRECISION PROVIDED THE NUMBER
C                   OF DECIMAL PLACES IN THE LARGEST
C                   INTEGER PLUS THE NUMBER OF DECIMAL
C                   PLACES CARRIED IN DOUBLE PRECISION DOES NOT
C                   EXCEED 6Ø. CNV21Ø IS CALLED BY SUBROUTINE
C                   CONVRT WHEN NECESSARY. THE USER SHOULD
C                   NEVER NEED TO CALL CNV21Ø DIRECTLY.

ALGORITHM 568
PDS—A Portable Directory System

DAVID R. HANSON
The University of Arizona

Key Words and Phrases: file system, UNIX, RATFOR
CR Categories: 4.19, 4.33, 4.35, 4.41
Language: RATFOR (FORTRAN)

1. DESCRIPTION

PDS is a set of procedures that provides a machine-independent method of file specification. PDS provides capabilities beyond those provided by many vendor-supplied systems. In addition, because PDS is portable, additional capabilities, such as protection schemes, file usage statistics, or some of the functions of a source code control system [5], can be added easily.

The basic function of PDS is to maintain a useful directory structure and provide a set of primitives for manipulating that structure. The PDS directory structure is identical to the tree structure of the UNIX [4] file system, and many of the PDS primitives are identical to UNIX primitives. PDS is, in large part, a portable implementation of the UNIX directory system. Besides PDS's machine-independence, the major differences are the extensibility of PDS and, as described in the next section, its i/o independence.

In the simplest terms, PDS provides a directory structure and a *mapping* from machine-independent file names to machine-dependent names. It deals only with the information *describing* a file; it does not use or manipulate actual files in any way. The importance of this approach is that PDS is used to specify a file but does not participate in the actual i/o to that file. Consequently, there is no impact on i/o efficiency when PDS is used.

PDS manipulates a rooted tree structure in which the leaves are files or directories and the nodes are directories. A directory is simply a list of files and directories. An example is shown in Figure 1, in which circles indicate directories and squares indicate files. The root of the tree is denoted by "/", and files and directories are denoted by their "path," which specifies their absolute position in the tree. A path is composed of the names of the nodes on the path from the root to the desired file or directory. The path components are separated by slashes; for example, the path for file "file2" in Figure 1 is "/m/n/file2." The directory entries "." and ".." refer, respectively, to the directory itself and to the immediate ancestor. These names may be used as path components, providing an explicit means of using the structural properties of the tree. If a path does not begin with "/", it is taken to be rooted at the "current directory." For example, with the

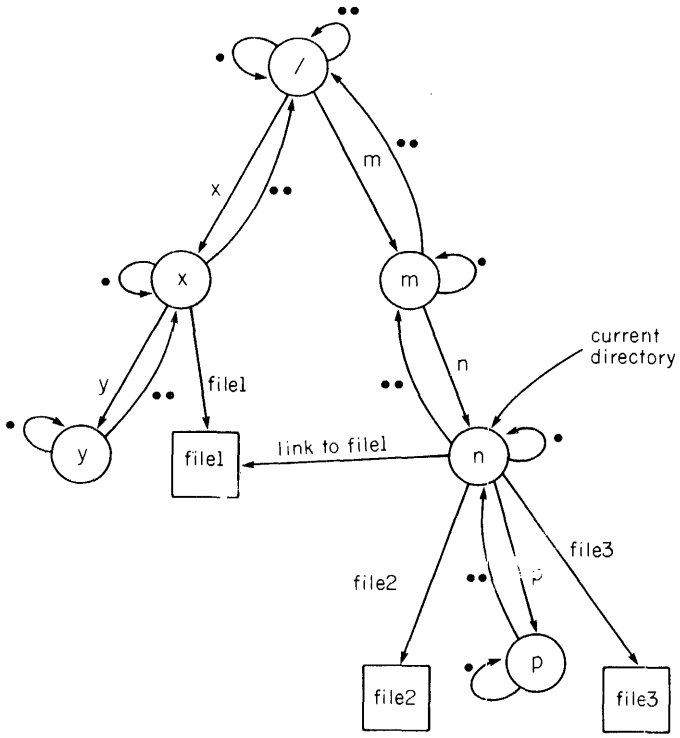

Fig. 1. A directory system.

current directory at "n" in Figure 1, the path "file3" is equivalent to "/m/n/file3."

Files and directories are equivalent with the exception that directories are manipulated by PDS and files are not. Files simply "contain" the machine-dependent names of the actual files. These machine-dependent names are referred to as *host names*. The basic function of PDS is to map paths into host names.

There are ten PDS primitives; they are summarized in Table I. Detailed descriptions of each primitive are given in [1] and in the machine-readable comments. The most important primitives are *openf* and *creatf*, which map a path to a host name and perform machine-dependent operations concerned with preparing files for i/o. The rest are concerned primarily with manipulating the directory structure.

openf obtains the host name corresponding to *path* and calls a machine-dependent routine to actually open the file. *mode* indicates how the file is to be opened (e.g., "read", "write", "append", etc.). *mode* is not modified by *openf*, so it can be whatever is most appropriate on the host system. *openf* returns what the machine-dependent open routine returns, which is whatever is most useful as an argument in calling machine-dependent i/o routines that perform the actual i/o (e.g., **read** and **write**). Typically, a channel number or FORTRAN unit number is returned.

creatf is similar to *openf*, except that *path* is created along with a host name and file. The generation of the host name is performed automatically. After the file is created, it is opened according to *mode* as if *openf* had been called.

openf and *creatf* are insensitive to the values of *mode*. It is, however, useful to introduce standard values representing common file usage, such as reading and writing. This approach promotes machine-independence in programs that use PDS and is used, for example, with the programs described in [3]. Such *mode* values are scrutinized by the machine-dependent i/o interface routines, however, permitting PDS to be used in almost any environment—not just those in which i/o capabilities conform to preconceived notions of "common" file usage.

PDS has *no* other i/o primitives; it is completely independent of the actual i/o. Thus, additional overhead is incurred in opening files, but none is incurred in accessing them. The effect of the additional overhead is minimal since the former

Table I. PDS Primitives

chdir(*path*)	change current directory to *path*
chds(*root, ilist*)	change to another directory system
creatf(*path, mode*)	create *path* and open it for i/o
link(*path*1, *path*2)	make a link to *path*1 named *path*2
mkdir(*path*)	make a directory named *path*
mkds(*root, ilist*)	make a directory system
mkfile(*path, hname*)	make a file *path* with host name *hname*
openf(*path, mode*)	open *path* for i/o according to *mode*
stat(*path, array*)	return information about *path*
unlink(*path*)	unlink *path*

is performed much less frequently than the latter. The contribution of PDS is a portable hierarchical directory system with absolutely no time impact on i/o efficiency.

2. USAGE

PDS is packaged as a set of RATFOR [2, 3] (and hence FORTRAN) functions and subroutines, which is loaded with the program or system that uses it. PDS is useful in programs or systems that use named files extensively, or where a machine-independent means of naming files and a flexible directory structure would enhance utility. Another use would be in a set of tools, such as those described in [3], implemented on computers with limited file systems.

The following program, saveall, illustrates a typical use of PDS. It copies all of the files in the current directory to files of the same name in the directory "../backup". saveall is written in RATFOR in the style of [3].

```
# saveall - save all files in ../backup
  character dline(MAXLINE), bname(MAXLINE)
  integer fd, fdi, fdo
  integer openf, creatf, getlin
  string dot "."
  string backup "../backup/"

  fd = openf(dot, READ)
  while (getlin(dline, fd) ~= EOF) {
    fdi = openf(dline(5), READ)
    call strcat(backup, dline(5), bname)
    fdo = creatf(bname, WRITE)
    call fcopy(fdi, fdo)
    call close(fdi)
    call close(fdo)
    }
  call close(fd)
  end
```

Uppercase names denote defined constants; for example, a typical value for *MAXLINE* might be 80. The **string** statement declares a character array large enough to accommodate the indicated character string. The program begins by opening the current directory for reading using *openf*. The **while** loop reads the directory, line-by-line, until end-of-file, placing each line in the character array *dline*. As described in the next section, each line in a directory contains a file name beginning in column 5. Thus the body of the **while** loop opens each file for reading (*openf*), constructs the path name of the backup copy (*strcat*), creates the backup file and opens it for writing (*creatf*), copies the file (*fcopy*), and finally closes the original and backup files (*close*).

This program makes use of the i/o routines described in [3] (*getlin* and *close*), but any other set of routines—including standard FORTRAN **read** and **write** statements—could be used.

Another example of the use of PDS is as a simple command preprocessor that translates machine-independent system commands to the appropriate host command sequence. In commands, files are referred to by their PDS names and are

mapped to the corresponding host names during the generation of host commands. For example, the command

list *files* . . .

lists the named files on the line printer. The preprocessor translates the **list** into whatever is appropriate on the host system. For example,

list ../backup/saveall.r saveall.r

results in the DEC-10 command sequence

r queue
ilist.120, save.rat

where "ilist.120" and "save.rat" are the host names for "../backup/saveall.r" and "saveall.r", respectively.

3. IMPLEMENTATION

PDS is designed to use only simple sequential i/o (i.e., FORTRAN i/o). It is implemented in RATFOR for portability reasons and because FORTRAN is the only widely available high-level language to which calls from other languages can be made.

The implementation is similar to the implementation of the UNIX file system [7]. The basic technique is to separate the information about a file from the presence of that file in a directory. An *i-node* is associated with each file and directory, and it contains all of the information, including the host name, concerning the file. All of the i-nodes are stored in a single file in which i-node n is line n. This file, referred to as the *i-list*, is stored in character format so that it can be read easily with FORTRAN i/o or its equivalent.

The i-list maps i-node number, or i-number, to a host name. Directories provide a map of PDS name to i-number, thereby completing the mapping from PDS name to host name. A directory is a file of lines, each line containing an i-number and the corresponding PDS name.

Further implementation details are given in [1].

4. INSTALLATION

PDS consists of about 1000 lines of RATFOR including comments. Of this total, however, 300 lines are utility subroutines commonly available in a RATFOR environment. After preprocessing by RATFOR, the resulting FORTRAN code is about 1200 lines in length. The resulting FORTRAN conforms to the portable subset of ANSI standard FORTRAN as defined by PFORT [6].

On a DEC-10 (36-bit words, 512-word pages), the code area for the entire system occupies 6 pages and the data area occupies 17 pages. Small adjustments in the size of the data area can be made by changing various parameters, although the tendency seems to be to *increase* those parameters.

As mentioned in the previous section, PDS operates using sequential i/o only. It is therefore possible to use FORTRAN i/o, although in practice modifications are necessary to avoid having to use FORTRAN unit numbers and to make use of named host files. PDS is written to use the i/o interface described in [3]; a FORTRAN version of these routines is provided along with suggested modifications.

Installation of the system using the FORTRAN version of the i/o interface can be accomplished in 1-2 man-days. The implementation of more sophisticated i/o systems requires substantial time investment, typically 3-6 man-months depending on the target system. This is unnecessary unless heavy use of the RATFOR i/o interface is anticipated. System-specific i/o systems are supplied for the DEC-10 and Cyber 175.

PDS can be modified to use standard FORTRAN i/o facilities directly (i.e., **read** and **write** statements). The modification requires replacing parts of the RATFOR i/o interface—the 300 lines of code mentioned above—with the appro-

priate standard FORTRAN i/o statements. While these modifications have *not* been made, similar experience suggests that 1-2 man-weeks is a conservative estimate of the effort required.

PDS is distributed with the following components:

PDS written in RATFOR
PDS written in FORTRAN (RATFOR output)
RATFOR and RATFOR i/o system written in RATFOR
RATFOR and RATFOR i/o system written in FORTRAN
DEC-10 i/o system
Cyber 175 i/o system

ALGORITHM 569
COLSYS: Collocation Software for Boundary-Value ODEs [D2]

U. ASCHER
University of British Columbia, Canada
and
J. CHRISTIANSEN and R. D. RUSSELL
Simon Fraser University, British Columbia, Canada

Key Words and Phrases: ordinary differential equations, boundary-value problems, collocation, B-spline, mesh selection, error estimates, damped Newton's method, general-purpose code
CR Categories: 5.17
Language: FORTRAN

DESCRIPTION

This package is a complement to [1] where its usage is described and demonstrated.

COLSYS uses the following non-American National Standard FORTRAN conventions:

(1) No run-time subscript range checking.
(2) Simple expressions used as subscripts.
(3) Specifications of array values in DATA statements (used in subroutine CONSTS) by referring to the array name only.

C              IF V(X) IS THE APPROXIMATE SOLUTION VECTOR.
C
C     FIXPNT - AN ARRAY OF DIMENSION IPAR(11).    IT CONTAINS
C              THE POINTS, OTHER THAN ALEFT AND ARIGHT, WHICH
C              ARE TO BE INCLUDED IN EVERY MESH.
C
C     ISPACE - AN INTEGER WORK ARRAY OF DIMENSION IPAR(6).
C              ITS SIZE PROVIDES A CONSTRAINT ON NMAX,
C              THE MAXIMUM NUMBER OF SUBINTERVALS.  CHOOSE
C              IPAR(6) ACCORDING TO THE FORMULA
```

```
C                       IPAR(6)  .GE.  NMAX*NSIZEI
C                 WHERE
C                       NSIZEI = 3 + KDM - NREC
C                 WITH
C                       KDM = KD + MSTAR  ;  KD = K * NCOMP ;
C                       NREC = NO. OF RIGHT END BOUNDARY CONDITIONS.
C
C
C     FSPACE - A REAL WORK ARRAY OF DIMENSION IPAR(5).
C              ITS SIZE PROVIDES A CONSTRAINT ON NMAX.
C              CHOOSE IPAR(5) ACCORDING TO THE FORMULA
C                       IPAR(5)  .GE.  NMAX*NSIZEF
C                 WHERE
C                       NSIZEF = 4 + K + 2 * KD + (4+2*K) * MSTAR +
C                                (KDM-NREC) * (KDM+1).
C
C
C     IFLAG - THE MODE OF RETURN FROM COLSYS.
C           = 1 FOR NORMAL RETURN
C           = 0 IF THE COLLOCATION MATRIX IS SINGULAR.
C           =-1 IF THE EXPECTED NO. OF SUBINTERVALS EXCEEDS STORAGE
C               SPECIFICATIONS.
C           =-2 IF THE NONLINEAR ITERATION HAS NOT CONVERGED.
C           =-3 IF THERE IS AN INPUT DATA ERROR.

C
C                       SUBROUTINE SOLUTN (X , Z , DMVAL)
C
C             NOTE THAT THIS SUBROUTINE IS NEEDED ONLY IF USING
C             IPAR(9) = 1, AND THEN ALL  MSTAR  COMPONENTS OF Z
C             AND  NCOMP  COMPONENTS OF  DMVAL  SHOULD BE SPECIFIED
C             FOR ANY X,  ALEFT .LE. X .LE. ARIGHT .
C
C
C*********************************************************************
C
C     ***************     OUTPUT FROM COLSYS    ***************
C
C
C     UPON RETURN FROM   COLSYS , THE USER MAY PRODUCE THE
C     SOLUTION VECTOR  Z( U(X) )  AT A POINT X, ALEFT.LE.X.LE.ARIGHT
C     BY CALLING :
C
C           CALL APPSLN (X, Z, FSPACE, ISPACE)
C
C     THIS SETS UP A STANDARD CALL TO  APPROX . FOR A MORE
C     EFFICIENT OR SOPHISTICATED RETRIEVAL OF THE SOLUTION
C     VALUES, CALL  APPROX  DIRECTLY (SEE DOCUMENTATION IN
C     APPROX - THE PARAMETERS NEEDED IN THE CALL TO  APPROX
C     BY THE USER ARE SAVED IN  ISPACE  AND  FSPACE  BEFORE
C     COLSYS  RETURNS).
C
C     IN ORDER TO SAVE THE COEFFICIENTS OF THE SOLUTION FOR LATER
C     REFERENCE,     ISPACE(1), ..., ISPACE(7+MSTAR)   AND
C                    FSPACE(1), ..., FSPACE(ISPACE(7))  SHOULD BE
C     SAVED, SINCE THESE ARE USED IN THE CALL TO  APPSLN (APPROX).
C
C     ONE CAN ALSO USE THE FORMERLY OBTAINED APPROXIMATE
C     SOLUTION AS A FIRST APPROXIMATION FOR THE NONLINEAR ITERATION
C     ON A NEW PROBLEM (E.G. FOR CONTINUATION PURPOSES).   THIS
C     INVOLVES USING IGUESS = 2, 3, OR 4, AS FOLLOWS:
C
C     FOR IGUESS= 2 OR 3, THE USER SHOULD PUT THE ABOVE SAVED
C     VALUES BACK INTO FSPACE(1),...,FSPACE(ISPACE(6)).
C     THE SIZE OF THE FORMER MESH, NOLD, IS PROVIDED IN IPAR(3).  IF
C     IGUESS=2 THEN THE SIZE OF THE NEW MESH, N, IS TAKEN TO BE =NOLD.
C     IF IGUESS=3 THEN N := NOLD/2 AND THE NEW MESH IS TO BE TWICE AS
C     COARSE.
C     FOR IGUESS=4, PUT N IN IPAR(3) AND NOLD IN ISPACE(1).  THE
C     VALUES OF THE FORMER SOLUTION, SAVED AS DESCRIBED ABOVE,
C     SHOULD BE PUT INTO FSPACE(N+2),...,FSPACE(ISPACE(6)+N+1),   AND
C     A NEW MESH UNRELATED TO THE FORMER ONE IS PRESCRIBED IN
C     FSPACE(1),...,FSPACE(N+1).
C

C*********************************************************************
C
C     ***************      PACKAGE SUBROUTINES      ***************
C
C     THE FOLLOWING DESCRIPTION GIVES A BRIEF OVERVIEW OF HOW THE
C     PROCEDURE IS BROKEN DOWN INTO THE SUBROUTINES WHICH MAKE UP
C     THE PACKAGE CALLED  COLSYS . FOR FURTHER DETAILS THE
C     USER SHOULD REFER TO DOCUMENTATION IN THE VARIOUS SUBROUTINES
C     AND TO THE REFERENCES CITED ABOVE.
C
C     THE SUBROUTINES FALL INTO FOUR GROUPS:
C
C PART 1 - THE MAIN STORAGE ALLOCATION AND PROGRAM CONTROL SUBROUTINES.
C
C     COLSYS - TESTS INPUT VALUES, DOES INITIALIZATION AND BREAKS UP
C              THE WORK AREAS, FSPACE AND ISPACE, INTO THE ARRAYS
C              USED BY THE PROGRAM.
C
```

```
C     CONTRL - IS THE ACTUAL DRIVER OF THE PACKAGE.  THIS ROUTINE
C              CONTAINS THE STRATEGY FOR NONLINEAR PROBLEMS.
C
C
C PART 2 - MESH SELECTION AND ERROR ESTIMATION SUBROUTINES
C
C     CONSTS - IS CALLED ONCE BY  COLSYS  TO INITIALIZE CONSTANTS
C              WHICH ARE USED FOR ERROR ESTIMATION AND MESH SELECTION.
C
C     NEWMSH - GENERATES MESHES.  IT CONTAINS THE TEST TO DECIDE
C              WHETHER OR NOT TO REDISTRIBUTE A MESH.
C
C     ERRCHK - PRODUCES ERROR ESTIMATES AND CHECKS AGAINST THE
C              TOLERANCES AT EACH SUBINTERVAL
C
C
C PART 3 - COLLOCATION SYSTEM SET-UP SUBROUTINES
C
C     LSYSLV - CONTROLS THE SET-UP AND SOLUTION OF THE LINEAR
C              ALGEBRAIC SYSTEMS OF COLLOCATION EQUATIONS WHICH
C              ARISE AT EACH NEWTON ITERATION.
C
C     BLDBLK - IS USED BY LSYSLV TO SET UP THE EQUATION(S) ASSOCIATED
C              WITH A SIDE CONDITION POINT OR A COLLOCATION POINT.
C
C
C PART 4 - B-SPLINE SUBROUTINES
C
C     APPSLN - SETS UP A STANDARD CALL TO  APPROX
C
C     APPROX - EVALUATES A PIECEWISE POLYNOMIAL SOLUTION.
C
C     BSPFIX - EVALUATES THE MESH INDEPENDENT B-SPLINES
C              (I.E.  THE FIXED B-SPLINES)
C
C     BSPVAR - EVALUATES THE MESH DEPENDENT B-SPLINES (I.E.  THE
C              VARYING B-SPLINES)
C
C     BSPDER - GENERATES VALUES FOR THE DERIVATIVES NEEDED TO SET
C              UP THE COLLOCATION EQUATIONS.
C
C     APPDIF - GENERATES A DIVIDED DIFFERENCE TABLE FROM THE B-SPLINE
C              COEFFICIENTS FOR A COLLOCATION SOLUTION.  THE TABLE
C              IS USED IN  APPROX
C
C     HORDER - EVALUATES THE HIGHEST ORDER DERIVATIVES OF THE
C              CURRENT COLLOCATION SOLUTION USED FOR MESH REFINEMENT.
C
C
C     TO SOLVE THE LINEAR SYSTEMS OF COLLOCATION EQUATIONS
C     CONSTRUCTED IN PART 3,  COLSYS  USES THE PACKAGE
C     SOLVEBLOK  OF DE BOOR - WEISS (TO APPEAR IN TOMS).

ALGORITHM 571
Statistics for von Mises' and Fisher's Distributions of Directions: $I_1(x)/I_0(x)$, $I_{1.5}(x)/I_{0.5}(x)$, and Their Inverses [S14]

GEOFFREY W. HILL
CSIRO, Australia

Key Words and Phrases: direction statistics, von Mises distribution, Fisher distribution, modified Bessel function ratio, continued fraction, function inversion, Newton–Raphson
CR Categories: 5.5, 5.12
Language: FORTRAN

DESCRIPTION

Two pairs of FORTRAN functions provide for evaluation of the ratio of modified Bessel functions of the first kind, $A(\kappa) = I_1(\kappa)/I_0(\kappa)$ or $B(\kappa) = I_{1.5}(\kappa)/I_{0.5}(\kappa) = \coth \kappa - 1/\kappa$ or their inverses, $A^{-1}(R)$, $B^{-1}(R)$. $A(\kappa)$ is the expected value of the mean modulus $\bar{R}$ of random unit vectors in two dimensions, distributed with concentration parameter κ in von Mises' [5] distribution of directions on a circle, whereas $B(\kappa) = E(\bar{R})$ for Fisher's [1] distribution of three-dimensional directions on a sphere. The inverse functions, $A^{-1}(\bar{R})$ and $B^{-1}(\bar{R})$ are corresponding maximum likelihood estimators of κ for observed $\bar{R}$.

Other versions of each function are fairly readily achieved, which provide some choice of precision level in the real valued result, summarized in Table I.

The function BESRAT is illustrated as a 9.3S version, which selects between continued fractions detailed in [3] for backward recursive evaluation from a depth determined by parameter values C1 and C2, assigned with CX to DATA constants as indicated in comment cards. Within the tested range of precision the values specified for these parameters prevent occurrence of zero divisors in evaluation of the continued fractions. A version with S decimal digit precision assignable-at-call (up to limitations imposed by processor precision) can be obtained by changing the first card to read FUNCTION BESRAT(V, S), by deleting C from column 1 of cards defining C1, C2, and CX, and by suppressing the DATA card.

The function VKAPPA achieves 8S results by means of different initial approximations and up to two Newton–Raphson improvements adapted for several subintervals of the range of valid arguments. The Newton–Raphson steps call on BESRAT in a 9.3S version to compensate for some loss of precision for R near 1, such as occurs in Algorithm AS81 [6]. None of the five expressions

Received 28 November 1978, 5 September 1979, and 24 October 1979.

Author's address: Division of Mineral Chemistry, CSIRO, Port Melbourne, Australia 3207.

Table I

FORTRAN Function	Argument[a]	Result	Precision[b]
BESRAT(V)	$0 \le \kappa = \lvert V \rvert$	$A(\kappa)$ in (0, 1)	9.3 (5–14)
VKAPPA(R)	$0 \le R < 1$	$A^{-1}(R) \ge 0$	8 (5)
SPHERR(CAPPA)	$0 \le \kappa = \lvert$CAPPA$\rvert$	$B(\kappa)$ in (0, 1)	13 (5–20)
CAPPA3(R)	$0 \le R < 1$	$B^{-1}(R) \ge 0$	16 (8, 25)

[a] Definition of κ as the modulus of the actual parameter value avoids an error condition, whereas for invalid argument $R < 0$ or $R \ge 1$ the value -1.0 is returned as an error signal result.

[b] Precision is quoted as the least number of correct significant decimal digits in test results on a CDC 7600 of the FORTRAN version illustrated (range of precision tested is noted in parentheses). It is assumed that argument values are represented exactly and that the result precision is not appreciably limited by that of the processor.

occurring as divisors in the code can become zero for arguments within the relevant subintervals, so that processor arithmetic overflow cannot occur.

For analysis of observational data, less precise versions may be adequate [2], such as a fast 5*S* version of VKAPPA, obtained by assigning the value 0.74 to V1 and 0.89 to V2 in the DATA statement and by replacing the two conditional statements before label 30 by columns 29 to 72 of either to leave one unconditional Newton–Raphson call of a 6*S* version of BESRAT. In any case, the backward recursive evaluation of the continued fractions reduces accumulation of roundoff error and enables a substantially faster and more compact code than previously published procedures [2, 6], which involve some ten or more evaluations of numerator and denominator of the Bessel function ratio.

The function SPHERR determines $B(\kappa)$ either by backward recursive evaluation of the continued fraction form of $\coth \kappa - 1/\kappa$ or, if $\kappa > 1$, by means of the exponential form of coth, as outlined in [3]. Unnecessary evaluation of the exponential function and possible overflow for large argument is avoided by evaluating $B(\kappa)$ as $1 - 1/\kappa$ for large values of $\kappa >$ BIGX $= 1.1513 \times S + 0.4$, which ensures S decimal digit precision in the result. The depth of recursion is also simply determined as a function of desired precision S, as indicated in comment cards defining DATA constants. A version with precision assignable-at-call may be obtained by including S as a formal parameter and replacing the DATA statement by the assignments SON4 $= S/4$ and BIGX $= 1.1513 \times S + 0.4$.

The function CAPPA3 achieves 8*S* precision in the result $B^{-1}(R)$ by means of inverses of the continued fraction and exponential forms of $\coth \kappa - 1/\kappa$, empirically extended over different subintervals of the argument [3]. Unnecessary evaluation of the exponential function and possible overflow for argument R near 1.0 are avoided by accepting $1/(1 - R)$ as the result, if that value exceeds BIGX $= 1.1513 \times S + 0.4$. Of course, the effective precision of the argument and therefore that of the result are limited by that of the difference, $1 - R$.

Precision of the initial approximation may be extended by Newton–Raphson inversion of $B(\kappa)$, using SPHERR(−) to provide the Bessel function ratio to a precision of $S + 1$ decimals to allow for loss of up to one decimal digit precision in the improvement. A version with precision up to 8*S* is obtained by deleting statements between label 20 and 30 of the version below, which caters for precision up to 16*S*. Precision could be extended to 25*S* by repeating the statement preceding label 30 or 32*S* by repeating the three statements preceding label 30, changing the DATA constants W1, W2 from 10.0, 0.01 to 20.0 and 0.001, respectively, and adjusting the precision of the auxiliary procedure SPHERR(−) accordingly.

Test programs on a CDC 7600 checked precision claims using single-precision (48*B*) versions of BESRAT and VKAPPA and double-precision (96*B*) versions of SPHERR and CAPPA3. Tabulated values checked against tables to 5*D* [5] identified some errors in published tables [4], but otherwise confirmed the validity of the functions BESRAT, VKAPPA, SPHERR, and CAPPA3.

ALGORITHM 572
Solution of the Helmholtz Equation for the Dirichlet Problem on General Bounded Three-Dimensional Regions [D3]

DIANNE P. O'LEARY
University of Maryland
and
OLOF WIDLUND
New York University

Key Words and Phrases: Helmholtz equation, capacitance matrix, fast Poisson solvers, conjugate gradients
CR Categories: 5.17
Language: FORTRAN

DESCRIPTION

This algorithm provides an approximate solution to the Helmholtz equation

$$-\Delta u + cu = g \qquad \text{in } \Omega$$

with a Dirichlet boundary condition

$$u = f \qquad \text{on } \Gamma, \text{ the boundary of } \Omega.$$

Here Ω, a three-dimensional bounded region, c, an arbitrary real constant (positive, negative, or zero), and the functions f and g are specified by the user. The Laplace operator Δ is in Cartesian coordinates.

A second-order accurate finite-difference method is used to discretize the Helmholtz equation. The resulting linear system of equations is reduced to a capacitance matrix equation that is solved approximately by a conjugate gradient method. We sketch the basic ideas below, but a detailed discussion of this and similar methods can be found in [1].

To perform the discretization, the region Ω is embedded in a cube and a uniform rectangular finite-difference grid is imposed. A simple seven-point difference approximation is used for all mesh points except those that are in Ω and are near the boundary Γ. For these boundary neighbors, second-order accurate equations incorporating the boundary data are used. The resulting difference

Received 29 January 1979, 22 October 1979, and 21 December 1979.

The work of D. P. O'Leary was supported by National Science Foundation Grant MCS 76-06595, while at the University of Michigan; the work of O. Widlund was supported by the Energy Research and Development Agency under Contract EY-76-C-02-3077.
Authors' addresses: D. P. O'Leary, Computer Science Department, University of Maryland, College Park, MD 20742; O. Widlund, Courant Institute of Mathematical Sciences, New York University, New York, NY 10012.

scheme is known as the Shortley-Weller method. Thus the discrete system of equations has a matrix that differs from that for a Helmholtz problem on the cube only in those rows that correspond to points near Γ. We take advantage of this by reformulating the problem as one of dimension equal to the number of boundary neighbors rather than the number of mesh points in the region. The resulting linear system is the capacitance matrix equation. In our implementation this reduced equation is then solved using an iterative algorithm, the conjugate gradient method. A special scaling method, based on so-called discrete dipoles, is used to enhance the convergence. A fast Poisson solver on the cube is one of the components necessary to evaluate the product of the capacitance matrix with a given vector.

Let NX, NY, and NZ be the numbers of mesh points in the cube along the three coordinate axes, where NX and NY are powers of 2. We denote the number of mesh points in Ω with at least one of their six nearest neighbors on or outside the boundary Γ by IPP1 + IPP2, where IPP2 points have two such neighbors along at least one coordinate mesh line. The program requires as input certain scalar parameters, the coordinates of each of the IPP1 + IPP2 points and their distances to the boundary along mesh lines, the values of the Dirichlet data f at points of intersection of mesh lines and the boundary Γ, and the value of the function g at mesh points in Ω. The user communicates with the package through the subroutine HELM3D. A complete description of the input parameters is given in the comments at the beginning of this subroutine.

HELM3D controls the conjugate gradient iteration and calls upon a fast solver (CUBE) and subroutines UTAMLT, UTATRN, BNDRY, VMULT, and VTRANS to perform the necessary matrix-vector products. CUBE solves the Helmholtz equation on a cube using fast discrete Fourier transform routines RFORT and FORT to reduce the systems to tridiagonal form. The resulting linear systems are solved by a Toeplitz method, and then an inverse Fourier transform is performed. RFORT and FORT were provided by Dr. W. Proskurowski, who has modified a code written by Dr. J. Cooley. HELM3D also employs an error-checking module HELMCK to check the input data. It diagnoses errors in the integer parameters, missing boundary points, and inconsistencies in the given boundary data.

The program requires two arrays of dimension NX $\times$ NY $\times$ NZ (one if $g = 0$), four integer and six real arrays of dimension IPP1 + 2 * IPP2, and one real array of dimension max(IPP1 + 2 * IPP2, NX * NZ, NY * NZ). Each conjugate gradient iteration requires time proportional to NX * NY * NZ * LOG (NX * NY), and the number of iterations will usually be small unless a value of c is used that makes the discrete Helmholtz operator almost singular. Double precision is required on machines with a short word length.

Data on timing for many sample problems are given in [1]. As an example, a discrete Laplace problem on a cube with a sphere cut out of it having 10464 mesh points and embedded in a cube of dimension 32 $\times$ 32 $\times$ 24 required 84K words of storage and 171 seconds on a CDC 6600 (FTN compiler, OPT = 2) to find a solution of the linear system with a maximum error equal to 0.55×10^{-3} of the maximum value of the solution.

A sample driver is included with the algorithm. Possible enhancements to the algorithm are discussed in [1].

C              4 IF THE REGION IS THE SAME AS ON THE PREVIOUS CALL
C                 AND  G1  IS NONZERO
C              5 IF THE PROBLEM IS THE SAME AS ON THE  PREVIOUS CALL,
C                 G1=0,  AND THE ONLY CHANGE IS THAT  EPS  AND/OR  NIT
C                 MAY HAVE BEEN CHANGED
C              6 IF THE PROBLEM IS THE SAME AS ON THE PREVIOUS CALL,
C                 G1  IS NONZERO, AND THE ONLY CHANGE IS THAT  EPS
C                 AND/OR  NIT  MAY HAVE BEEN CHANGED
C        IF  MODE = 3,4,5, OR 6  DELTA,  ICOORD,  INDORD,  NXDIM,
C       NYDIM,  NZDIM,  NNX,  NNY,  NNZ,  IPP1,  AND IPP2  MUST BE
C       UNCHANGED FROM THE PREVIOUS CALL.  THE CURRENT VALUE OF  S
C       WILL BE USED AS THE INITIAL GUESS FOR THE DIPOLE STRENGTHS.
C       (S=0 WILL BE USED IF MODE=1 OR 2.)
C       TO IMPROVE THE ACCURACY OF A PREVIOUSLY CALCULATED SOLUTION,
C       USE  MODE=5  OR MODE=6  IF ROUNDOFF IS NOT SUSPECTED.  IF
C       ROUNDOFF IS SUSPECTED, REINITIALIZE THE BOUNDARY VALUES IN  R,
C       AP,  AND  P,  AND USE  MODE = 3 TO FORCE THE RESIDUAL TO BE
C       RECOMPUTED; IF G1 IS NONZERO, ADD GG TO THE SOLUTION
C       RETURNED BY THE SUBROUTINE.
C
C    -- W(NXDIM, NYDIM, NZDIM) IS UNINITIALIZED.
C    -- GG(NXDIM, NYDIM, NZDIM) INITIALIZED TO  G1*HZ*HZ  IN THE
C                               REGION, WITH ARBITRARY VALUES OUTSIDE.
C         FOR  I=1,...,NNX,  J=1,...,NNY, AND  K=1,...,NNZ,
C         GG(I,J,K) CORRESPONDS TO G1((I-1)*HX,(J-1)*HY,(K-1)*HZ)*HZ**2.
C         IF  MODE = 1, 3 OR 5,  G1  MAY BE A DUMMY ARRAY (I.E.,
C         IT NEED NOT BE DIMENSIONED BY THE CALLING PROGRAM).
C
C    -- IPP1 IS THE NUMBER OF IRREGULAR POINTS WITH AT LEAST 1
C          INTERIOR NEIGHBOR IN EACH DIRECTION X, Y, AND Z.
```

```
C     -- IPP2 IS THE NUMBER OF IRREGULAR POINTS WHICH, ALONG
C           AT LEAST ONE DIRECTION, HAVE TWO EXTERIOR NEIGHBORS.
C
C        IN THE EXCEPTIONAL CASE WHEN  IPP1+IPP2.EQ.0,  THE ROUTINE
C        WILL SOLVE THE PROBLEM ON THE WHOLE CUBE WITH THE
C        BOUNDARY CONDITIONS#
C              G1(X,Y,Z) = 0     Z .LT. 0     OR Z .GT. 1
C              W(0,Y,Z) = W(1,Y,Z)  AND  W(X,0,Z) = W(X,1,Z)
C              W(X,Y,0)=0 AND W(X,Y,Z) BOUNDED FOR ALL Z.
C        ARRAY  GG  MUST BE INITIALIZED TO  G1*HZ*HZ  AND  MODE = 2.
C        W  MAY BE A DUMMY ARRAY.  THE ANSWER WILL BE STORED
C        IN THE ARRAY  GG  IN THIS CASE.
C
C     -- DELTA(3, NIPDIM)  RECORDS + OR - DISTANCE TO BOUNDARY
C           FROM IRREGULAR POINT  L  IN THE  X,  Y,  AND  Z
C           DIRECTIONS  (3*IPP1 + 6*IPP2  VALUES).  THESE DISTANCES
C           ARE EXPRESSED AS MULTIPLES OF THE MESH SPACING:  I.E.,
C           IF A  DELTA  HAS THE VALUE  Q,  THE DISTANCE IS  Q*H.
C         THERE ARE THREE DELTAS FOR EACH OF THE  IPP1  POINTS
C         FOR  L=1,IPP1,
C          DELTA(1,L) = SHORTER DISTANCE TO BOUNDARY ALONG X DIRECTION
C          DELTA(2,L) = SHORTER DISTANCE TO BOUNDARY ALONG Y DIRECTION
C          DELTA(3,L) = SHORTER DISTANCE TO BOUNDARY ALONG Z DIRECTION
C         THERE ARE SIX DELTAS FOR EACH OF THE IPP2 POINTS,
C         FOR  L=1,IPP2  ,  LL=IPP1+2*L-1,
C          DELTA(1,LL)  AND  DELTA(1,LL+1)  ARE THE DISTANCES TO THE
C             BOUNDARY ALONG THE POSITIVE AND NEGATIVE  X  DIRECTIONS
C          DELTA(2,LL)  AND  DELTA(2,LL+1)  ARE THE DISTANCES TO THE
C             BOUNDARY ALONG THE POSITIVE AND NEGATIVE  Y  DIRECTIONS
C          DELTA(3,LL)  AND  DELTA(3,LL+1)  ARE THE DISTANCES TO THE
C             BOUNDARY ALONG THE POSITIVE AND NEGATIVE  Z  DIRECTIONS
C         THE PROGRAM WILL INTERCHANGE  DELTAS  IF NECESSARY SO THAT
C         FOR  L=1,IPP2  ,  LL=IPP1+2*L-1,
C         ABS(DELTA(S,LL))  LE.  ABS(DELTA(S,LL+1)).
C         NO  DELTA  CAN BE SO CLOSE TO  0  AS TO CAUSE OVERFLOW
C         UPON DIVISION BY A PRODUCT OF TWO  DELTAS.  SUCH SMALL
C         DELTAS  SHOULD BE AVOIDED BY CHANGING THE REGION
C         SLIGHTLY OR BY SHIFTING IT INSIDE THE CUBE OR BY
C         USING ANOTHER MESH SIZE.
C

ALGORITHM 573
NL2SOL—An Adaptive Nonlinear Least-Squares Algorithm [E4]

JOHN E. DENNIS, JR.
Rice University
and
DAVID M. GAY and ROY E. WELSCH
Massachusetts Institute of Technology

Key Words and Phrases: unconstrained optimization, nonlinear least squares, nonlinear regression, quasi-Newton methods, secant methods
CR Categories: 5.14, 5.5
Language: FORTRAN

1. PURPOSE

Given a continuously differentiable function (residual vector) $R(x) = (R_1(x), R_2(x), \ldots, R_n(x))^T$ of p parameters $x = (x_1, x_2, \ldots, x_p)^T$, NL2SOL attempts to find a parameter vector x^* that minimizes the sum-of-squares function $F(x) = \sum_{i=1}^{n} R_i(x)^2$.

2. METHOD

Reference [1] explains the algorithm realized by NL2SOL in detail. The algorithm amounts to a variation on Newton's method in which part of the Hessian matrix is computed exactly and part is approximated by a secant (quasi-Newton) updating method. Once the iterates come sufficiently close to a local solution, they usually converge quite rapidly. To promote convergence from poor starting guesses, NL2SOL uses a model/trust-region technique along with an adaptive choice of the model Hessian. Consequently, the algorithm sometimes reduces to a Gauss–Newton or Levenberg–Marquardt method. On large residual problems (in which $F(x^*)$ is large), however, NL2SOL often works much better than these methods.

Received 13 September 1977; revised 18 August 1979 and 25 September 1980; accepted 8 April 1981.

Research leading to the NL2SOL package was supported in part by National Science Foundation Grants DCR75-10143, MCS76-00324, and SOC76-14311 to the National Bureau of Economic Research, Inc., and MCS79-06671 to the Massachusetts Institute of Technology, and was sponsored in part by NSF Grant MCS78-09525 and United States Army Contract DAAG29-75-C-0024 to the Mathematics Research Center at the University of Wisconsin.

3. DESCRIPTION

3.1 Calling Sequence

CALL NL2SOL (N, P, X, CALCR, CALCJ, IV, V, UIPARM, URPARM, UFPARM)

Note: NL2SOL is written in American National Standard FORTRAN (1966) and the comments below assume that the calling program is also written in FORTRAN. These comments refer to the single-precision version of NL2SOL. In the double-precision version, all quantities termed REAL below are actually DOUBLE PRECISION.

N (input INTEGER) is the number of components in the residual vector R.

P (input INTEGER) is the number of parameters on which R depends.

X (I/O REAL array of length P) on input is an initial guess at the desired solution x^*. When NL2SOL returns, X contains the best parameter estimate found so far.

CALCR (input subroutine) computes the residual vector R = R(X) when invoked by

CALL CALCR(N, P, X, NF, R, UIPARM, URPARM, UFPARM)

When CALCR is called, NF is the invocation count for CALCR; it is included for possible use with CALCJ. If X is out of bounds (e.g., if R(X) would overflow), then CALCR should set NF to 0, which will cause a shorter step to be attempted. CALCR should not change N, P, or X and should be declared EXTERNAL in the calling program. R should be declared REAL R(N).

CALCJ (input subroutine) computes the Jacobian matrix J = J(X) of first partials, $J_{ij} = \partial J_i(X)/\partial x_j$, when invoked by

CALL CALCJ(N, P, X, NF, J, UIPARM, URPARM, UFPARM)

When CALCJ is called, NF is the invocation count for CALCR at the time when R(X) was evaluated. The X passed to CALCJ is usually the one passed to CALCR on either its most recent invocation or the one prior to it. Thus if CALCR saves intermediate results for use by CALCJ, then it is possible to tell from NF whether they are valid for the current X (or which copy is valid if two are kept). If J cannot be computed at X, then CALCJ should set NF to 0. CALCJ should not change N, P, or X and should be declared EXTERNAL in the calling program. J should be declared REAL J(N, P).

IV (I/O INTEGER array of length P + 60) on input contains certain values (such as limits on the number of iterations and calls on CALCR) that control the behavior of NL2SOL and on output contains various counts and other items of interest: see Sections 3.3 and 3.4. If IV(1) = 0 on input, then default values are supplied for the input components of both IV and V. The caller may supply nondefault values for selected components of IV and V by CALLing DFAULT(IV, V) and then assigning the appropriate nondefault values before calling NL2SOL.

V (I/O REAL array of length 93 + N(P + 3) + P(3P + 33)/2) on input contains certain values (such as convergence tolerances) that control the behavior of NL2SOL and on output contains various items of interest (such as F(X) and R(X)): see Sections 3.5 and 3.15.

UIPARM (INTEGER array of length determined by the caller) is passed without change to CALCR and CALCJ and may be used by them in any way that the caller may find convenient.

URPARM (REAL array of length determined by the caller), like UIPARM, is passed without change to CALCR and CALCJ.

UFPARM (subroutine), like UIPARM, is passed without change (and without having been invoked) to CALCR and CALCJ. If there is no need for such a subroutine, then on many systems it suffices to pass an arbitrary variable or constant for UFPARM. But if an actual subroutine is passed, then it must be declared EXTERNAL in the calling program.

3.2 Example

Let $n = 3, p = 2$, and

$$R(x) = \begin{bmatrix} x_1^2 + x_2^2 + x_1x_2 \\ \sin x_1 \\ \cos x_2 \end{bmatrix}.$$

(This problem is due to Madsen [3].) The following FORTRAN code minimizes $F(x) = \frac{1}{2}R(x)^TR(x)$, starting from the initial guess $(3, 1)^T$, using a single-precision version of NL2SOL.

```
INTEGER IV(62), UI(1)
REAL V(147), X(2), UR(1)
EXTERNAL MADR, MADJ
X(1) = 3.0
X(2) = 1.0
IV(1) = 0
CALL NL2SOL (3, 2, X, MADR, MADJ, IV, V, UI, UR, MADR)
STOP
END
SUBROUTINE MADR (N, P, X, NF, R, UI, UR, UF)
INTEGER N, P, NF, UI(1)
REAL X(P), R(N), UR(1)
EXTERNAL UF
R(1) = X(1)**2 + X(2)**2 + X(1)*X(2)
R(2) = SIN(X(1))
R(3) = COS(X(2))
RETURN
END
SUBROUTINE MADJ (N, P, X, NF, J, UI, UR, UF)
INTEGER N, P, NF, UI(1)
REAL X(P), J(N, P), UR(1)
EXTERNAL UF
J(1, 1) = 2.0*X(1) + X(2)
J(1, 2) = 2.0*X(2) + X(1)
J(2, 1) = COS(X(1))
J(2, 2) = 0.0
J(3, 1) = 0.0
J(3, 2) = -SIN(X(2))
RETURN
END
```

The main program above passes MADR as CALCR and MADJ as CALCJ. No use is made of UIPARM, URPARM, or UFPARM in this simple example.

When the above is executed, NL2SOL prints the initial X vector, a summary of the iterations performed, the final X vector, and some statistics, including the final F(X) and a covariance matrix. If REAL is changed to DOUBLE PRECISION and the above is run on an IBM 370 computer, then NL2SOL reports relative function convergence (IV(1) = 4—see Section 3.3) after 12 calls on MADR and MADJ and returns X(1) = −0.155437, X(2) = 0.694564, and F(X) = 0.386600.

If, say, we wanted to suppress the iteration summary, we could do so by replacing the statement IV(1) = 0 in the main program by

```
CALL DFAULT(IV, V)
IV(19) = 0
```

(See the description of IV(OUTLEV) in Section 3.4.)

3.3 Return Codes

When NL2SOL returns, IV(1) contains one of the following return codes:

3	= X-convergence. The scaled relative difference between the current parameter vector X and a locally optimal parameter x^* is very likely at most V(XCTOL): see Section 3.5.
4	= relative function-convergence. The relative difference between the current function value and its locally optimal value is very likely at most V(RFCTOL): see Section 3.5.
5	= both X and relative function-convergence, that is, the conditions for IV(1) = 3 and IV(1) = 4 both hold.
6	= absolute function-convergence. The current function value (half the sum of squares) is at most V(AFCTOL): see Section 3.5.
7	= singular convergence. The Hessian near the current X appears to be singular or nearly so, and a step of scaled length at most V(LMAX0) is unlikely to yield a relative function decrease of more than V(RFCTOL). This means that the model is overspecified (i.e., contains too many parameters), at least near X. It is possible that a different starting guess would lead NL2SOL to find an X giving a smaller F(X) and strong convergence (IV(1) = 3, 4, 5, or 6).
8	= false convergence. The iterates appear to be converging to a noncritical point. This may mean that the false convergence tolerance (V(XFTOL)—see Section 3.5) is too large, that the convergence tolerances (V(AFCTOL), V(RFCTOL), V(XCTOL)) are too small for the accuracy to which CALCR and CALCJ compute R and J, that there is an error in computing the Jacobian matrix J, or that R is discontinuous near X. If the NPRELDF value printed in the summary statistics (or in the iteration summary for the final iteration) is negative and not too much larger than V(RFCTOL) in absolute value, then V(RFCTOL) is too small and singular convergence would be detected if V(RFCTOL) were increased above |NPRELDF|: see Sections 3.5 and 3.11.
9	= function evaluation limit reached without other convergences: see IV(MXFCAL) in Section 3.4.
10	= iteration limit reached without other convergence: see IV(MXITER) in Section 3.4.
11	= STOPX returned .TRUE. (external interrupt): see Section 3.14.
13	= F(X) cannot be computed at the initial X.
14	= bad parameters passed to ASSESS. (This should not occur.)
15	= the Jacobian could not be computed at X (see CALCJ above).
16	= N or P (or parameter NN to NL2ITR) out of range: P < 0 or N < P or NN < N.
17	= a restart was attempted with N, P, or parameter NN to NL2ITR changed: see Section 3.7.
18	= IV(INITS) out of range: see Section 3.4.
19–45	= V(IV(1)) is out of range.
50	= IV(1) was out of range when NL2SOL (or NL2SNO or NL2ITR) was called.
87 . . . (86 + P)	= JTOL(IV(1)-86), that is, V(IV(1)), is not positive: see V(DFAC) in Section 3.5.

Just before NL2SOL returns, a brief description of the return code is printed (unless all printing is turned off by IV(PRUNIT) = 0).

3.4 IV Values

3.4.1 *IV Input Values (Supplied by DFAULT)*

IV(1) . . . IV(1) should have a value between 0 and 12 when NL2SOL is called. 0 and 12 both mean that this is a fresh start; 0 means DFAULT(IV, V) should be invoked to supply default values to the input components of IV and V, while 12 (the value that DFAULT assigns to IV(1)) means that the caller has already called DFAULT(IV, V) and has possibly changed some IV or V entries to nondefault values. IV(1) input values between 3 and 11 mean that NL2SOL should restart; see Section 3.7. Default = 12.

IV(COVPRT) . . . IV(14) = 1 means print a covariance matrix at the solution. This matrix is computed as IV(COVREQ) dictates just before a return with IV(1) = 3, 4, 5, or 6. IV(COVPRT) = 0 means skip this printing. Default = 1.

IV(COVREQ): IV(15) $\neq$ 0 means compute a covariance matrix before a return with IV(1) = 3, 4, 5, or 6. In this case, an approximate covariance matrix is obtained in one of several ways. Let k = | IV(COVREQ) | and let σ = 2F(X)/ max (1, N−P), where 2F(X) is the residual sum of squares. If k = 1 or 2, then a finite-difference Hessian approximation H is obtained. If H is positive-definite (or, for k = 3, if the Jacobian has full rank), then one of the following is computed:

$$k = 1 \Rightarrow \sigma H^{-1}(J^{\mathrm{T}}J)H^{-1}$$

$$k = 2 \Rightarrow \sigma H^{-1}$$

$$k = 3 \Rightarrow \sigma(J^{\mathrm{T}}J)^{-1}.$$

If IV(COVREQ) > 0, then both function and gradient values (calls on CALCR and CALCJ) are used in computing H (with step sizes determined by V(DELTA0); see Section 3.5), while if IV(COVREQ) < 0, then only function values (calls on CALCR) are used (with step sizes determined by V(DLTFDC)). If IV(COVREQ) = 0, then no attempt is made to compute a covariance matrix (unless IV(COVPRT) = 1, in which case NL2SOL assumes IV(COVREQ) = 1 and NL2SNO assumes IV(COVREQ) = −1). See IV(COVMAT) below. Default = 1.

IV(DTYPE) . . . IV(16) tells how the scale vector D (see [1]) should be chosen. IV(DTYPE) > 0 means choose D as described below with V(DFAC). IV(DTYPE) $\leq$ 0 means the caller has chosen D and has stored it in V starting at V(94 + 2N + P(3P + 31)/2). Default = 1.

IV(INITS) . . . IV(25) tells how the S matrix (see [1]) should be initialized. 0 means initialize S to all zeros and start with the Gauss–Newton model. 1 and 2 mean that the caller has stored the lower triangle of the initial S rowwise in V starting at V(87 + 2P). IV(INITS) = 1 means start with the Gauss–Newton model, while IV(INITS) = 2 means start with the augmented model; see [1]. Default = 0.

IV(MXFCAL) . . . IV(17) gives the maximum number of function evaluations (calls on CALCR, excluding those used to compute the covariance matrix and, in the case of NL2SNO, the Jacobian matrices) allowed. If this number does not suffice, then NL2SOL returns with IV(1) = 9. Default = 200.

IV(MXITER) . . . IV(18) gives the maximum number of iterations allowed. It also indirectly limits the number of gradient evaluations (calls on CALCJ) to IV(MXITER) + 1. If IV(MXITER) iterations do not suffice, then NL2SOL returns with IV(1) = 10. Default = 150.

IV(OUTLEV) . . . IV(19) controls the number and length of iteration summary lines printed (by ITSMRY). IV(OUTLEV) = 0 means do not print any summary lines. Otherwise print a summary line after each | IV(OUTLEV) |

iterations. Long summary lines are printed if IV(OUTLEV) > 0, short lines if IV(OUTLEV) < 0. See Section 3.11 for more details. Default = 1.

IV(PARPRT) ... IV(20) = 1 means print any nondefault V values on a fresh start or any changed V values on a restart. IV(PARPRT) = 0 means skip this printing. Default = 1.

IV(PRUNIT) ... IV(21) is the output unit number on which all printing is done. IV(PRUNIT) = 0 means suppress all printing. (Setting IV(PRUNIT) to 0 is the only way to suppress the one-line termination message printed before NL2SOL returns.) Default = standard output unit (unit 6 on most systems); the default for IV(PRUNIT) is actually IMDCON(1); see Section 3.12.

IV(SOLPRT) ... IV(22) = 1 means print the final X (the one returned), along with the final gradient and scale vector D. IV(SOLPRT) = 0 means skip this printing. Default = 1.

IV(STATPR) ... IV(23) = 1 means print summary statistics upon returning. These consist of the function value (half the residual sum of squares) at X, the scaled relative size of the last step taken (see V(RELDX) below), the number of function and gradient evaluations (calls on CALCR and CALCJ, excluding any calls made only for computing covariance matrices), the relative function reductions predicted for the last step taken and for a Newton step (or perhaps a step of length bounded by V(LMAX0)—see the descriptions of PRELDF and NPRELDF in Section 3.11 below), and, if an attempt was made to compute a covariance matrix, the number of calls on CALCR and CALCJ used in trying to compute the covariance matrix. IV(STATPR) = 0 means skip this printing. Default = 1.

IV(X0PRT) ... IV(24) = 1 means print the initial X and scale vector D (on a fresh start only). IV(X0PRT) = 0 means skip this printing. Default = 1.

3.4.2 *IV Output Values of Primary Interest*

IV(1) ... IV(1) is the return code; see Section 3.3.

IV(COVMAT) ... IV(26) tells whether a covariance matrix was computed. If IV(COVMAT) > 0, then the lower triangle of the covariance matrix is stored row-wise in V, starting at V(IV(COVMAT)). If IV(COVMAT) = 0, then no attempt was made to compute a covariance matrix. If IV(COVMAT) = −1, then the finite-difference Hessian H was indefinite (or, for | IV(COVREQ) | = 3, the current Jacobian matrix is rank deficient): like singular convergence (see Section 3.3), this may mean that the model is overspecified (contains too many parameters). And if IV(COVMAT) = −2, then a successful finite-difference step could not be found for some component of X (i.e., CALCR set NF to 0 for each of two trial steps).

Note that IV(COVMAT) is reset to 0 after each successful step, so if such a step is taken after a restart, then the covariance matrix will be recomputed.

IV(D) ... IV(27) is the starting subscript in V of the current scale vector D.

IV(G) ... IV(28) is the starting subscript in V of the current least-squares gradient vector $J^T R$.

IV(NFCALL) ... IV(6) is the number of calls so far made on CALCR (i.e., function evaluations, including those used in computing covariance matrices).

IV(NFCOV) ... IV(40) is the number of calls made on CALCR when computing covariance matrices.

IV(NGCALL) ... IV(30) is the number of calls on CALCJ (gradient evaluations) so far made, including those used in computing covariance matrices.

IV(NGCOV) . . . IV(41) is the number of calls made on CALCJ when computing covariance matrices.

IV(NITER) . . . IV(31) is the number of iterations performed.

IV(R) . . . IV(50) is the starting subscript in V of the residual vector R corresponding to the final X.

3.5 V Values of Primary Interest

Many of the V input components described here and in Section 3.15 must lie in certain intervals. If such a component lies outside the interval indicated for it below (or in Section 3.15) at the beginning of its description, then module PARCHK will print an error message (unless IV(PRUNIT) = 0) and will force NL2SOL to return immediately with IV(1) > 18.

Frequent reference is made below to two quantities: MACHEP and the scale vector D. MACHEP is the unit roundoff for the floating-point arithmetic being used—see Section 3.12. The scale vector D is the diagonal of the diagonal scale matrix D_k discussed in [1, Sections 5 and 7]; this scale matrix is denoted by diag(D) below.

3.5.1 *V Input Values of Primary Interest (Supplied by DFAULT)*

V(AFCTOL) . . . V(31) > 0 is the absolute function convergence tolerance. If NL2SOL finds a point where the function value (half the sum of squares) is less than V(AFCTOL), and if NL2SOL does not return with IV(1) = 3, 4, or 5, then it returns with IV(1) = 6.

$$\text{Default} = \max\{10^{-20}, \text{MACHEP}^2\}.$$

V(DELTA0) . . . V(44) $\in$ [MACHEP, 1] is a factor used in choosing the finite-difference step sizes used in computing covariance matrices when IV(COVREQ) = 1 or 2. For differences involving X(i), step size

$$\text{V(DELTA0)} \cdot \max\{|\text{X}(i)|, 1/\text{D}(i)\} \cdot \text{sign}(\text{X}(i))$$

is used, where D is the current scale vector; see [1]. If this results in CALCR setting NF to 0, then −0.5 times this step is also tried. Default = MACHEP$^{1/2}$.

V(DFAC) . . . V(41) $\in$ [0, 1] and the D0 and JTOL arrays (see V(D0INIT) and V(JTINIT)) are used in updating the scale vector D when IV(DTYPE) > 0. (D is initialized according to V(DINIT).) Let

$$\text{D1}(i) = \max\{[\text{JCNORM}(i)^2 + \max\{S_{ii}, 0\}]^{1/2}, \text{V(DFAC)D}(i)\},$$

where JCNORM(i) is the 2-norm of the ith column of the current Jacobian matrix and S is the S matrix of [1]. If IV(DTYPE) = 1, then D(i) is set to D1(i) unless D1(i) < JTOL(i), in which case D(i) is set to max{(D0(i), JTOL(i)}. If IV(DTYPE) > 1, then D is updated during the first iteration as for IV(DTYPE) = 1 (after any initialization due to V(DINIT)) and is left unchanged thereafter. Default = 0.6.

V(DINIT) . . . V(38) ≥ -10: if V(DINIT) ≥ 0, then it is the value to which all components of the scale vector D are initialized during a fresh start. Default = 0.

V(DLTFDC) . . . V(40) $\in$ [MACHEP, 1] helps choose the step sizes used in computing covariance matrices when IV(COVREQ) = −1 or −2. For differences involving X(i), the step size first tried is

$$\text{V(DLTFDC)} \cdot \max\{|\text{X}(i)|, 1/\text{D}(i)\},$$

where D is the current scale vector (see [1]). If this step is too big the first time it is tried, that is, if CALCR sets NF to 0, then −0.5 times this step is also tried. Default = MACHEP$^{1/3}$.

V(DLTFDJ) ... V(36) ∈ [MACHEP, 1] helps choose the step sizes used when NL2SNO computes a finite-difference approximation to the Jacobian matrix. For differences involving X(i), the step size first tried is

$$\mathrm{V(DLTFDJ)} \cdot \max\{|\,\mathrm{X}(i)\,|, 1/\mathrm{D}(i)\},$$

where D is the current scale vector (see [1]). If the first step is too big, that is, if CALCR sets NF to 0, then smaller steps are tried until the step size is shrunk below 1000 · MACHEP. Default = $\mathrm{MACHEP}^{1/2}$.

V(D0INIT) ... V(37) ≥ 0: if V(D0INIT) > 0, it is the value to which all components of the D0 vector (see V(DFAC)) are initialized. If V(D0INIT) = 0, then it is assumed that the caller has stored D0 in V starting at V(P + 87). Default = 1.0.

V(JTINIT) ... V(39) ≥ 0: if V(JTINIT) > 0, it is the value to which all components of the JTOL array (see V(DFAC)) are initialized. If V(JTINIT) = 0, then it is assumed that the caller has stored JTOL in V starting at V(87). Default = 10^{-6}.

V(LMAX0) ... V(35) > 0 gives the maximum 2-norm allowed for diag(D) times the very first step that NL2SOL attempts. It is also used in testing for singular convergence: if the function reduction predicted for a step of length bounded by V(LMAX0) is at most V(RFCTOL) $|F_0|$, where F_0 is the function value at the start of the current iteration, and if NL2SOL does not return with IV(1) = 3, 4, 5, or 6, then it returns with IV(1) = 7. Default = 100.

V(RFCTOL) ... V(32) ∈ [MACHEP, 0.1] is the relative function-convergence tolerance. If the current model predicts a maximum possible function reduction (see V(NREDUC)) of at most V(RFCTOL) $|F_0|$, where F_0 is the function value at the start of the current iteration, and if the last step attempted achieved no more than twice the predicted function decrease, then NL2SOL returns with IV(1) = 4 (or 5). Default = $\max\{10^{-10}, \mathrm{MACHEP}^{2/3}\}$.

V(TUNER1) ... V(26) ∈ [0, 0.5] helps decide when to check for false convergence and to consider switching models. This is done if the actual function decrease from the current step is no more than V(TUNER1) times its predicted value. Default = 0.1.

V(XCTOL) ... V(33) ∈ [0, 1] is the X-convergence tolerance. If a Newton step (see V(NREDUC)) is tried that has V(RELDX) ≤ V(XCTOL) and if this step yields at most twice the predicted function decrease, then NL2SOL returns with IV(1) = 3 (or 5). Default = $\mathrm{MACHEP}^{1/2}$.

V(XFTOL) ... V(34) ∈ [0, 1] is the false-convergence tolerance. If a step is tried that gives no more than V(TUNER1) times the predicted function reduction and that has V(RELDX) ≤ V(XFTOL), and if NL2SOL does not return with IV(1) = 3, 4, 5, 6, or 7, then it returns with IV(1) = 8. (See the description of V(RELDX) below.) Default = 100·MACHEP.

V(*) ... DFAULT supplies to V a number of tuning constants, with which it should normally be unnecessary to tinker. See Section 3.15.

3.5.2 *V Output Values of Primary Interest*

V(DGNORM) ... V(1) = $\| \mathrm{diag}(D)^{-1} g \|_2$, where g is the most recently computed gradient and D is the corresponding scale vector.

V(DSTNRM) ... V(2) = $\| \mathrm{diag}(D) \Delta x \|_2$, where Δx is the most recently computed step and D is the current scale vector.

V(F) ... V(10) is the current function value (half the residual sum of squares).

V(F0) ... V(13) is the function value at the start of the current iteration.

V(NREDUC) ... V(6), if positive, is the maximum function reduction possible according to the current model, that is, the function reduction predicted for a Newton step: $\Delta x = -H^{-1}g$, where $g = J^{T}R$ is the current gradient and H is the current Hessian approximation:

$H = J^{T}J$ for the Gauss–Newton model

$H = J^{T}J + S$ for the augmented model.

V(NREDUC) = 0 means H is not positive definite.

If V(NREDUC) < 0, then V(NREDUC) is used in the singular convergence test: It is the negative of the function reduction predicted for a step computed with a step bound of V(LMAX0).

V(PREDUC) ... V(7) is the function reduction predicted (by the current quadratic model) for the current step. This (divided by V(F0)) is used in testing for relative function convergence.

V(RADIUS) ... V(8) is the trust region radius (i.e., step bound) used for the last step tried.

V(RELDX) ... V(17) is the scaled relative change in X caused by the current step, Δx, computed as

$$\max_i\{|D(i)[X(i) - X_0(i)]|\}/\max_i\{D(i)[|X(i)| + |X_0(i)|]\},$$

where $X = X_0 + \Delta x$.

3.6 Finite-Difference Jacobians: NL2SNO

Those who do not wish to code a subroutine CALCJ for (analytically) computing the Jacobian matrix may avoid doing so by calling NL2SNO instead of NL2SOL. NL2SNO computes an approximate Jacobian matrix by forward differences (using a step size determined by V(DLTFDJ)—see Section 3.5). The calling sequence for NL2SNO amounts to the one for NL2SOL with CALCJ omitted:

```
CALL NL2SNO (N, P, X, CALCR, IV, V, UIPARM, URPARM, UFPARM)
```

The parameters for NL2SNO are the same as the corresponding ones for NL2SOL, with the minor exception of IV(COVREQ): If IV(COVPRT) = 1 and IV(COVREQ) = 0, then NL2SNO sets IV(COVREQ) to −1; otherwise, it sets IV(COVREQ) to − | IV(COVREQ) | . Thus NL2SNO uses function values only in computing covariance matrices and V(DELTA0) is not used.

3.7 Restarting

After any return with $3 \le$ IV(1) ≤ 11, it is possible to change some of the IV and V input components (such as the convergence tolerances and the iteration and function evaluation limits) and call NL2SOL (or NL2SNO) again with IV(1) unchanged. This causes the algorithm to be resumed at the point where it was interrupted. (It is even possible to save IV, V, and X and then restart in a subsequent run.)

3.8 Scaling

Problems sometimes arise that are poorly scaled in the sense that the various components of X are expressed in widely differing units. With the default choice of the scale vector D (see V(DFAC) and the beginning of Section 3.5), the behavior of NL2SOL is largely insensitive to this kind of poor scaling. On well-scaled problems, the performance of NL2SOL can sometimes be improved by choosing D to be a vector of ones, that is, by setting IV(DTYPE) to 0 and V(DINIT) to 1.0. Occasionally it may also be worthwhile to fix D(i), $1 \le i \le$ P, at the 2-norm of the ith column of the initial Jacobian matrix by setting IV(DTYPE) to 2.

3.9 LMAX0: The Initial Step Bound

On some problems it is necessary to give V(LMAX0) = V(35) a small value to prevent a disasterously large first step, one that might result in exponent overflow or arguments out of range to intrinsic functions. Even if no disaster occurs, if NL2SOL takes a number of function evaluations on the first iteration, then this number can be reduced on subsequent reruns by setting V(LMAX0) to the value in the D*STEP column of the iteration summary for iteration 1.

3.10 Local Solutions

It can easily happen that NL2SOL only finds a local minimizer of the sum-of-squares function F(X) and that a different starting guess would cause a point to be found at which F has a still smaller value. Except for cases where special conditions (such as convexity of the objective function) prevail, this shortcoming is shared by all minimization algorithm implementations.

3.11 Printed Output

Any printing is done by one of two modules: ITSMRY and PARCHK. PARCHK reports any V input components that are out of range and optionally lists any such components that have nondefault or changed values (on a fresh start or restart, respectively). ITSMRY does the remaining printing. Various IV input components control what printing is done; see Section 3.4.

If IV(OUTLEV) > 0, then ITSMRY produces an iteration summary which includes the following values: IT, the current iteration number; NF, the number of function evaluations (calls on CALCR), excluding any extra ones needed for computing covariance matrices and, in the case of NL2SNO, excluding the extra ones needed to compute finite-difference Jacobian matrices; F, the current function value (half the residual sum of squares); RELDF, the relative difference between the previous and the current function value (i.e., the difference in function values divided by the previous function value); PRELDF, the value of RELDF predicted by the quadratic model used to compute the step just taken; RELDX, the relative change in X caused by the step just taken—see V(RELDX) in Section 3.5; MODEL, a code that tells which models were used in choosing the current step (G = the Gauss–Newton model; S = the augmented model; G-S means the Gauss–Newton model was tried first and a switch was then made to the augmented model; S-G, G-S-G, and S-G-S have analogous meanings); STPPAR, the Marquardt parameter λ for the last step, Δx, computed: $\lambda > 0$ means Δx satisfies

$$[H + \lambda \operatorname{diag}(D)^2]\Delta x = -g,$$

where H and g are the old Hessian approximation and gradient, respectively (the ones used in computing the step just taken); SIZE, the sizing factor used in updating the S matrix (see [1]); D*STEP, the 2-norm of diag(D) times the step just taken (see V(DSTNRM) in Section 3.5); and NPRELDF: if NPRELDF > 0, then it is the relative function reduction (i.e., value of RELDF) predicted for a full Newton step; if NPRELDF = 0, then the Hessian approximation failed to be positive definite; and if NPRELDF < 0, then it is the negative of the relative function reduction predicted for a step of length bounded by V(LMAX0). These summary lines are produced every IV(OUTLEV) iterations, and they are 118 characters long (including the carriage control character). If IV(OUTLEV) < 0, then short summary lines are produced every −IV(OUTLEV) iterations; these lines are 79 characters long (55 if IV(COVPRT) = 0), and they include only the first six items listed above (i.e., IT, NF, F, RELDF, PRELDF, and RELDX).

3.12 Changing Computers

The NL2SOL distribution tape contains both single- and double-precision versions of the NL2SOL source code, so it should be unnecessary to change precisions. (On computers having only 32 or 36 bits per REAL word, double precision often gives better performance.)

Only the functions IMDCON and RMDCON contain machine-dependent constants. To change from one computer to another, it should suffice to change the DATA statements in these functions. The DATA statement in IMDCON sets IMDCON(1) to the output unit number that DFAULT supplies to IV(PRUNIT). The machine-dependent DATA statement in RMDCON provides three values: BIG, ETA, and MACHEP. BIG is the largest floating-point number such that a FORTRAN program can compute SQRT(0.999*BIG)**2 (i.e., DSQRT(0.999D0*BIG)**2 in double precision) without overflowing. Similarly, ETA is the smallest floating-point number such that SQRT(1.001*ETA)**2 (or DSQRT(1.001D0*ETA)**2, respectively) does not underflow. MACHEP is the unit roundoff, that is, the smallest floating-point number such that 1 + MACHEP yields a stored floating-point number greater than 1. (Some computers feature registers that carry more bits than can be stored; MACHEP should only reflect the accuracy of numbers that can be stored.) DATA statements giving suitable values for BIG, ETA, and MACHEP for a variety of computers appear as comments in RMDCON.

Intrinsic functions are explicitly declared in the NL2SOL source code. On certain computers (e.g., Univac), it may be necessary to comment out these declarations. So that this may be done automatically by a simple program, such declarations are preceded by a comment having C/+ in columns 1–3 and blanks in columns 4–72 and are followed by a comment having C/ in columns 1 and 2 and blanks in columns 3–72.

3.13 Using Reverse Communication: NL2ITR

Instead of writing subroutines CALCR and CALCJ to compute the residual vector R(X) and Jacobian matrix J(X), one can call NL2ITR and provide R and J by reverse communication. The calling sequence is

```
CALL NL2ITR (D, IV, J, N, NN, P, R, V, X)
```

Parameters IV, N, P, V, and X are the same as the corresponding ones to NL2SOL, with the following exceptions: V need only contain 93 + 2N + P(3P + 31)/2 elements, since the storage that NL2SOL and NL2SNO allocate for D, J, and R at the end of V is not needed; and components IV(D), IV(J), and IV(R) are not referenced. D is the scale vector (dimensioned D(P)). NN is the (integer) lead dimension for the J array, which is dimensioned J(NN, P); NN must satisfy NN $\geq$ N.

When NL2ITR is first called (with IV(1) = 0 or 12), J must have been set to J(X), R to R(X). When NL2ITR wants R to be evaluated at a new X, it returns with IV(1) = 1; the caller should then set R to R(X) (unless X is out of range, in which case the caller should set IV(TOOBIG), that is, IV(2), to 1) and call NL2ITR again. Similarly, when NL2ITR wants J to be evaluated at X, it returns with IV(1) = 2, and the caller should then set J to J(X) and call NL2ITR again. (If J cannot be evaluated at X, the caller may set IV(NFGCAL), that is, IV(7), to 0; this will cause NL2ITR to give the error return IV(1) = 15.)

3.14 STOPX

It is possible to arrange for NL2SOL (NL2SNO and NL2ITR) to be interrupted before each evaluation of R(X) when used in an interactive environment. To do this, it is necessary to replace the logical function STOPX supplied with the NL2SOL package (which always returns .FALSE.) by a system-dependent STOPX that returns .TRUE. if and only if the "break" (i.e., "interrupt") key has been pressed since the last call on STOPX. Once this is done, NL2SOL will return with IV(1) = 11 when the "break" key is pressed before some other return has occurred. It is then possible to change some of the IV and V input components and restart; see Section 3.7.

3.15 Other V Input Values

V(COSMIN) ... V(43) $\in$ [MACHEP, 1] is the minimum absolute cosine allowed between the step just taken, Δx, and the corresponding change in gradients, Δg, for a full update of the S matrix to be made. If $|\Delta x^T \Delta g| / (\|\Delta x\|_2 \cdot \|\Delta g\|_2) <$ V(COSMIN), then $\Delta x^T \Delta g$ is replaced in the update formula by sign $(\Delta x^T \Delta g)$V(COSMIN) $\|\Delta x\|_2 \|\Delta g\|_2$. Default = max{$10^{-6}$, 100 MACHEP}.

V(DECFAC) ... V(22) $\in$ [0.01, 0.8] is the factor by which the trust region radius is shrunk if CALCR sets NF to 0 (or NL2ITR is called with IV(1) = 1 and IV(TOOBIG) = 1). Default = 0.5.

V(EPSLON) ... V(19) $\in$ [0.001, 0.9] is the maximum relative difference allowed between $g^T \Delta x + 1/2 \Delta x^T H \Delta x$ and its optimal value subject to the constraint $\|\text{diag}(D)\Delta x\|_2 \leq$ V(RADIUS), where Δx is the step being computed, g is the current gradient, and H is the current Hessian approximation. This is used in detecting and handling the special case discussed in [2]. Default = 0.1.

V(FUZZ) ... V(45) $\in$ [1.01, 100] is used in the test that decides whether to switch models. If q is the current model for F (near the point X) and $\tilde{q}$ is the other model, and if

$$\text{V(FUZZ)}\,|\tilde{q}(\text{X} + \Delta x) - \text{F}(\text{X} + \Delta x)| < |q(\text{X} + \Delta x) - \text{F}(\text{X} + \Delta x)|,$$

then the models are switched. Default = 1.5.

V(INCFAC) ... V(23) $\in$ [1.2, 100] is the minimum factor by which the trust region radius is increased (when it is increased at all). Default = 2.

V(PHMNFC) ... V(20) $\in$ [−0.99, −0.001] is the minimum value allowed for $[\|\text{diag}(D)\Delta x\|_2 - \text{V(RADIUS)}]/\text{V(RADIUS)}$. Default = −0.1.

V(PHMXFC) ... V(21) $\in$ [1.2, 100] is the maximum value allowed for $[\|\text{diag}(D)\Delta x\|_2 - \text{V(RADIUS)}]/\text{V(RADIUS)}$. Default = 0.1.

V(RDFCMN) ... V(24) $\in$ [0.01, 0.8] is the minimum factor by which the trust region radius, V(RADIUS), may be shrunk. Default = 0.1.

V(RDFCMX) ... V(25) $\in$ [1.2, 100] is the maximum factor by which the trust region radius, V(RADIUS), may be increased at one time. Default = 4.0.

V(RLIMIT) ... V(42) $\geq 10^{10}$ is the largest value allowed for $\|\text{R(X)}\|_2$ before F(X) is considered to overflow. Default = $(0.999 \cdot \text{BIG})^{1/2}$, where BIG is described in Section 3.12.

V(TUNER2) ... V(27) $\in$ [0, 0.5]. For a step to be accepted, the actual function reduction must be more than V(TUNER2) times its predicted value. Default = 0.0001.

V(TUNER3) ... V(28) $\in$ [0.001, 1]. If the actual function decrease is at least V(TUNER3) times the inner product of the step and the gradient (at the start of the step), then the trust region radius is increased. Default = 0.75.

V(TUNER4) ... V(29) $\in$ [−1, 1]. If the disposition of the new radius has not yet been decided and either

$$\|\text{diag}(D)^{-1}[H\Delta x - (g - g_0)]\| < \text{V(TUNER4)}\,\|\text{diag}(D)^{-1} g\|$$

or $g^T \Delta x <$ V(TUNER5) $g_0^T \Delta x$, where Δx is the step just taken, H is the Hessian approximation used in computing Δx, g_0 is the old gradient, g is the new gradient, and D is the newly updated scale vector, then the radius is increased by a factor of V(INCFAC). Otherwise, it is left unchanged. Default = 0.5.

V(TUNER5) ... V(30) $\geq$ MACHEP is described above with V(TUNER4). Default = 0.75.

3.16 Storage Requirements

NL2SOL, NL2SNO, and the subroutines from the NL2SOL package that they call amount to around 2360 FORTRAN statements (including nonexecutable statements, such as type statements, but excluding comments); the many comments bring the source code up to nearly 5200 lines. When compiled by the *H*-extended compiler on the IBM 370/168 at the Massachusetts Institute of Technology, this source code results in about 56,300 bytes of object code. The amount of variable storage used is listed above in Section 3.1.

ALGORITHM 574
Shape-Preserving Osculatory Quadratic Splines [E1, E2]

D. F. McALLISTER
North Carolina State University
and
J. A. ROULIER
University of Connecticut

Key Words and Phrases: polynomial interpolation, osculation, shape preserving, convexity preserving, monotonicity preserving, Bernstein polynomial
CR Categories: 5.18, 8.2
Language: FORTRAN

DESCRIPTION

This algorithm is a FORTRAN implementation for the procedure developed in [3]. Let n data points $\{(x_i, y_i)\}_{i=1}^n$ and n first derivatives $\{m_i\}_{i=1}^n$ at these data points be given, with $x_i \leq x_{i+1}$, $1 \leq i \leq n-1$. The algorithm constructs a smooth osculatory quadratic spline S, which satisfies

(1) $S(x_i) = y_i$, $1 \leq i \leq n$;
(2) $S'(x_i) = m_i$, $1 \leq i \leq n$;
(3) S preserves monotonicity and convexity in the case that the slopes m_i are consistent with the shape of the data;
(4) the knots of the spline S include the data points and at most two additional knots between adjacent data points.

The spline S is a piecewise quadratic Bernstein polynomial with a continuous first derivative.

Subroutine SLOPES

This subroutine will calculate values for the slopes $\{m_i\}_{i=1}^n$, which will always be consistent with the shape of the data and which guarantee that at most one additional knot is required between adjacent data points. This subroutine is called before the main routine MEVAL if the user does not wish to provide these values.

Subroutine MEVAL

The input to MEVAL is the set of data points $\{(x_i, y_i)\}_{i=1}^{n}$, the slopes $\{m_i\}_{i=1}^{n}$, and a vector of abscissas $u = (u_1, \ldots, u_m)$ at which the spline S is to be evaluated. In addition, a nonnegative tolerance parameter EPS must be specified for use by the subroutine CHOOSE to distinguish various cases which the algorithm must consider. This parameter is described later. If an argument u_j is determined by the subroutine SEARCH to lie in the interval $[x_i, x_{i+1}]$, then MEVAL calls the subroutines CHOOSE and CASES, in that order, to compute the parameters of S for the interval. The subroutine then calls a function subprogram SPLINE which evaluates S at the argument u_j. Extrapolation is performed for those components of u that lie outside the interval $[x_1, x_n]$.

On exit from MEVAL the error parameter ERR is zero if processing proceeded normally and no extrapolation was required. ERR is 1 if at least one component of the vector u lies outside the interval $[x_1, x_n]$. A value of 2 indicates that the components of the vector u were not in ascending order, in which case no values of S are returned.

Subroutine SEARCH

This subroutine is a binary search used by MEVAL to locate the interval in which an argument of S lies.

Subroutine CHOOSE

The value of S on an interval $[x_i, x_{i+1}]$ depends only on the points (x_i, y_i) and (x_{i+1}, y_{i+1}) and the slopes m_i and m_{i+1} at these points. The subroutine determines which of Cases 1–4 applies [3]. The tolerance parameter EPS is used by CHOOSE to handle the pathologies that may occur. When the user provides values for the slopes other than those computed by the subroutine SLOPES, small perturbations may cause unwanted changes in the shape of the resulting spline. If the values of m_i or m_{i+1} are relatively close to either the slope S_i of the line joining the points (x_i, y_i) and (x_{i+1}, y_{i+1}) or to $2S_i$, roundoff may affect both the monotonicity and convexity of the spline. For example, if $|M - S_i| \leq \text{EPS}\,|S_i|$ for $M = m_i$ or m_{i+1}, then the algorithm assumes that $M = S_i$ and chooses either Case 2 or Case 3. We avoid Case 1 to preclude a nearly linear spline joining the two data points. Similarly, in order to avoid a spline with sharp bends at the endpoints, if $|m_i| > 2|S_i|$ and $|m_{i+1}| > (2 - \text{EPS})|S_i|$, then the algorithm assumes $|m_{i+1}| > 2|S_i|$ and selects Case 4 rather than Case 3. These choices are for aesthetics only and can easily be overridden by modifying the slopes m_i and m_{i+1} and/or setting EPS to a smaller value. If EPS $\neq 0$, then EPS should be greater than or equal to machine epsilon.

Subroutine CASES

After CHOOSE determines the correct case number, the subroutine CASES calculates the knots and other parameters which define S on the interval $[x_i, x_{i+1}]$. The spline S will have a single knot between x_i and x_{i+1} if NCASE is 1, 2, or 3. Case 4 requires two knots.

Function Subprogram SPLINE

Given the case number determined by CHOOSE and the parameters calculated by CASES, SPLINE determines the location of the argument relative to the knots in the interval and computes $S(u_j)$, which is the value of a quadratic Bernstein polynomial.

ACKNOWLEDGMENTS

The authors would like to thank Steven L. Dodd and Marie Roulier of North Carolina State University for their help in coding the algorithm.

ALGORITHM 575
Permutations for a Zero-Free Diagonal [F1]

I.S. Duff
AERE Harwell, England

Key Words and Phrases: unsymmetric permutations, maximum transversal, maximum assignment, block triangular form, sparse matrices
CR Categories: 5.0, 5.1, 5.3, 5.4
Language: FORTRAN

DESCRIPTION

The subroutine is evoked by the FORTRAN statement

CALL MC21A(N, ICN, LICN, IP, LENR, IPERM, NUMNZ, IW)

where the parameters are described in the listing given here.

Given the pattern of nonzeros of a sparse matrix, this subroutine attempts to find a row permutation that makes the matrix have no zeros on its diagonal. It is possible that the user may input a matrix for which there is no permutation that makes the diagonal zero-free. An example of this is

$$\begin{pmatrix} X & 0 \\ X & 0 \end{pmatrix}$$

In such instances the algorithm will produce a permutation that will put as many nonzeros on the diagonal as possible (1 in the above example). This number will be output in NUMNZ. The array IPERM will still hold a permutation of the integers 1, 2, . . . , N, but in this case N-NUMNZ of the elements (IPERM(I), I) will be zero.

It is envisaged that a common use of the subroutine will be as the first part of a two-stage process for the determination of the block triangular form of a sparse matrix (see, for example, [1]). The second stage could be performed by Harwell subroutine MC13D [4], and the two stages are combined by using subroutine MC23A in the Harwell package MA28 [2].

The subroutine is based on a depth first search with look-ahead technique and is described in detail in [3]. There, numerical results from using this subroutine, which has been tested on a wide range of both structured and randomly generated matrices, are also discussed.

This subroutine has been written in American National Standard FORTRAN. Special comment cards have been included so that Harwell subroutine OE04A can be used to make an IBM FORTRAN version that uses half-length integers (INTEGER*2) for all the arrays except IP. This approximately halves the core requirements at the cost of restricting the order of the system to $2^{15} - 1$.

ALGORITHM 576
A FORTRAN Program for Solving $\mathbf{Ax} = \mathbf{b}$ [F4]

I. BARRODALE
University of Victoria
and
G. F. STUART
Camosun College

Key Words and Phrases: linear equations, Gaussian elimination, new pivoting strategy
CR Categories: 5.13, 5.14
Language: FORTRAN

DESCRIPTION

Given any $n \times n$ system of linear equations

$$\mathbf{Ax} = \mathbf{b} \tag{1}$$

and a number ϵ, the algorithm calculates the solution $\mathbf{x}$ to (1), if $\epsilon \leq 0$, or an approximation solution $\mathbf{x}^{(k)}$ satisfying

$$\| \mathbf{b} - \mathbf{Ax}^{(k)} \|_\infty < \epsilon, \tag{2}$$

if $\epsilon > 0$. Furthermore, if $\mathbf{A}$ appears to be singular, an approximate solution to (1) is still determined, although it does not satisfy (2).

The algorithm consists of Gaussian elimination combined with a new pivoting strategy based on the following fact. Suppose after the kth step ($k = 0, 1, \ldots, n - 1$) of Gaussian elimination that $\mathbf{x}^{(k)} = [x_1^{(k)}, \ldots, x_k^{(k)}, 0, \ldots, 0]^T$ is the approximate solution obtained by back substitution in the first k equations. *Then the right-hand sides of the last $n - k$ equations are the nonzero components of the residual vector* $\mathbf{r}^{(k)} = \mathbf{b} - \mathbf{Ax}^{(k)}$; this is proved in [1]. Our pivoting strategy thus chooses the equation with the absolutely largest residual as the next equation to be eliminated, and the $(k + 1)$th pivot is then selected as the absolutely largest of the $n - k$ coefficients on the left-hand side of the chosen equation. Finally, the pivot is positioned on the principal diagonal by, if necessary, a row interchange and a column interchange.

When $\epsilon > 0$, the algorithm terminates after k Gaussian elimination steps and yields $\mathbf{x}^{(k)}$ by back substitution in the first k equations. Normally, $\mathbf{x}^{(k)}$ has k nonzero components and it satisfies k of the eqs. (1) exactly (ignoring rounding errors). However, if ϵ is a *small* positive number, in order to satisfy (2) it may be necessary to determine the solution $\mathbf{x}$ rather than $\mathbf{x}^{(k)}$: in such a case, k has the value n on output.

Received 13 July 1976, revised 22 April 1980, accepted 13 May 1980.

This work was supported by National Research Council of Canada Grant A-5251.
Authors' addresses: I. Barrodale, Department of Mathematics, University of Victoria, Victoria, B.C., Canada; G.F. Stuart, Camosun College, Victoria, B.C., Canada.

The elimination is performed by subroutine MODGE, which terminates after stage k if there is not a suitably large residual among the remaining $(n - k)$ right-hand sides, or if the coefficient matrix of the remaining $(n - k)$ rows is considered to be singular. The first condition is detected by comparing all residuals with the real input parameter EPS. Hence EPS should be set to a small positive value representing an insignificant residual for cases in which premature termination is sought; otherwise EPS should be set less than or equal to zero. The second premature termination condition is controlled by the real input parameter TOLER. The equation with the absolutely largest residual is rejected as the pivot row if the absolute value of the pivot is not greater than TOLER. In this case complete pivoting is performed during the $(k + 1)$th stage. However, if this produces no pivot greater in absolute value than TOLER, the elimination is terminated and an approximate solution is determined by back substitution in the first k equations.

The algorithm can thus be applied to any $n \times n$ system of linear equations, although it is particularly well suited to problems where the residuals (right-hand sides) can be made small by solving for fewer than n of the unknowns. Interpolation problems are often of this type, since some of the parameters x_j frequently turn out to be quite small in practice. Also, ill-conditioned (and even singular) systems of equations can often be handled satisfactorily by choosing appropriate values for EPS and TOLER (see Examples 3 and 4).

The accuracy of a computed solution to $\mathbf{Ax} = \mathbf{b}$ can usually be increased by iterative improvement, and subroutine REFINE is supplied for this purpose. A feature of this subroutine is that the $(t + 1)$th residual vector $\mathbf{r}_{t+1}$ is computed as

$$\mathbf{r}_{t+1} = \mathbf{r}_t - \mathbf{A}\mathbf{x}_t, \qquad t = 0, 1, 2, \ldots \tag{3}$$

where the residual $\mathbf{r}_t$ and the computed solution $\mathbf{x}_t$ are taken from the previous iteration, and $\mathbf{r}_0 = \mathbf{b}$. (It has been our experience that (3) permits better control of convergence than the more usual computation $\mathbf{r}_{t+1} = \mathbf{b} - \mathbf{A}(\mathbf{x}_0 + \mathbf{x}_1 + \cdots + \mathbf{x}_t)$.) In this subroutine the output parameter DIGITS is used to estimate (usually fairly conservatively) the number of significant digits in the initial solution $\mathbf{x}_0$. Basically, this is determined as $\log_{10} D$, where $D = \min_i |x_{0,i}/x_{1,i}|$, excluding values of i for which $x_{0,i} = 0$ or $x_{1,i} = 0$. However, if the quantity $\log_{10} D$ is greater than $\log_{10}(1/E)$, where $E = \max(\text{ERR}, 10^{-d})$ and d represents the number of decimal digits of accuracy available on the computer, then DIGITS is set equal to $\log_{10}(1/E)$ rather than $\log_{10} D$.

The following four examples were solved on an IBM 370/148 using a WATFIV compiler. All of the computations were performed in single-precision arithmetic (about 7 decimal digits) apart from the calculation of the residuals (3), which were formed in double-precision arithmetic and then assigned to a single-precision vector.

Example 1. Determine parameters x_1, x_2, and x_3 such that the quadratic polynomial $x_1 + x_2 t + x_3 t^2$ interpolates the data {(1, 89), (4, 209), (5, 201)}. Equivalently, solve the 3×3 system of linear equations

$$\begin{bmatrix} 1 & 1 & 1 \\ 1 & 4 & 16 \\ 1 & 5 & 25 \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \\ x_3 \end{bmatrix} = \begin{bmatrix} 89 \\ 209 \\ 201 \end{bmatrix}.$$

This example is used in [1] to illustrate our algorithm: the exact solution is $x_1 = 1$, $x_2 = 100$, and $x_3 = -12$.

Setting EPS = 0 and TOLER = 10^{-6}, subroutine MODGE gives $x_1 = 1.000010$, $x_2 = 99.99998$, and $x_3 = -11.99999$.

Setting EPS = 1 and TOLER = 10^{-6}, subroutine MODGE terminates after two Gaussian elimination steps and gives $x_1 = 0$, $x_2 = 100.4500$, and $x_3 = -12.04999$.

Example 2. Determine $x_1, x_2, \ldots, x_5$ such that the function $x_1 t + x_2 t^2 + x_3 t^3 + x_4 t^4 + x_5 t^5$ interpolates te^{-t} for $t = 0.25(0.25)1.25$. Equivalently, solve $\mathbf{Ax} = \mathbf{b}$ where

$$\mathbf{A} = \begin{bmatrix} 0.25 & 0.25^2 & \cdots & 0.25^5 \\ 0.50 & 0.50^2 & \cdots & 0.50^5 \\ 0.75 & 0.75^2 & \cdots & 0.75^5 \\ 1.00 & 1.00^2 & \cdots & 1.00^5 \\ 1.25 & 1.25^2 & \cdots & 1.25^5 \end{bmatrix} \quad \text{and} \quad \mathbf{b} = \begin{bmatrix} 0.25e^{-0.25} \\ 0.50e^{-0.50} \\ 0.75e^{-0.75} \\ 1.00e^{-1.00} \\ 1.25e^{-1.25} \end{bmatrix}.$$

Generating the elements of **A** and **b** within the computer (rather than reading them in as data), and setting EPS = 0 and TOLER = 10^{-6}, subroutine MODGE gives $x_1 = 0.9994718$, $x_2 = -0.9950786$, $x_3 = 0.4832436$, $x_4 = -0.1396533$, and $x_5 = 0.01989542$. (This solution contains almost one extra significant digit than the solution that can be obtained from Gaussian elimination with partial pivoting, using the modified version [3] of the subroutines in [2].) Iterative improvement is then applied to this initial solution.

Setting ERR = 10^{-7} and ITER = 14, subroutine REFINE converges after two iterations to $x_1 = 0.9994708$, $x_2 = -0.9950703$, $x_3 = 0.4832247$, $x_4 = -0.1396357$, and $x_5 = 0.01988983$. The output parameter DIGITS indicates that the initial solution contains approximately 3.6 significant digits.

Example 3. Determine $x_1, x_2, \ldots, x_9$ such that the function $x_1 + x_2t + x_3(t-1) + x_4t^2 + x_5(t^2 - t) + x_6t^3 + x_7(t^3 - t^2) + x_8t^4 + x_9(t^4 - t^3)$ interpolates e^t for $t = 0(0.125)1$.

Setting EPS = TOLER = 10^{-6}, subroutine MODGE gives $x_1 = 0.9999993$, $x_2 = 0.9994056$, $x_3 = 0$, $x_4 = 0.5071687$, $x_5 = x_6 = x_7 = 0$, $x_8 = 0.2117074$, and $x_9 = -0.1439046$. The output parameters OCODE and PIVOT have the values 3 and 2, respectively, indicating that the computation was terminated prematurely because a pivot was chosen (by complete pivoting) whose magnitude is less than TOLER.

Setting ERR = 10^{-7} and ITER = 14, subroutine REFINE converges after two iterations to $x_1 = 1.000000$, $x_2 = 0.9994109$, $x_4 = 0.5071452$, $x_8 = 0.2117255$, and $x_9 = -0.1439375$. DIGITS has the value 3.6 on output.

Example 4. Determine $x_1, x_2, \ldots, x_{32}$ such that the function

$$P(s, t) = x_1 + \sum_{j=1}^{15} (x_{2j} \operatorname{Re}(z^j) + x_{2j+1} \operatorname{Im}(z^j)) + x_{32} \operatorname{Re}(z^{16}),$$

where $z = s + it$, interpolates $Q(s, t) = e^{s^2 - st + 2t^2}$ on the 32 points (s, t) for which $s = 0(0.125)1$, $t = 0(0.125)1$. This problem arises when attempting to solve approximately the Dirichlet problem for Laplace's equation on a unit square with boundary value Q. The coefficients x_j of the harmonic polynomial P are determined by collocation, that is, by requiring that $P = Q$ on the 32 specified boundary points. (We arranged the resulting 32 linear equations in order by proceeding in an anticlockwise direction around the boundary of the square, starting from the origin.)

Setting EPS = 0 and TOLER = 10^{-6}, subroutine MODGE gives an initial solution containing *no* significant digits: many of the 32 computed coefficients x_j have exponents of size 10^3 or 10^4 and only eight coefficients have magnitudes less than 20. (The initial solution that can be obtained from Gaussian elimination with partial pivoting also contains no significant digits.) Setting ERR = 10^{-7} and ITER = 14, subroutine REFINE diverges, that is, all 14 iterations are performed without improvement in the accuracy of the coefficients x_j. The output parameter DIGITS has a *negative* value, clearly indicating that the initial solution contains no significant digits.

However, setting EPS = 0.05 and TOLER = 10^{-6}, subroutine MODGE terminates after 22 Gaussian elimination steps and gives an initial approximate solution in which 10 coefficients are set to zero and the remaining 22 coefficients vary from a minimum of $x_{27} = -9.698888$ to a maximum of $x_{29} = 12.78670$. Setting ERR = 10^{-7} and ITER = 14, subroutine REFINE converges after three iterations: in this final solution $x_{27} = -9.699727$ and $x_{29} = 12.78701$. The output parameter

DIGITS indicates that the initial approximate solution contains approximately 2.9 significant digits.

This example illustrates how our algorithm can be used to produce a meaningful approximate solution to a system of linear equations whose numerical solution may be difficult to determine. The harmonic polynomial P^*, say, given by the above approximate solution satisfies $\| Q - P^* \|_\infty \leq 0.05$ on the 32 specified boundary bounds, and a fine grid search establishes that $\| Q - P^* \|_\infty \doteq 0.06$ on the complete boundary. By the maximum principle, it follows that the latter inequality also applies on the whole square.

ACKNOWLEDGMENTS

We wish to thank both the referees for their constructive criticisms of this paper and Mr. K.B. Wilson for his programming assistance.

```
      SUBROUTINE MODGE(N, NDIM, A, B, EPS, TOLER, P, Q, Z,
     * X, K, OCODE, OPIVOT)
C THIS SUBROUTINE SOLVES ANY N-BY-N SYSTEM OF LINEAR
C EQUATIONS AX=B, USING A MODIFICATION OF GAUSSIAN
C ELIMINATION. THE MODIFICATION OCCURS IN THE CHOICE OF
C PIVOTS: AT EACH STAGE THE PIVOT ROW IS DETERMINED BY THE
C ABSOLUTELY LARGEST RESIDUAL (RIGHT HAND SIDE), AND THEN
C THE PIVOT IS CHOSEN AS THE ABSOLUTELY LARGEST COEFFICIENT
C IN THE PIVOT ROW. THE PIVOT IS POSITIONED ON THE PRINCIPAL
C DIAGONAL BY (IF NECESSARY) A ROW INTERCHANGE AND A COLUMN
C INTERCHANGE.
C
C IF AFTER THE K-TH STAGE THE LARGEST RESIDUAL IS TOO SMALL
C (.LT.EPS), THE ELIMINATION IS TERMINATED. BACK
C SUBSTITUTION IS THEN USED TO OBTAIN AN APPROXIMATE
C SOLUTION WHICH SATISFIES THE FIRST K EQUATIONS.
C
C IF THE (K+1)-TH PIVOT IS TOO SMALL (.LE.TOLER), THE
C ELIMINATION IS TERMINATED. BACK SUBSTITUTION IS THEN USED
C TO OBTAIN AN APPROXIMATE SOLUTION WHICH SATISFIES THE
C FIRST K EQUATIONS.
C
C DESCRIPTION OF PARAMETERS:
C N       AN INTEGER DENOTING THE NUMBER OF EQUATIONS
C         (N.GE.1).
C NDIM    AN INTEGER PARAMETER FOR ADJUSTABLE DIMENSIONS
C         (NDIM.GE.N).
C A       A REAL ARRAY OF NDIM ROWS AND AT LEAST N
C         COLUMNS WHICH ON ENTRY MUST CONTAIN THE COEFFICIENT
C         MATRIX A IN ITS FIRST N ROWS AND N COLUMNS.
C         ON EXIT THE FIRST K ROWS AND K COLUMNS (K.LE.N) OF
C         A CONTAIN THE LU DECOMPOSITION OF THE K EQUATIONS
C         SATISFIED.
C B       A REAL ARRAY OF DIMENSION AT LEAST N WHICH
```

```
C          ON ENTRY MUST CONTAIN IN POSITIONS 1 TO N THE RIGHT
C          HAND SIDE VECTOR B.
C          ON EXIT THE POSITIONS K+1 TO N CONTAIN THE RESIDUALS
C          OF THE UNSATISFIED EQUATIONS.
C EPS      A REAL INPUT TOLERANCE. IF THE (ABSOLUTELY) LARGEST
C          RESIDUAL AT ANY STAGE OF THE ELIMINATION IS LESS
C          THAN EPS THEN THE ELIMINATION IS TERMINATED AND
C          BACK SUBSTITUTION COMMENCES. PREMATURE TERMINATION
C          OF THIS TYPE CAN BE AVOIDED BY SETTING EPS TO ZERO.
C TOLER    A REAL POSITIVE INPUT TOLERANCE. IF THE ABSOLUTE
C          VALUE OF THE PIVOT AT ANY STAGE OF THE ELIMINATION
C          IS LESS THAN OR EQUAL TO TOLER, THEN COMPLETE
C          PIVOTING IS USED FOR THIS STAGE. IF THE ABSOLUTE
C          VALUE OF THE NEW PIVOT IS LESS THAN OR EQUAL TO
C          TOLER, THE REMAINING EQUATIONS ARE CONSIDERED
C          TO BE LINEARLY DEPENDENT, AND SO THE ELIMINATION
C          IS TERMINATED AND BACK SUBSTITUTION COMMENCES.
C          TOLER SHOULD NORMALLY BE SET TO APPROXIMATELY
C          10**(-D+1), WHERE D REPRESENTS THE NUMBER OF
C          DECIMAL DIGITS OF ACCURACY AVAILABLE. HOWEVER,
C          PROBLEMS WHICH ARE NOT 'REASONABLY SCALED'
C          BEFOREHAND COULD REQUIRE A MUCH LARGER OR
C          SMALLER VALUE FOR TOLER THAN IS RECOMMENDED
C          HERE.
C P        AN INTEGER ARRAY OF DIMENSION AT LEAST N USED TO
C          RECORD COLUMN INTERCHANGES OF THE ARRAY A.
C          ON EXIT P(I) IS THE INDEX OF THE ORIGINAL POSITION
C          OF COLUMN I.
C Q        AN INTEGER ARRAY OF DIMENSION AT LEAST N USED TO
C          RECORD ROW INTERCHANGES OF THE ARRAYS A AND B.
C          ON EXIT Q(I) IS THE INDEX OF THE ORIGINAL POSITION
C          OF ROW I.
C Z        A REAL WORK SPACE ARRAY OF DIMENSION AT LEAST N.
C X        A REAL OUTPUT ARRAY OF DIMENSION AT LEAST N
C          WHICH CONTAINS THE SOLUTION (IN CORRECT ORDER) OF
C          THE N LINEAR EQUATIONS IN POSITIONS 1 TO N.
C          IF THE SOLUTION IS OBTAINED USING LESS THAN N
C          EQUATIONS, THEN THE REMAINING COMPONENTS OF X ARE
C          SET TO ZERO.
C K        AN INTEGER WHICH ON OUTPUT DENOTES THE NUMBER OF
C          EQUATIONS SATISFIED (K.LE.N).
C OCODE    AN INTEGER EXIT CODE WITH VALUES:
C            0- EITHER N.LE.0 OR (N.EQ.1 AND A(1,1).EQ.0).
C            1- THE SYSTEM AX=B IS SOLVED.
C            2- THE ELIMINATION IS TERMINATED BY USE OF
C               EPS (SMALL RESIDUAL).
C            3- THE ELIMINATION IS TERMINATED BY USE OF
C               TOLER (SMALL PIVOT).
C OPIVOT AN INTEGER EXIT CODE WITH VALUES:
C            1- COMPLETE PIVOTING IS NOT EMPLOYED.
C            2- COMPLETE PIVOTING IS EMPLOYED, HENCE SMALL
C               RESIDUALS (.LT.EPS) MAY HAVE BEEN ALLOWED.
C
C AN IMPLEMENTATION NOTE:
C IF YOUR FORTRAN COMPILER PERMITS A SINGLE COLUMN OF A TWO
C DIMENSIONAL ARRAY TO BE PASSED TO A ONE DIMENSIONAL ARRAY
C THROUGH A SUBROUTINE CALL, CONSIDERABLE SAVINGS IN
C EXECUTION TIME MAY BE ACHIEVED BY USING SUBROUTINE
C SAXPY (SEE A.C.M. TRANSACTIONS ON MATHEMATICAL
C SOFTWARE VOL.5 NUM.3 1979 PP.308-323)
      SUBROUTINE REFINE(N, NDIM, A, B, ALU, P, Q, KMAX,
     * ERR, R, S, XNEW, DX, X, ITER, DIGITS)
C THIS SUBROUTINE PERFORMS ITERATIVE IMPROVEMENT ON THE
C COMPUTED SOLUTION X OBTAINED FROM SUBROUTINE MODGE.
C THE ITERATIONS CONTINUE UNTIL EITHER THE CORRECTIONS
C TO X ARE NEGLIGIBLE, I.E. CONVERGENCE OCCURS (SEE
C DESCRIPTION OF ERR), OR UNTIL COMPLETION OF THE
C MAXIMUM NUMBER OF ITERATIONS ALLOWED (ITER).
C
C THE FOLLOWING TABLE GIVES THE CORRESPONDENCE BETWEEN THE
C OUTPUT PARAMETERS OF MODGE AND THE INPUT PARAMETERS OF
```

```
C REFINE:
C         NAME ON OUTPUT FROM MODGE:  NAME ON INPUT TO REFINE:
C         N                           N
C         NDIM                        NDIM

C         X                           X
C
C DESCRIPTION OF PARAMETERS:
C N       AN INTEGER DENOTING THE NUMBER OF EQUATIONS
C         (N.GE.1).
C NDIM    AN INTEGER PARAMETER FOR ADJUSTABLE DIMENSIONS
C         (NDIM.GE.N).
C A       A REAL ARRAY OF NDIM ROWS AND AT LEAST N COLUMNS
C         WHICH ON ENTRY MUST CONTAIN THE COEFFICIENT
C         MATRIX A IN ITS FIRST N ROWS AND N COLUMNS.
C         A IS NOT ALTERED BY REFINE.
C B       A REAL ARRAY OF DIMENSION AT LEAST N WHICH ON
C         ENTRY MUST CONTAIN IN POSITIONS 1 TO N THE RIGHT
C         HAND SIDE VECTOR B.  B IS NOT ALTERED BY REFINE.
C ALU     THE REAL OUTPUT ARRAY A OF SUBROUTINE MODGE.  ALU IS
C         NOT ALTERED BY REFINE.
C P       AN INTEGER ARRAY OF DIMENSION AT LEAST N, USED
C         TO RECORD COLUMN INTERCHANGES OF THE ARRAY A.
C         P IS THE OUTPUT ARRAY P OF SUBROUTINE MODGE.
C Q       AN INTEGER ARRAY OF DIMENSION AT LEAST N, USED
C         TO RECORD ROW INTERCHANGES OF THE ARRAYS A AND B.
C         Q IS THE OUTPUT ARRAY Q OF SUBROUTINE MODGE.
C KMAX    THE INTEGER OUTPUT PARAMETER K OF MODGE.
C ERR     A REAL INPUT PARAMETER USED TO TEST FOR
C         CONVERGENCE.  ERR SHOULD NOT BE LESS THAN 10**(-D),
C         WHERE D REPRESENTS THE NUMBER OF DECIMAL DIGITS
C         OF ACCURACY AVAILABLE.
C         THE CONVERGENCE CRITERION IS:
C         EXIT IF THE FOLLOWING RELATIONSHIP IS TRUE FOR
C         ALL I=1 TO KMAX:
C         ABS(DX(I)).LE.ABS(ERR*X(I)).OR.X(I).EQ.0.0 .
C R       A REAL WORK SPACE ARRAY OF DIMENSION AT LEAST N.
C         (USED BY REFINE TO CALCULATE THE RESIDUALS AT EACH
C         ITERATION.)
C S       A REAL WORK SPACE ARRAY OF DIMENSION AT LEAST N.
C         (USED BY REFINE TO CALCULATE THE CORRECTIONS, DX,
C         AT EACH ITERATION.)
C XNEW    A REAL WORK SPACE ARRAY OF THE SAME DIMENSION AS X.
C DX      A REAL WORK SPACE ARRAY OF DIMENSION AT LEAST N.
C         (USED BY REFINE TO CALCULATE A CORRECTION TO X
C         AT EACH ITERATION.)
C X       THE REAL OUTPUT ARRAY X OF SUBROUTINE MODGE.
C         ON EXIT X CONTAINS (USUALLY) A BETTER SOLUTION
C         TO THE LINEAR SYSTEM AX=B.
C ITER    AN INTEGER DENOTING, ON INPUT, THE MAXIMUM NUMBER
C         OF ITERATIONS OF ITERATIVE IMPROVEMENT ALLOWED.
C         ITER SHOULD NOT EXCEED 2*D, WHERE D REPRESENTS
C         THE NUMBER OF DECIMAL DIGITS OF ACCURACY AVAILABLE.
C         ON OUTPUT ITER IS THE ACTUAL NUMBER OF ITERATIONS
C         COMPLETED.
C DIGITS A REAL PARAMETER WHICH ON OUTPUT INDICATES THE
C         APPROXIMATE NUMBER OF SIGNIFICANT DIGITS IN THE
C         INITIAL SOLUTION (I.E.  THE SOLUTION FROM
C         MODGE).
```

ALGORITHM 577
Algorithms for Incomplete Elliptic Integrals [S21]

B. C. CARLSON and ELAINE M. NOTIS
Iowa State University

Key Words and Phrases: elliptic integrals, logarithms, inverse circular functions, inverse hyperbolic functions, *R*-functions
CR Categories: 5.12
Language: FORTRAN

DESCRIPTION

Robust and highly portable FORTRAN programs, implementing algorithms proved in [1], are presented for the symmetric elliptic integral of the first kind,

$$R_F(x, y, z) = \frac{1}{2}\int_0^\infty [(t + x)(t + y)(t + z)]^{-1/2}\, dt, \tag{1}$$

and a symmetric elliptic integral of the third kind,

$$R_J(x, y, z, \rho) = \frac{3}{2}\int_0^\infty [(t + x)(t + y)(t + z)]^{-1/2}(t + \rho)^{-1}\, dt. \tag{2}$$

All arguments are nonnegative, and if $x = 0$, the integrals are complete. The accessible range of argument values can be extended beyond the range admissible in the programs by using homogeneity:

$$R_F(kx, ky, kz) = k^{-1/2}R_F(x, y, z), \qquad R_J(kx, ky, kz, k\rho) = k^{-3/2}R_J(x, y, z, \rho).$$

The range of function values is indicated by

$$M^{-1/2} \le R_F(x, y, z) < 2m^{-1/2}, \qquad M_1^{-3/2} \le R_J(x, y, z, \rho) < 5m_1^{-3/2},$$
$$M = \max\{x, y, z\}, \qquad M_1 = \max\{M, \rho\},$$
$$m = \min\{x + y, x + z, y + z\}, \qquad m_1 = \min\{m, \rho\}.$$

Enough simplifications occur in degenerate cases to justify separate programs for

$$R_C(x, y) = R_F(x, y, y) \quad \text{and} \quad R_D(x, y, z) = R_J(x, y, z, z). \tag{3}$$

Received 21 September 1979, revised 17 March 1980, accepted 9 April 1980.

This work was supported by the U.S. Department of Energy, Division of Basic Energy Sciences, under Contract W-7405-Eng-82.
This work was presented at the 1979 SIAM Spring Meeting, Toronto, Ont., Canada, June 12, 1979.
Authors' address: Department of Mathematics, Iowa State University, Ames, IA 50011.

The latter is an integral of the second kind, while R_C is an elementary function from which inverse circular functions can be computed if $x < y$ and logarithms or inverse hyperbolic functions if $x > y$ (see [1] for explicit formulas). The subroutine RJ calls RC in each cycle of iteration. All four subroutines proceed by successive applications of the duplication theorem, followed by expansion in Taylor series to fifth order. The programs require little space, convergence is linear but quite fast, serious cancellations do not occur, and accuracy is adjustable.

Legendre's elliptic integrals can be computed from these functions, but enumeration of cases is avoided (because of symmetry) by expressing a given elliptic integral directly in terms of R_F, R_D, and R_J. Compact tables of elliptic integrals in terms of these functions are being prepared (e.g., see [2]).

The codes have been verified by PFORT, but fall short of complete portability because they involve two machine-dependent constants, LOLIM and UPLIM, which define the range of admissible arguments. No argument may be greater than UPLIM. The role of LOLIM is less simple, but in most cases it is a lower bound for the sum of two arguments. For R_C and R_F, which are homogeneous of degree $-\frac{1}{2}$, LOLIM and UPLIM differ from the machine minimum and maximum, respectively, by a factor of only 5. For R_D and R_J, which are homogeneous of degree $-\frac{3}{2}$, the limits are inevitably much more restrictive. Values of LOLIM and UPLIM are suggested in the program comments for several types of computers, and formulas are given for use with other machines. A larger (smaller) value of LOLIM (UPLIM) may be used with no ill effects, except that the range of valid arguments will be narrowed. Since the subroutine RJ calls RC, the values of LOLIM and UPLIM for the two programs must be coordinated as specified in the comments.

Our codes have been modified by Dr. J.L. Schonfelder for inclusion in a future edition of the NAG library, and in the case of RC and RF his versions admit all machine-representable arguments. He uses LOLIM and UPLIM to define various regions in which different scaling procedures are used. This entails a significant elaboration of the codes, but will be valuable for users who need to work near the fringes of machine representability.

The accuracy of each program is controlled by a variable called ERRTOL, which determines the maximum error committed in truncating a Taylor series at terms of fifth order. If lower precision is sufficient, a larger value of ERRTOL will speed up the program by requiring fewer iterations of the duplication theorem before computing the Taylor series. Decreasing ERRTOL by a factor of 10 yields six more decimal digits of accuracy at the expense of one or two more iterations. More precisely, decreasing ERRTOL by a factor of 4 requires one more iteration and reduces the error ultimately by a factor of $4^6 = 4096$. Since required accuracy may vary from one run to another, ERRTOL is treated as an input variable. (Its value is set automatically when RC is called by RJ.) On the other hand, LOLIM and UPLIM are set within each subroutine because they will usually be fixed once and for all at a given installation. An exception to the last statement occurs because UPLIM in the case of RD depends on ERRTOL (essentially because the number of iterations depends on ERRTOL, and underflow in computing SIGMA becomes more likely in successive iterations as POWER4 decreases). For nearly all purposes ERRTOL may be replaced by 10^{-5} in the formula for UPLIM, but users who need to admit very large arguments or who want 30 decimal digits of accuracy without losing robustness should recompute UPLIM from the value actually used for ERRTOL.

The programs have been tested for robustness on an ITEL AS/6 computer by running them at extreme points of the region of valid arguments (such as $X = 0$ and $Y =$ UPLIM in the case of RC). In order to achieve robustness the Taylor series given in [1] had to be rearranged in terms of elementary symmetric functions because underflows occurred in computing the power sums $s_n^{(m)}$. By means of [1, e.g., (5.10)] the series in [1, eq. (2.5)] becomes

$$1 - \tfrac{1}{10}E_2 + \tfrac{1}{14}E_3 + \tfrac{1}{24}E_2^2 - \tfrac{3}{44}E_2E_3 + r_n, \tag{4}$$

where E_r is the elementary symmetric function (see [1, Appendix]) of degree r in X_n, Y_n, Z_n. Similarly, the series in [1, (2.19) and (2.27)] become

$$1 - \tfrac{3}{14}E_2 + \tfrac{1}{6}E_3 - \tfrac{3}{22}E_4 + \tfrac{9}{88}E_2^2 + \tfrac{3}{26}E_5 - \tfrac{9}{52}E_2E_3 + r_n, \tag{5}$$

where E_r is an elementary symmetric function of X_n, Y_n, Z_n, P_n, P_n for the case of [1, (2.19)] and X_n, Y_n, Z_n, Z_n, Z_n for [1, (2.27)]. In all cases, $E_1 = 0$.

Some check values are

$$\begin{aligned} R_C(0, \tfrac{1}{4}) &= R_C(\tfrac{1}{16}, \tfrac{1}{8}) = \pi, \\ R_C(\tfrac{9}{4}, 2) &= \log_e 2, \\ R_F(0, 1, 2) &= A = 1.31102\ 87771\ 46059\ 90523\ 24198, \\ R_D(0, 2, 1) &= 3B = 3\pi/4A = 1.79721\ 03521\ 03388\ 31115\ 98837, \\ R_J(2, 3, 4, 5) &= 0.14297\ 57966\ 71567\ 53833\ 23308. \end{aligned} \tag{6}$$

The lemniscate constants A and B are given to 50D in [3]. Consistency checks are provided in the program comments. Values of $(\log x)/(x - 1)$ and $\arctan x$ computed from library routines for the AS/6 computer agree well with those computed from RC, usually to within four units in the last (sixteenth) decimal place. There is similar agreement between RF and the FUNPACK routine for the complete elliptic integral $K(k)$. Because of homogeneity a substantially wider range of values of k^2 can be used with RF than with FUNPACK.

ACKNOWLEDGMENTS

We are grateful for helpful comments and suggestions from J.L. Schonfelder and Edward W. Ng. An important misprint was pointed out by Wayne Fullerton. We owe an exceptional debt to Robert L. Pexton for his interest, encouragement, and unselfish help. He ran many tests on a CDC 7600, and his excellent suggestions and advice have made the programs far better than they would otherwise have been.

Solution of Real Linear Equations in a Paged Virtual Store [F4]

J. J. DU CROZ and S. M. NUGENT
NAG Central Office, England
J. K. REID
AERE Harwell, England
and
D. B. TAYLOR
University of Edinburgh, Scotland

Key Words and Phrases: Gaussian elimination, paged virtual store
CR Categories: 5.14
Language: FORTRAN

DESCRIPTION

BLCFAC is a routine for performing Gaussian elimination with partial pivoting on a real square matrix A, with the operations on blocks of consecutive columns grouped together to minimize the number of page swaps on a machine with a paged virtual store, as described in [1]. Given that A has been factorized by BLCFAC, the routine BLCSOL will solve either of the systems

$$AX = B$$

or

$$A^{T}X = B$$

with multiple right-hand sides. The operations on blocks of consecutive right-hand sides are grouped together for the same reason. BLCFAC and BLCSOL are essentially the same as the routines F01BTF and F04AYF in the NAG FORTRAN Library.

The routines need two environmental parameters, which are supplied in the functions SRELPR and NSACT. SRELPR is the relative precision, as defined in [2]; NSACT is the target active set size in real storage units. The choice of a suitable value, which depends on the particular machine, is discussed in Section 4 of [1]. The value zero is suitable on nonpaged machines.

Received 16 October 1980; revised 9 March 1981; accepted 30 April 1981

Authors' addresses: J.J. Du Croz and S.M. Nugent, NAG Central Office, 7 Banbury Road, Oxford, Oxon., England; J.K. Reid, Computer Science and Systems Division, Building 8.9, AERE Harwell, Didcot, Oxon., England; D.B. Taylor, Regional Computing Centre, University of Edinburgh, Edinburgh, Scotland.

DOCUMENTATION

The routines are fully documented by embedded comments.

EXAMPLE

To solve the set of linear equations $Ax = b$, where

$$A = \begin{bmatrix} 3 & -6 & 12 & 3 \\ -1 & 4 & -10 & -1 \\ 4 & -13 & 30 & 2 \\ 2 & -11 & 30 & 7 \end{bmatrix} \quad \text{and} \quad b = \begin{bmatrix} -3 \\ 1 \\ -9 \\ 9 \end{bmatrix}$$

```
      INTEGER I, IA, IB, IFAIL, IR, J, N, NIN, NOUT
      LOGICAL TRANS
      REAL A(5, 5), B(5), P(5)
      DATA NIN /5/, NOUT /6/
      N = 4
      READ (NIN, 99999) ((A(I, J), J = 1, N), I = 1, N)
      IA = 5
      IFAIL = 1
C     GAUSSIAN ELIMINATION
      CALL BLCFAC(N, A, IA, P, IFAIL)
      IF (IFAIL.EQ.0) GO TO 20
      WRITE (NOUT, 99998) IFAIL
      STOP
   20 IR = 1
      TRANS = .FALSE.
      READ (NIN, 99999) (B(I), I = 1, N)
      IB = 5
C     APPROXIMATE SOLUTION OF LINEAR EQUATIONS
      CALL BLCSOL(N, IR, TRANS, A, IA, P, B, IB, IFAIL)
      WRITE (NOUT, 99997) (B(I), I = 1, N)
      STOP
99999 FORMAT (4F5.0)
99998 FORMAT (25H0ERROR IN BLCFAC IFAIL = , I2)
99997 FORMAT (10H0SOLUTIONS/(1H , F4.1))
      END
```

The following are suitable data:

```
 3   -6   12   3
-1    4  -10  -1
 4  -13   30   2
 2  -11   30   7
-3    1   -9   9
```

and the following results should be obtained:

```
SOLUTIONS
-1.0
 3.0
 1.0
 2.0
```

ALGORITHM 579
CPSC: Complex Power Series Coefficients [D4]

BENGT FORNBERG
California Institute of Technology

Key Words and Phrases: numerical differentiation, Taylor series coefficients, analytic functions
CR Categories: 5.16
Language: FORTRAN

DESCRIPTION

An algorithm CPSC is presented here. It evaluates numerically the leading coefficients in a power series expansion of an analytic function (or, equivalently, a number of leading derivatives of an analytic function). A detailed description of the theoretical background of the code is given in [1], together with some warnings about cases in which full accuracy may not be reached.

Such cases are

(1) very low-order polynomials (for example, $f(z) = 1 + z$);
(2) functions whose Taylor expansions contain very large isolated terms (for example, $f(z) = 10^6 + (1/(1 - z))$);
(3) certain entire functions (for example, $f(z) = e^z$);
(4) functions whose radius of convergence is limited by a branch point at which the function remains many times differentiable (for example, $f(z) = (1 + z)^{10} \log(1 + z)$ expanded around $z = 0$).

In the case 1, the routine will normally fail to even approximate the correct answer. In cases 2, 3, and 4, problems are normally encountered only if large numbers of coefficients are wanted (e.g., more than 30). The supplied error estimate will, in most of these cases, give correct information about the lowered accuracy.

Inevitably there is a risk that the routine will attempt to evaluate the given function exactly at a singularity. This will happen, for example, for $f(z) = 1/(1 - z)$ expanded around zero if the initial radius is of the form $r = 2^p$, with p any integer. The risk for such exact coincidences in floating point can be minimized by choosing "irregular" initial radii. A practical procedure may be to start each case by the obtained final radius from a previous case.

Received 28 August 1978; revised 6 February 1980; accepted 19 June 1981

This work was supported by Control Data Corporation and by the Department of Energy (Office of Basic Energy Sciences).

ALGORITHM

The user must enter the machine accuracy in a data statement. The routine adjusts the calculations accordingly in order to obtain the best possible accuracy. However, since a few decimal places are always lost in this routine, we do not recommend its general use if the machine accuracy is less than 10 significant decimal places. For example, for use on IBM System 370 machines, we recommend double or quadruple precision. The code below is for IBM double precision.

ALGORITHM 580
QRUP: A Set of FORTRAN Routines for Updating QR Factorizations [F5]

A. BUCKLEY
Concordia University, Canada

Key Words and Phrases: matrix factorization, orthogonalization
CR Categories: 5.14
Language: FORTRAN

DESCRIPTION

This algorithm is a translation into FORTRAN of the ALGOL routines published by Daniel et al. [2]. Given an $m \times n$ matrix A with $m \geq n$, these routines compute a QR factorization of A based on the Gram–Schmidt orthogonalization process, and they provide for updating the factorization when rows or columns are added to or deleted from A. Also the factors may be updated when A is modified by the addition or subtraction of a rank one matrix.

The translation is in most instances straightforward, but there are some points that need to be noted. Most of these are discussed in detail in the descriptive routine DESCRB, which is part of the algorithm.

However, a few comments belong here. Notice that DESCRB contains both a complete description of the routines and a fairly lengthy set of tests to ensure the accuracy of the translation. The tests basically consist of an initial factorization of a 7×7 Hilbert matrix, followed by random deletion of rows and columns of the matrix until it is just 1×1, after which the rows and columns are, in a random order, reinserted to recreate the original matrix. Rank one matrices are introduced (then deleted) at several points as well. At each step, the factorization is updated and its accuracy is checked against the matrix being factored. A copy of the output from an execution of the tests follows the algorithm. The routines have also been tested through their use in an implementation of the minimization algorithm described in [1].

The translation is written in a portable subset of American National Standard FORTRAN, 1966, and has been thoroughly checked by the PFORT verifier. Except for some minor points noted in the routine DESCRB, the code is machine independent.

The routines are written simultaneously in single and double precision. As listed, compilation will give a single-precision version. It is straightforward,

Author's address: Mathematics Department, Layola Campus, Concordia University, 7141 Sherbrooke Street W, Montreal, Que., H4B 1R6, Canada.

however, to obtain a double-precision version: just follow the simple instructions in DESCRB to interchange a few well-marked statements.

Notice that the basic linear algebra operations, such as taking norms or computing inner products, are done via calls to the BLAS described by Lawson et al. [3]. These routines are available through the International Mathematical and Statistical Libraries, Inc.,[1] or through SIAM.[2]

ACKNOWLEDGMENT

The author wishes to indicate his appreciation of the support received from NSERC, Canada.

ALGORITHM 581
An Improved Algorithm for Computing the Singular Value Decomposition [F1]

TONY F. CHAN
Department of Computer Science, Yale University

Categories and Subject Descriptors: D.3.2 [**Programming Languages**]: Language Classifications—*FORTRAN*; G.1.3 [**Numerical Analysis**]: Numerical Linear Algebra—*pseudoinverses*; G.1.6 [**Numerical Analysis**]: Optimizations—*least squares methods*

General Terms: Algorithms

Additional Key Words and Phrases: singular value decomposition

DESCRIPTION

The set of FORTRAN subroutines given here is an implementation of the algorithm [1] for computing the Singular Value Decomposition (SVD) of a general m by n rectangular matrix A defined as

$$A = UWV^{T},$$

where U is an $m \times \min(m,n)$ matrix containing the left singular vectors, W is a diagonal matrix of size $\min(m, n)$ containing the singular values, and V is an $n \times \min(m, n)$ matrix containing the right singular vectors. Note that m is allowed to be greater than or less than n. For ease of presentation, we assume m to be greater than or equal to n in the following discussion.

The algorithm is an improvement of the Golub–Reinsch algorithm [4], which is implemented in subroutines SVD and MINFIT in EISPACK [3] and in subroutine SSVDC in LINPACK [2]. It should be more efficient than the Golub–Reinsch algorithm when m is approximately larger than $2n$, as is the case in many least squares applications.

The algorithm has a hybrid nature. When m is about equal to n, the Golub–Reinsch algorithm is employed. When the ratio m/n is larger than a threshold value, which is determined by detailed operation counts [1], the improved algorithm is used.

The improved algorithm first computes the QR factorization of A using Householder transformations, and then uses the Golub–Reinsch algorithm on R. A further improvement over the Golub–Reinsch algorithm is when the left singular vectors are to be accumulated and saved. Here, instead of accumulating the Givens transformations (in the second phase of the algorithm where the singular values of the bidiagonal matrix are computed) on the $m \times n$ matrix containing the left singular vectors, we accumulate them on a temporary $n \times n$ matrix. This requires a small overhead in storage of an $n \times n$ matrix (small compared with $m \times n$) but offers big savings in time.

Author's address: Department of Computer Science, Yale University, 10 Hillhouse Avenue, P.O. Box 2158 Yale Station, New Haven CT 06520.

An additional feature of the new algorithm is that it can accumulate all the left orthogonal transformations on a number of given vectors, which can then be used in computing least squares solutions. In this fashion, it is similar to the EISPACK routine MINFIT.

There are three main routines in the package:

HYBSVD: This is the main routine which implements the hybrid algorithm.
MGNSVD: This performs the same thing as HYBSVD, except that it assumes m .ge. n.
GRSVD: This is a slightly modified version of routine SVD in EISPACK which implements the Golub-Reinsch algorithm.

Besides, there are two utility routines:

SSWAP: BLAS routine for swapping two vectors.
SRELPR: Routine for computing the machine relative precision.

These five routines must be used together. They have been tested extensively on the IBM 370/168, 360/91 at the Stanford Linear Accelerator Center, and on the DEC 2060 in the Computer Science Department at Yale. They produce results that agree (up to machine precision) with those produced by SVD, MINFIT, and SSVDC. They have been verified by PFORT verifier [5] for portability.

ALGORITHM 582
The Gibbs-Poole-Stockmeyer and Gibbs-King Algorithms for Reordering Sparse Matrices

JOHN G. LEWIS
Boeing Computer Services Co.

Categories and Subject Descriptors: G.1.3 [**Numerical Analysis**]: Numerical Linear Algebra—*sparse and very large systems*; G.m [**Mathematics of Computing**]: Miscellaneous—*FORTRAN*

General Terms: Algorithms

Additional Key Words and Phrases: Matrix bandwidth, matrix profile, matrix wavefront, banded matrix, Gibbs-Poole-Stockmeyer algorithm, Gibbs-King algorithm

DESCRIPTION

Given the structure of a symmetric or structurally symmetric sparse matrix, GPSKCA attempts to find a symmetric reordering of the matrix that produces a smaller bandwidth or profile. References [1], [4], [5], and [6] explain in detail the algorithms realized by GPSKCA. This algorithm provides the same mathematical capabilities as provided by REDUCE, Algorithms 508, and 509, but requires less memory and time and removes some implicit restrictions on the matrices that can be reordered. A description of the differences in the implementation and their effects is given in [7]; GPSKCA and REDUCE produce the same bandwidth and profile on all problems for which REDUCE executes successfully.

The package of subroutines is evoked by the FORTRAN statement

```
CALL GPSKCA (N, NZ, CONNEC, RSTART, DEGREE, OPTPRO, PERMUT, WORK,
             WRKLEN, ERROR, SPACE)
```

where the parameters are described in the listing given here. The subroutines attempt to find a symmetric (row and column) permutation that reduces the bandwidth or profile of the reordered matrix. Whether to emphasize profile reduction or bandwidth reduction is determined by the logical parameter OPTPRO.

A common use for this algorithm will be prior to the solution of sparse linear algebraic equations or algebraic eigenvalue problems of moderately large size. The algorithm is supplied together with a FORTRAN program that accepts a sparse symmetric matrix in a standard sparse format and produces the equivalent reordered matrix in a format suitable for solving linear algebraic equations with the banded solvers in LINPACK [2] or the envelope solver in SPARSPAK [3].

The algorithm has been written in 1966 American National Standard FORTRAN. The package consists of 17 subroutines, GPSKCA, GPSKCB, ...,

Received 28 May 1980; revised 6 January 1982; accepted 10 January 1982

GPSKCQ. Special comment cards have been included so that the user can easily convert the code to an IBM FORTRAN version that uses half-length integers (INTEGER * 2) for all of the arrays except RSTART. This reduces the memory requirements by nearly a factor of 2 at the cost of restricting the order of the matrix to 32,767 or smaller. There would be no immediate restriction on the number of nonzeros in the matrix.

The primary difference in the usage of GPSKCA and its predecessor, REDUCE, is in the representation of the structure of the matrix. The format used herein is often much more efficient in space than that used in REDUCE. For the convenience of those users of REDUCE who would like to obtain the faster execution speeds of GPSKCA, but who cannot conveniently convert to the new, compact, format, an alternative version, GPSKRA, which accepts the older format for the matrix, will be supplied by the author upon request (not by the ACM distribution service).

ALGORITHM 583
LSQR: Sparse Linear Equations and Least Squares Problems

CHRISTOPHER C. PAIGE
McGill University, Canada
and
MICHAEL A. SAUNDERS
Stanford University

Categories and Subject Descriptors: G.1.3 [**Numerical Analysis**]: Numerical Linear Algebra—*linear systems (direct and iterative methods)*; G.3 [**Mathematics of Computing**]: Probability and Statistics—*statistical computing; statistical software*; G.m [**Mathematics of Computing**]: Miscellaneous—*FORTRAN program units*

General Terms: Algorithms

Additional Key Words and Phrases: Analysis of variance, conjugate-gradient method, least squares, linear equations, regression, sparse matrix

1. INTRODUCTION

LSQR finds a solution x to the following problems:

Unsymmetric equations:	solve	$Ax = b$	(1.1)
Linear least squares:	minimize	$\|Ax - b\|_2$	(1.2)
Damped least squares:	minimize	$\left\| \begin{bmatrix} A \\ \lambda I \end{bmatrix} x - \begin{bmatrix} b \\ 0 \end{bmatrix} \right\|_2$	(1.3)

where A is a matrix with m rows and n columns, b is an m-vector, λ is a scalar, and the given data A, b, λ are real. The matrix A will normally be large and sparse. It is defined by means of a user-written subroutine APROD, whose essential function is to compute products of the form Ax and $A^T y$ for given vectors x and y.

Problems (1.1) and (1.2) are treated as special cases of (1.3), which we shall write as

$$\min \|\bar{A}\, x - \bar{b}\|_2, \qquad \bar{A} = \begin{bmatrix} A \\ \lambda I \end{bmatrix}, \qquad \bar{b} = \begin{bmatrix} b \\ 0 \end{bmatrix}. \tag{1.4}$$

Table I. Comparison of CGLS and LSQR

	Storage	Work per iteration
CGLS, $\lambda = 0$	$2m + 2n$	$2m + 3n$
CGLS, $\lambda \neq 0$	$2m + 2n$	$2m + 5n$
LSQR, any λ	$m + 2n$	$3m + 5n$

An earlier successful method for such problems is the *conjugate-gradient method for least squares systems* given by Hestenes and Stiefel [3]. (This method is described as algorithm CGLS in [6, sect. 7.1].) CGLS and LSQR are iterative methods with similar qualitative properties. Their computational requirements are summarized in Table I. In addition they require a product Ax and a product A^Ty each iteration.

In order to achieve the storage shown for LSQR, we ask the user to implement the matrix-vector products in the form

$$y \leftarrow y + Ax \qquad \text{and} \qquad x \leftarrow x + A^Ty, \tag{1.5}$$

where $\leftarrow$ means that one of the given vectors is overwritten by the expression shown. (A parameter specifies which expression the user's subroutine APROD should compute on any given entry.) We see that LSQR has a storage advantage if the operations (1.5) can be performed with no additional storage beyond that required to represent A. For least squares applications with many observations ($m \gg n$), this could be useful.

The work shown in Table I is the number of floating-point multiplications per iteration, excluding the work involved in the products Ax, A^Ty. Since CGLS is somewhat more efficient, we would not discourage using that method whenever A or $\bar{A}$ is well conditioned. However, LSQR is likely to obtain a more accurate solution in fewer iterations if $\bar{A}$ is moderately or severely ill-conditioned.

Let $\bar{r}_k = \bar{b} - \bar{A}x_k$ be the residual vector associated with the kth iteration. LSQR provides estimates of $\| x_k \|_2$, $\| \bar{r}_k \|_2$, $\| \bar{A}^T\bar{r}_k \|_2$, the norm of $\bar{A}$, the condition number of $\bar{A}$, and standard errors for the components of x. The last two items require a further $2n$ multiplications per iteration and an additional n-vector of storage.

Subroutine LSQR is written in the PFORT subset of American National Standard FORTRAN. It contains no machine-dependent constants. Auxiliary routines required are APROD, NORMLZ, SCOPY, SNRM2, and SSCAL. The last three correspond to members of the BLAS collection [5].

2. MATHEMATICAL BACKGROUND

Algorithmic details are given in [6], mainly for the case $\lambda = 0$. We summarize these here with λ reintroduced, and show that a given value of λ may be dealt with at negligible cost. The vector norm $\| v \|_2 = (v^Tv)^{1/2}$ is used throughout.

LSQR uses an algorithm of Golub and Kahan to reduce A to lower bidiagonal form. The quantities produced from A and b after $k + 1$ steps of the bidiagonalization (procedure Bidiag 1 [6]) are

$$\begin{aligned} \beta_1 &= \| b \|, \\ U_{k+1} &= [u_1, u_2, \ldots, u_{k+1}], \\ V_{k+1} &= [v_1, v_2, \ldots, v_{k+1}], \end{aligned} \qquad B_k = \begin{bmatrix} \alpha_1 & & & & \\ \beta_2 & \alpha_2 & & & \\ & \beta_3 & \ddots & & \\ & & \ddots & \alpha_k & \\ & & & \beta_{k+1} \end{bmatrix}. \tag{2.1}$$

The kth approximation to the solution x is then defined to be $x_k = V_k y_k$, where y_k solves the subproblem

$$\min \left\| \begin{bmatrix} B_k \\ \lambda I \end{bmatrix} y_k - \begin{bmatrix} \beta_1 e_1 \\ 0 \end{bmatrix} \right\|. \tag{2.2}$$

Letting the associated residual vectors be

$$\begin{aligned} t_{k+1} &= \beta_1 e_1 - B_k y_k \\ r_k &= b - A x_k \\ \bar{r}_k &= \bar{b} - \bar{A} x_k, \end{aligned} \tag{2.3}$$

we find that the relations

$$\begin{aligned} r_k &= U_{k+1} t_{k+1} \\ A^{\mathrm{T}} r_k &= \lambda^2 x_k + \alpha_{k+1} \tau_{k+1} v_{k+1} \end{aligned} \tag{2.4}$$

will hold to machine accuracy, where τ_{k+1} is the last component of t_{k+1}, and we therefore conclude that (r_k, x_k) will be an acceptable solution of (1.4) if the computed value of either $\| t_{k+1} \|$ or $| \alpha_{k+1} \tau_{k+1} |$ is suitably small.

Björck [1] has previously observed that subproblem (2.2) is the appropriate generalization of $\min \| B_k y_k - \beta_1 e_1 \|$, when $\lambda \neq 0$. He also discusses methods for computing y_k and x_k efficiently for various λ and k.

In LSQR we assume that a single value of λ is given, and to save storage and work, we do not compute y_k, r_k, or t_{k+1}. The orthogonal factorization

$$Q_k \begin{bmatrix} B_k & \beta_1 e_1 \\ \lambda I & 0 \end{bmatrix} = \begin{bmatrix} R_k & f_k \\ 0 & \bar{\phi}_{k+1} \\ 0 & q_k \end{bmatrix} \tag{2.5}$$

is computed ($Q_k^{\mathrm{T}} Q_k = I$; R_k upper bidiagonal, $k \times k$) and this would give $R_k y_k = f_k$, but instead we solve $R_k^{\mathrm{T}} D_k^{\mathrm{T}} = V_k^{\mathrm{T}}$ and form $x_k = D_k f_k$.

The factorization (2.5) is formed similarly to the case $\lambda = 0$ in [6], except that two rotations are required per step instead of one. For $k = 2$, the factorization proceeds according to

$$\begin{bmatrix} \alpha_1 & & \beta_1 \\ \beta_2 & \alpha_2 & \\ & \beta_3 & \\ \lambda & & \\ & \lambda & \end{bmatrix} \rightarrow \begin{bmatrix} \tilde{\rho}_1 & & \tilde{\phi}_1 \\ \beta_2 & \alpha_2 & \\ & \beta_3 & \\ & & \psi_1 \\ & \lambda & \end{bmatrix} \rightarrow \begin{bmatrix} \rho_1 & \theta_2 & \phi_1 \\ & \bar{\rho}_2 & \bar{\phi}_2 \\ & \beta_3 & \\ & & \psi_1 \\ & \lambda & \end{bmatrix}$$

$$\rightarrow \begin{bmatrix} \rho_1 & \theta_2 & \phi_1 \\ & \tilde{\rho}_2 & \tilde{\phi}_2 \\ & \beta_3 & \\ & & \psi_1 \\ & & \psi_2 \end{bmatrix} \rightarrow \begin{bmatrix} \rho_1 & \theta_2 & \phi_1 \\ & \rho_2 & \phi_2 \\ & & \bar{\phi}_3 \\ & & \psi_1 \\ & & \psi_2 \end{bmatrix}.$$

Note that the first λ is rotated into the diagonal element α_1. This alters the right-hand side $\beta_1 e_1$ to produce ψ_1, the first component of q_k. An alternative is to rotate λ into β_2 (and similarly for later λ), since this does not affect the right-hand side and it more closely simulates the algorithm that results when LSQR is applied to $\bar{A}$ and $\bar{b}$ directly. However, the rotations then have a greater effect on B_k, and in practice the first option has proved to give marginally more accurate results.

The estimates required to implement the stopping criteria are

$$\| \bar{r}_k \|^2 = \| r_k \|^2 + \lambda^2 \| x_k \|^2 \approx \bar{\phi}_{k+1}^2 + \| q_k \|^2,$$

$$\| \bar{A}^{\mathrm{T}} \bar{r}_k \| = \| A^{\mathrm{T}} r_k - \lambda^2 x_k \| \approx \left| \frac{\alpha_{k+1} \beta_{k+1} \phi_k}{\rho_k} \right|.$$

This is a simple generalization of the case $\lambda = 0$. No additional storage is needed for q_k, since only its norm is required. In short, although the presence of λ complicates the algorithm description, it adds essentially nothing to the storage and work per iteration.

3. REGULARIZATION AND RELATED WORK

Introducing λ as in (1.3) is just one way of "regularizing" the solution x, in the sense that it can reduce the size of the computed solution and make its components less sensitive to changes in the data. LSQR is applicable when a value of λ is known a priori. The value is entered via the subroutine parameter DAMP. A second method for regularizing x is available through LSQR's parameter ACOND, which can cause iterations to terminate before $\|x_k\|$ becomes large. A similar approach has recently been described by Wold et al. [9], who give an illuminating interpretation of the bidiagonalization as a partial least squares procedure. Their description will also be useful to those who prefer the notation of multiple regression.

Methods for choosing λ, and other approaches to regularization, are given in [1, 2, 4, 8] and elsewhere. For a philosophical discussion, see [7].

4. CODING APROD

The best way to compute $y + Ax$ and $x + A^Ty$ depends upon the origin of the matrix A. We shall illustrate a case that commonly arises, in which A is a sparse matrix whose nonzero coefficients are stored by *rows* in a simple list. Let A have M rows, N columns, and NZ nonzeros. Conceptually we need three arrays dimensioned as REAL RA(NZ) and INTEGER JA(NZ), NA(M), where

RA(L) is the Lth nonzero of A, counting across row 1, then across row 2, and so on;
JA(L) is the column in which the Lth nonzero of A lies;
NA(I) is the number of nonzero coefficients in the Ith row of A.

These quantities may be used in a straightforward way, as shown in Figure 1 (a FORTRAN implementation). We assume that they are made available to APROD through COMMON, and that the actual array dimensions are suitably large.

Blank or labeled COMMON will often be convenient for transmitting data to APROD. (Of course, some of the data could be local to APROD.) For greater generality, the parameter lists for LSQR and APROD include two workspace arrays IW, RW and their lengths LENIW, LENRW. LSQR does not use these parameters directly; it just passes them to APROD.

Figure 2 illustrates their use on the same example (sparse A stored by rows). An auxiliary subroutine APROD1 is needed to make the code readable. A similar scheme should be used to initialize the workspace parameters prior to calling LSQR.

Returning to the example itself, it may often be natural to store A by *columns* rather than rows, using analogous data structures. However, we note that in sparse least squares applications, A may have many more rows than columns ($M \gg N$). In such cases it is vital to store A by rows as shown, if the machine being used has a paged (virtual) memory. Random access is then restricted to arrays of length N rather than M, and page faults will therefore be kept to a minimum.

Note also that the arrays RA, JA, NA are adequate for computing both Ax and A^Ty; we do not need to store A by rows *and* by columns.

Regardless of the application, it will be apparent when coding APROD for the two values of MODE that the matrix A is effectively being defined *twice*. Great care must be taken to avoid coding inconsistent expressions $y + A_1x$ and $x + A_2^Ty$, where either A_1 or A_2 is different from the desired A. (If $A_1 \neq A_2$, algorithm LSQR will not converge.) Parameters ANORM, ACOND, and CONLIM provide a safeguard for such an event.

5. PRECONDITIONING

It is well known that conjugate-gradient methods can be accelerated if a nonsingular matrix M is available to approximate A in some useful sense. When A is

square and nonsingular, the system $Ax = b$ is equivalent to both of the following systems:

$$(M^{-1}A)x = c \quad \text{where} \quad Mc = b; \tag{5.1}$$

$$(AM^{-1})z = b \quad \text{where} \quad Mx = z. \tag{5.2}$$

For least squares systems (undamped), only the analogue of (5.2) is applicable:

$$\min\|Ax - b\|_2 = \min\|(AM^{-1})z - b\|_2, \quad \text{where} \quad Mx = z. \tag{5.3}$$

Figure 3 (continued)

We note only that subroutine *LSQR may be applied without change* to systems (5.1)-(5.3). The effect of M is localized to the user's own subroutine APROD. For example, when MODE = 1, APROD for the last two systems should compute $y + (AM^{-1})x$ by first solving $Mw = x$ and then computing $y + Aw$. Clearly it must be possible to solve systems involving M and M^T very efficiently.

6. OUTPUT

Subroutine LSQR produces printed output on file NOUT, if the parameter NOUT is positive. This is illustrated in Figure 3, in which the least squares problem solved is $P(20, 10, 1, 1)$ as defined in [6], with a slight generalization to include a damping parameter $\lambda = 10^{-3}$. (Single precision was used on an IBM 370/168.) The items printed at the kth iteration are as follows.

ITN — The iteration number k. Results are always printed for the first 10 and last 10 iterations. Intermediate results are printed if $m \leq 40$ or $n \leq 40$, or if one of the convergence conditions is nearly satisfied. Otherwise, information is printed every 10th iteration.

X(1) — The value of the first element of the approximate solution x_k.

FUNCTION — The value of the function being minimized, namely $\| \bar{r}_k \| = (\| r_k \|^2 + \lambda^2 \| x_k \|^2)^{1/2}$.

COMPATIBLE — A dimensionless quantity which should converge to zero *if and only if* $Ax = b$ is compatible. It is an estimate of $\| \bar{r}_k \| / \| b \|$, which decreases monotonically.

INCOMPATIBLE	A dimensionless quantity which should converge to zero *if and only if* the optimum $\|\bar{r}_k\|$ is nonzero. It is an estimate of $\|\bar{A}^T\bar{r}_k\|/(\|\bar{A}\|_F\|\bar{r}_k\|)$, which is usually *not* monotonic.
NORM(ABAR)	A monotonically increasing estimate of $\|\bar{A}\|_F$.
COND(ABAR)	A monotonically increasing estimate of cond($\bar{A}$) = $\|\bar{A}\|_F\|\bar{A}^+\|_F$, the condition number of $\bar{A}$.

ACKNOWLEDGMENT

The authors are grateful to Richard Hanson for suggestions that prompted several improvements to the implementation of LSQR.

ALGORITHM 584
CUBTRI: Automatic Cubature over a Triangle

D. P. LAURIE

National Research Institute for Mathematical Sciences, South Africa

Categories and Subject Descriptors: G.1.4 [**Numerical Analysis**]: Quadrature and Numerical Differentiation—*adaptive quadrature, multiple quadrature*; G.m [**Mathematics of Computing**]: Miscellaneous—*FORTRAN*

General Terms: Algorithms, Theory

Additional Key Words and Phrases: Quadrature rule

DESCRIPTION AND PURPOSE

Given a triangle T with vertices (t_{1j}, t_{2j}), $j = 1, 2, 3$, a function $f(x, y)$ defined on T, and a tolerance $\epsilon > 0$, CUBTRI attempts to compute a number A such that

$$\left| A - \int\int_T f(x, y)\, dx\, dy \right| < \max\{\epsilon, |A\epsilon|\}. \tag{1}$$

The method employed is similar to that of Haegemans [1] and consists of the following steps.

(1) Compute an approximate integral A and error estimate η for the original triangle T.
(2) If the current values of A and η satisfy $\eta < \max\{\epsilon, |A\epsilon|\}$, or if further computation will exceed specified limits, exit.
(3) Given a list of triangles whose union is T, together with an approximate integral and error estimate for each triangle, identify the triangle T_k with largest error estimate.
(4) Remove T_k from the data list and subtract its contributions from the current values of A and η.
(5) Divide T_k into four congruent triangles, append them to the data list, and compute an approximate integral and error estimate for each. Add these contributions to A and η.
(6) Diagnose whether round-off errors are contaminating the obtained values to a point where further subdivision is futile. If so, exit; else return to step 2.

The general strategy falls within the framework outlined by Rice [7], apart from the test for roundoff, which is due to Piessens [5] and also appears in Haegemans' routine TRIADA [1].

$$Q^{(i)}f = \frac{1}{6}\sum_{\substack{k=1\\k\neq l}}^{3}\sum_{l=1}^{3} f(\zeta_k^{(i)}, \zeta_l^{(i)})$$

$$Q_1 f = \Delta \sum_{i=0}^{2} w_1^{(i)} Q^{(i)} f$$

$$Q_2 f = \Delta \sum_{i=0}^{5} w_2^{(i)} Q^{(i)} f$$

Δ = area of triangle

$\zeta_k^{(i)}$ are barycentric coordinates

CUBTRI attempts to improve on TRIADA in terms of number of function evaluations and storage management.

NUMBER OF FUNCTION EVALUATIONS

Two cubature rules Q_1 and Q_2 are applied to each triangle to produce estimates A_1 and A_2, where A_2 is of a higher degree than A_1. This gives an approximate integral $A = A_2$ and error estimate $\eta = |A_2 - A_1|$ which is likely to be pessimistic, since it really estimates the error in A_1 rather than that in A_2. This effect is countered by employing a device given in [3] for sharpening the error estimate. It is, of course, possible to use two completely independent cubature rules (e.g., Haegemans [1] uses conic product Gauss formulas (see Stroud [8], Section 2.5) with 36 and 49 points, respectively), but it seems sensible to extend Kronrod's [2] idea, that Q_2 should reuse the points of Q_1, to the two-dimensional case.

In CUBTRI, Q_1 is the 7-point degree-5 rule of Radon [6], and Q_2 is a new 19-point degree-8 rule given in Table I. The theory of Lyness and Jespersen [4] shows that 19 points and degree 8 are optimal, given that Q_2 has D_3 symmetry and contains the 7 points of Q_1. A curious feature of Q_2 is that the 12 new points are the intersection points of three pairs of parallel lines (see Figure 1).

STORAGE MANAGEMENT

Most of the storage requirements arise from the need to store a list of triangles. In general, 6 numbers are necessary to describe a triangle (e.g., three vertices of two coordinates each), giving a total of $6n$ numbers for n triangles.

Haegemans [1] has improved on this by keeping a separate list of vertices; each triangle can then be described by 3 integers. The length of the list is only $n + 2$, because each subdivision creates as many new vertices (three) as the net increase in the number of triangles. This yields a total of $3n$ integers and $2n + 4$ reals.

In CUBTRI we take advantage of the fact that the sides of each subtriangle are parallel to those of the original triangle. Geometrically, one can visualize the subtriangle as being obtained by translation, scaling, and possibly rotation

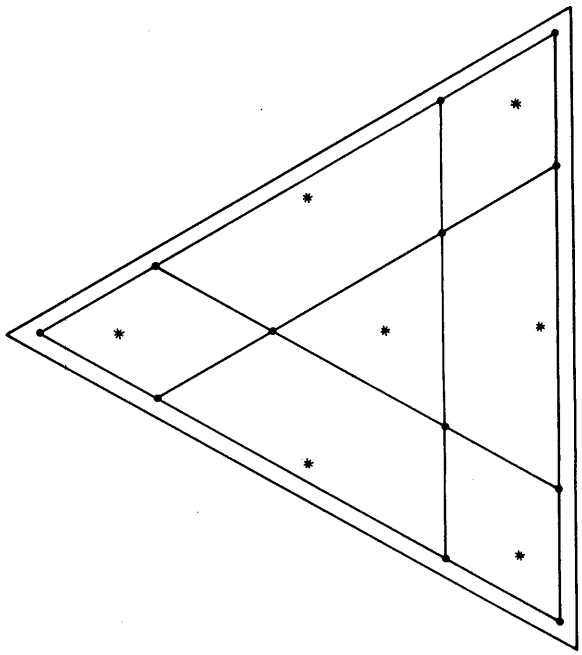

Fig. 1. Disposition of points in the degree-8 formula. •—Additional points of degree-8 formula. *—Points of Radon's degree-5 formula.

through 180°. These effects can be represented by two coordinates, a scale factor, and the sign of the scale factor, respectively: thus three numbers per triangle suffice. It is convenient to use barycentric coordinates for the translation vector, because in that case only numbers that are terminating binary fractions are generated; these are exact machine numbers (even in single precision) on most computers, and rounding errors are avoided. Only $3n$ reals are therefore required in addition to the vertices of T.

TESTS

The driver main program and function $f(x, y)$ supplied with the algorithm calculate the following seven integrals.

Case 1.

$$\int_0^1 \int_0^x (x^2 + 3y^2)^{-1/2}\, dy\, dx = \frac{\log(2 + \sqrt{3})}{\sqrt{3}}.$$

This integrand has a singularity at the origin.

Case 2. The same as Case 1, with a rapidly oscillatory relative error of magnitude 10^{-6} perturbing the integrand. This simulates the behavior of a machine with a short word length.

Case 3.

$$\int_0^1 \int_0^x f(x, y)\, dy\, dx = \frac{\pi}{8}$$

where

$$f(x, y) = \begin{cases} 1, & (x - \frac{1}{2})^2 + (y - \frac{1}{2})^2 \le \frac{1}{2}, \\ 0, & \text{otherwise.} \end{cases}$$

This integrand has a jump discontinuity along a curved line, the circle of radius $\frac{1}{2}$ centered at $(\frac{1}{2}, \frac{1}{2})$.

The following four test functions were suggested by Haegemans [1].

Case 4.

$$\int_0^1 \int_0^{1-x} \exp(\sin x \cos y)\, dy\, dx \approx 0.6918104506612316.$$

Table II. $f(x, y) = (x^2 + 3y^2)^{-1/2}$

Table III. $f(x, y) = (x^2 + 3y^2)^{-1/2}(1 + \eta), |\eta| \leq 10^{-6}$

	CUBTRI				TRIADA			
ϵ	NFE	EST	ERR	IER	NFE	EST	ERR	IER
1_{10-3}	323	6.2_{10-4}	6.1_{10-4}	0	765	9.1_{10-4}	3.0_{10-3}	0
1_{10-4}	551	8.5_{10-5}	7.5_{10-5}	0	2125	5.7_{10-5}	1.9_{10-4}	0
1_{10-5}	1007	8.2_{10-6}	1.5_{10-6}	0	3145	7.2_{10-6}	2.3_{10-5}	0
1_{10-6}	1919	8.6_{10-7}	2.8_{10-8}	0	4165	9.7_{10-7}	2.9_{10-6}	0
1_{10-7}	3135	9.8_{10-8}	1.1_{10-8}	0	6205	1.0_{10-7}	8.9_{10-9}	0
1_{10-8}	5415	1.3_{10-8}	1.5_{10-8}	4	9945	6.5_{10-8}	1.7_{10-10}	2

Table IV. $f(x, y) = \frac{1}{2} + \frac{1}{2}\operatorname{sign}\left\{\frac{1}{4} - \left(x - \frac{1}{2}\right)^2 - \left(y - \frac{1}{2}\right)^2\right\}$

	CUBTRI				TRIADA			
ϵ	NFE	EST	ERR	IER	NFE	EST	ERR	IER
1_{10-3}	551	3.9_{10-3}	2.6_{10-3}	4	10625	9.9_{10-4}	6.4_{10-5}	0
1_{10-4}	3059	2.0_{10-3}	5.7_{10-4}	4	14705	9.3_{10-4}	3.0_{10-4}	1

This integral seems to be impossible to evaluate analytically; the numerical "exact" value is given in [1].

Case 5.

$$\int_0^1 \int_0^{1-x} \frac{x^2}{(1 + x^2)}\, dy\, dx = \frac{1 + \log 2}{2} - \frac{\pi}{4}.$$

The integrand depends on x only.

Case 6.

$$\int_0^1 \int_0^{1-x} \sin(3x + 6y)\, dy\, dx = \frac{1}{9}\sin 3 - \frac{1}{18}\sin 6.$$

A mildly oscillating integrand.

Case 7.

$$\int_0^1 \int_0^{1-x} \sin(x + y)^{-1/2}\, dy\, dx = \frac{2}{3}.$$

The integrand has a gentler singularity at the origin than that of Case 1.

In Tables II–VIII we report the results obtained by CUBTRI as well as by TRIADA [2] on a CDC Cyber 174 (48-bit mantissa, binary floating point). The column legends are

IER Error flag. For TRIADA, IER = 1 denotes that the limit on NFE has been reached, and IER = 2 that the round-off error threshold has been reached. For CUBTRI, the meaning of IER is explained in the leading comments.

We can draw the following conclusions.

(1) *Reliability.* The error estimates produced by CUBTRI after subdivision range from 0.87 to 120 times the actual error, and in only one instance is the actual error underestimated. Before subdivision (i.e., when NFE = 19), the device [3] is unavailable, and the overestimation is much more pessimistic. The error estimates produced by TRIADA range from 0.3 to 500 times the actual error, and in 16 instances (all involving nonsmooth integrands) the actual error is underestimated.

(2) *Accuracy.* On smooth integrands TRIADA is slightly more accurate than CUBTRI (e.g., in Case 2, TRIADA with NFE = 85 produces ERR = 2.3_{10}^{-12}). On nonsmooth integrands CUBTRI is much more accurate than TRIADA (e.g., in Case 1, CUBTRI with NFE = 1919 produces ERR = 3.7_{10}^{-8}, whereas TRIADA with NFE = 2125 can only obtain ERR = 1.9_{10}^{-4}).

(3) *Efficiency.* On smooth integrands TRIADA in 15 instances out of 21 terminated at a given ϵ with fewer function evaluations than CUBTRI. On nonsmooth integrands, in 20 instances out of 21 CUBTRI terminated with fewer function evaluations than TRIADA.

On machines with a short word length, termination with IER = 4 can be expected when ϵ is smaller than machine accuracy, and the behavior of the algorithm when ϵ is close to machine accuracy might be somewhat different. The situation is simulated by the difference between Cases 1 and 2.

To summarize, CUBTRI is a reliable and efficient integrator on smooth as well as nonsmooth integrands, although not quite so accurate and efficient for smooth integrands as TRIADA.

ACKNOWLEDGMENTS

The referee of an early version of this paper drew my attention to [4]. Elsie de Lange wrote the driver main program and test functions. Ina Marais checked the correctness of Table I.

ALGORITHM 585
A Subroutine for the General Interpolation and Extrapolation Problems

C. BREZINSKI
University of Lille, France

Categories and Subject Descriptors: G.m [**Mathematics of Computing**]: Miscellaneous—*FORTRAN*

General Terms: Algorithms

Additional Key Words and Phrases: Convergence acceleration, extrapolation, interpolation, least squares approximation, Neville-Aitken scheme

1. INTRODUCTION

Recently a generalization of Neville-Aitken algorithm for extrapolation has been found by Håvie [10]. This general extrapolation scheme has also been studied by Brezinski [3], who showed that it includes most of the convergence acceleration methods actually known. This algorithm has been called the E-algorithm, or the BH-protocol [15, Chaps. 10 and 11, pp. 175–209].

Of course, after that, the next step was to look for a general interpolation scheme for interpolation by a linear combination of functions forming a Chebyshev system. Such an algorithm was in fact found some years ago by Mühlbach [12, 13]. Except for the initializations, it is the same as the E-algorithm. This algorithm has been called the Mühlbach–Neville-Aitken algorithm (MNA-algorithm). The same algorithm can also be used for the general interpolation problem [4] as described, for example, by Davis [7].

The E-algorithm and its programming are described in Section 2. A FORTRAN subroutine is given with an application. Section 3 is devoted to the MNA-algorithm, while Section 4 deals with least squares approximation and extrapolation.

2. THE E-ALGORITHM

Let (S_n) be a sequence of real numbers and let us consider the sequence transformation defined by

$$E_k(S_n) = \frac{\begin{vmatrix} S_n & S_{n+1} & \cdots & S_{n+k} \\ g_1(n) & g_1(n+1) & \cdots & g_1(n+k) \\ \vdots & \vdots & & \vdots \\ g_k(n) & g_k(n+1) & \cdots & g_k(n+k) \end{vmatrix}}{\begin{vmatrix} 1 & 1 & \cdots & 1 \\ g_1(n) & g_1(n+1) & \cdots & g_1(n+k) \\ \vdots & \vdots & & \vdots \\ g_k(n) & g_k(n+1) & \cdots & g_k(n+k) \end{vmatrix}}$$

where the g_i's are given sequences such that the denominator in $E_k(S_n)$ does not vanish.

The main basic algebraic property of this transformation is that $\forall n \geq N$, $E_k(S_n) = S$ if the sequence (S_n) satisfies, $\forall n \geq N$

$$S_n = S + a_1 g_1(n) + \cdots + a_k g_k(n).$$

This formalism is quite general since it includes most of the sequence transformations actually used to accelerate the convergence of the sequence (S_n). For example, if $g_i(n) = \Delta S_{n+i-1}$, it is Shanks' transformation [14]; if $g_i(n) = x_n^{i-1}\Delta S_n$, it is Levin's method [11]; for $g_i(n) = x_n^i$ we recover Richardson extrapolation process; and for $g_i(n) = (\Delta S_n)^i$, it is Germain-Bonne's method [9]; and so forth.

From the numerical point of view, a recursive method to avoid the computation of the determinants involved in $E_k(S_n)$ is needed. Such algorithms exist for the particular cases quoted above: Wynn's ϵ-algorithm [16] for Shanks' transformation, Neville-Aitken's scheme for Richardson process and Germain-Bonne's transformation, some special devices [5] for Levin's method, and so on. The corresponding FORTRAN subroutines can be found in [1]. Thus we have at least as many different algorithms as sequence transformations.

Recently a recursive algorithm working in the general case has been obtained by Håvie [10] and Brezinski [3]. This algorithm, called the E-algorithm, is as follows:

Initializations $\quad E_0^{(n)} = S_n, \qquad n = 0, 1, \ldots$

$\qquad\qquad\quad g_{0,i}^{(n)} = g_i(n), \qquad i = 1,2, \ldots$ and $n = 0, 1, \ldots$.

Then, for $k = 1, 2, \ldots$ and $n = 0, 1, \ldots$

$$E_k^{(n)} = E_{k-1}^{(n)} + g_{k-1,k}^{(n)} \frac{E_{k-1}^{(n)} - E_{k-1}^{(n+1)}}{g_{k-1,k}^{(n+1)} - g_{k-1,k}^{(n)}} \tag{2.1}$$

$$g_{k,i}^{(n)} = g_{k-1,i}^{(n)} + g_{k-1,k}^{(n)} \frac{g_{k-1,i}^{(n)} - g_{k-1,i}^{(n+1)}}{g_{k-1,k}^{(n+1)} - g_{k-1,k}^{(n)}}, \qquad i = k+1, k+2, \ldots. \tag{2.2}$$

It can very easily be proved, by using Sylvester's determinantal identity [8, Vol. 1, p. 32] that

$$E_k^{(n)} = E_k(S_n).$$

Usually the quantities $E_k^{(n)}$ are displayed in a two-dimensional array, called the E-array, as follows:

$$\begin{array}{llll} E_0^{(0)} = S_0 & & & \\ E_0^{(1)} = S_1 & E_1^{(0)} & & \\ E_0^{(2)} = S_2 & E_1^{(1)} & E_2^{(0)} & \\ E_0^{(3)} = S_3 & E_1^{(2)} & E_2^{(1)} & E_3^{(0)} \\ \vdots & \vdots & \vdots & \ddots \end{array}$$

The $g_{k,i}^{(n)}$'s can also be placed in similar arrays, the g_i-arrays, for a fixed value of the index i, where k indicates the column starting from zero. It is easy to check that $g_{k,i}^{(n)} = 0$ for $k \geq i$, and thus the g_i-array only contains the columns 0 to $i - 1$.

There are two methods for using, and thus for programming, convergence acceleration methods. The first one is to use them a posteriori, that is, to compute a fixed number of terms of the sequence (S_n) and then to apply the algorithm by computing each column of the array from the preceding one. This use is very easy to program, but it has the main disadvantage that all the computations must be started again from the beginning if one wants to add new terms to the initial sequence (S_n).

The second use, which is much more convenient in practice, is to use the algorithm "in parallel" with the computation of the successive terms of the original sequence (S_n): After the computation of each new term of the sequence

(S_n), one has to build the arrays as far as possible by computing each row from the preceding one and then to go back to the computation of the next term of (S_n). Of course, this way of implementing the algorithms is much more complicated to program, but is it the only reasonable way. For a complete description of this use see [1] and for its special application to the E-algorithm see [3].

Let us now describe the arguments of the subroutine EXTRAP for the parallel use of the E-algorithm.

The subroutine must be included in a loop where the successive terms of the sequence (S_n) are computed. Before the beginning of the loop the integer parameter INIT must be set to zero. Then the value of INIT is modified by the subroutine, and thus INIT might be set again to zero if one wants to use the subroutine later for another sequence.

In the subroutine, $E(I)$ contains $E_{I-1}^{(K-I)}$ for $I = 1, \ldots, \min(K, \text{MAXCOL} + 1)$ after the Kth call, while $G(I, J)(I = 1, \ldots, \min(K, \text{MAXCOL}))$ contains $g_{J-1,I}^{(K-J)}$ for $J = 1, \ldots, I - 1$, and $g_{I-1,J}^{(J-I)}$ for $J = I, \ldots, \min(K, \text{MAXCOL} + 1)$.

A partial listing of the subroutine EXTRAP follows:

```

```

Let us give an example of the use of this subroutine. It corresponds to the choice $g_i(n) = \Delta S_{n+i-1}$ (Shanks' transformation) for the sequence $S_n = 1/(n+1)$. For this sequence it is known that $E_k^{(0)} = \epsilon_{2k}^{(0)} = 1/(k+1)^2$.

```

This program gives the results shown in Table I on a computer with precision 10^{-18} (DEC 10). The numbers printed are $E_0^{(0)}, \ldots, E_5^{(0)}, E_5^{(1)}, \ldots, E_5^{(14)}$, where the exact values are given by $E_k^{(n)} = 1/((n+k+1)(k+1))$. The E-algorithm can be quite sensitive to the propagation of rounding errors. Several possibilities exist for their control. The first one is to compute the "amplification factors" defined by Håvie [9] which can be used to obtain an upper bound for the amplification of the initial errors and which can be considered as a measurement of the numerical stability of the algorithm. The second possibility consists in using the particular rules given in [4] although they are quite difficult to program and will lead to a much longer program. The third possibility is to use an exact arithmetic such as p-adic or rational arithmetic. Such an arithmetic is actually under consideration.

A quite important practical problem when using convergence acceleration methods is that of the termination criteria. For some special sequences and some particular methods such a criterion can be obtained (see, for example, the discussion on totally monotonic and totally oscillating sequences and their treatment by Shanks's transformation in [1]). In the general case some theorems exist [3, Theorem 3], but in practice the computations are stopped when two successive elements of the same column or the same diagonal of the E-array are nearly equal.

To end this section let us mention that the relationships of the E-algorithm, as they are written in [3], are numerically unstable. These relations must be written

Table I

as they are in (2.1) and (2.2) and in the subroutine. In that way they will be much more stable. For example, if the unstable version of these rules is used, then, for the preceding example, we shall obtain for the last entry a result that is less accurate by three digits.

3. THE MÜHLBACH–NEVILLE-AITKEN ALGORITHM

Let $\{f_i\}_{i\geq 0}$ be a family of linearly independent elements of a real vector space E. $\{f_i\}$ is assumed to be a complete Chebyshev system with respect to the linear functionals $\{L_j\}$, which means that all the Gram determinants $|L_j(f_i)|_{i,j=0,\ldots,k}$ are not zero whenever $L_0, \ldots, L_k$ are linearly independent.

The problem is to construct a generalized polynomial

$$P_k = a_0 f_0 + \cdots + a_k f_k$$

such that

$$L_i(P_k) = w_i, \qquad i = 0, \ldots, k,$$

where the w_i's are given numbers not all zero.

More generally one wants to construct

$$P_k^{(n)} = a_0 f_0 + \cdots + a_k f_k$$

such that

$$L_i(P_k^{(n)}) = w_i, \qquad i = n, \ldots, n + k.$$

This is the general interpolation problem as described, for example, by Davis [7].

Usually on a computer (and also often in numerical analysis) one deals with numbers and not with elements of a vector space. This means that, in practice, one has to compute the numerical values $L(P_k^{(n)})$ where L is a linear functional on E. (If E is a vector space of functions, then, for example, $L(f)$ is the value of the function f at some prescribed point x.)

Mühlbach [12, 13] showed that these values can be recursively computed by an algorithm that generalizes the Neville-Aitken scheme. For this reason it has been called the Mühlbach–Neville-Aitken algorithm (briefly, the MNA-algorithm). A very simple proof of the MNA-algorithm has been given in [4] using Sylvester's determinantal identify. Except for the initializations, it is similar to the E-algorithm.

$$L(P_0^{(n)}) = w_n \frac{L(f_0)}{L_n(f_0)}$$

$$L(f_{0,i}^{(n)}) = L_n(f_i)\frac{L(f_0)}{L_n(f_0)} - L(f_i)$$

$$L(P_k^{(n)}) = \frac{L(f_{k-1,k}^{(n+1)})L(P_{k-1}^{(n)}) - L(f_{k-1,k}^{(n)})L(P_{k-1}^{(n+1)})}{L(f_{k-1,k}^{(n+1)}) - L(f_{k-1,k}^{(n)})}$$

$$L(f_{k,i}^{(n)}) = \frac{L(f_{k-1,k}^{(n+1)})L(f_{k-1,i}^{(n)}) - L(f_{k-1,k}^{(n)})L(f_{k-1,i}^{(n+1)})}{L(f_{k-1,k}^{(n+1)}) - L(f_{k-1,k}^{(n)})}.$$

Thus the subroutine EXTRAP can still be used for computing the values of $L(P_k^{(n)})$. For example, if we choose

$$f_0(x) = e^{-x} \qquad f_1(x) = \sin x \qquad f_2(x) = x^2 \qquad f_3(x) = \log x$$

$$L_0(f_i) = f_i(1) \qquad L_1(f_i) = f_i'(2) \qquad L_2(f_i) = \int_0^1 f_i(x)\,dx \qquad L_3(f_i) = f_i''(1)$$

$$w_i = L_i(f) \quad i = 0, \ldots, 3 \quad \text{with} \quad f(x) = 3f_0(x) + 4f_1(x) - f_2(x) + f_3(x)$$

and $L(P_k^{(n)}) = P_k^{(n)}(x)$, then the calling sequence is as follows:

Of course, $L(P_4^{(0)}) = L(f)$ for all x, as can be checked from the numerical results shown in Table II.

The MNA-algorithm can also be used to implement another convergence acceleration process due to Germain-Bonne [9, pp. 33–43] that is based on generalized inverse interpolation.

4. LEAST SQUARES APPROXIMATION AND EXTRAPOLATION

Let E be an inner product space. The least squares approximation of $f \in E$ by a combination of the given independent elements $f_0, \ldots, f_k$ of E consists in determining $a_0, \ldots, a_k$ such that

$$\| f - (a_0 f_0 + \cdots + a_k f_k) \|$$

be minimum where $\| \cdot \|^2 = (\cdot, \cdot)$. It is well known (e.g., see [7, p. 182]) that the solution $F_k = a_0 f_0 + \cdots + a_k f_k$ of this minimization problem is given by a ratio of determinants completely similar to the one defining $P_k^{(0)}$ in the general interpolation problem; one only has to replace $L_i(f_j)$ by (f_i, f_j) and w_i by (f_i, f). If L is a linear functional on E, then the sequence $(L(F_k))$ can be obtained via the MNA algorithm with the initializations

$$P_0^{(n)} = (f_n, f) \frac{L(f_0)}{(f_n, f_0)}$$

$$f_{0,i}^{(n)} = (f_n, f_i) \frac{L(f_0)}{(f_n, f_0)} - L(f_i).$$

We shall obtain

$$P_k^{(0)} = L(F_k).$$

A special case of this general problem is to find F_k, which satisfies the system of linear equations

$$L_i(F_k) = w_i, \qquad i = 0, \ldots, m \geq k$$

in the least squares sense. The solution of this problem can be obtained by the MNA-algorithm where the scalar product is defined by

$$(f, g) = \sum_{i=0}^{m} L_i(f) L_i(g).$$

Another special case is the biconjugate gradient method for solving systems of linear equations whose successive iterates are still given by a similar ratio of determinants [2, p. 87] and which can therefore be computed by the MNA-algorithm.

The subroutine EXTRAP can be used for implementing all these least squares approximation problems. This subroutine can also be used for a convergence acceleration process due to Cordellier [6] that is based on least squares. Let us explain this process.

The E-transformation of sequences described in Section 2 was obtained by assuming that the given sequence (S_n) satisfied

$$S_{n+i} = S + a_1 g_1(n + i) + \cdots + a_k g_k(n + i)$$

for $i = 0, \ldots, k$ and then solving this system for the unknown S. Cordellier's idea consists of writing this system for $i = 0, \ldots, m \geq k$ and then solving it in the least squares sense for the unknown S. This least squares solution can be obtained by the E-algorithm as we now see. We set

$$g_i = (g_i(n); \ldots; g_i(n + m))^{\mathrm{T}}, \qquad i \geq 1$$

$$g_0 = (1; \ldots; 1)^{\mathrm{T}}$$

$$V = (S_n; \ldots; S_{n+m})^{\mathrm{T}}.$$

Thus the system becomes

$$\begin{pmatrix} 1 & \frac{(g_0, g_1)}{(g_0, g_0)} & \cdots & \frac{(g_0, g_k)}{(g_0, g_0)} \\ - & - & - & - \\ 1 & \frac{(g_k, g_1)}{(g_k, g_0)} & \cdots & \frac{(g_k, g_k)}{(g_k, g_0)} \end{pmatrix} \begin{pmatrix} S \\ a_1 \\ \vdots \\ a_k \end{pmatrix} = \begin{pmatrix} \frac{(g_0, V)}{(g_0, g_0)} \\ \vdots \\ \frac{(g_k, V)}{(g_k, g_0)} \end{pmatrix}$$

The value of S thus obtained will depend on m, k, and n, and we denote it by ${}_mE_k^{(n)}$. Since the preceding system has the same form as the system implicitly solved by the E-algorithm, we can use it to obtain the sequence ${}_mE_k^{(n)}$ for $k = 0, \ldots, m$ and n and m fixed. In this case the initializations must be

$$E_0^{(n)} = \frac{(g_n, V)}{(g_n, g_0)}$$

$$g_{0,i}^{(n)} = \frac{(g_n, g_i)}{(g_n, g_0)}, \qquad i \geq 1$$

and we shall get

$$E_k^{(0)} = {}_mE_k^{(n)}.$$

If the value of n or m is modified, then the definition of the scalar product is also modified and all the computations have to be started again from the beginning. For $k = m$ the least squares extrapolated value will be identical to the value obtained by the E-transformation as described in Section 2. This is also

Table III

true for the value obtained by least squares approximation that will be equal to the value obtained by interpolation when $m = k$.

The basic advantage of least squares extrapolation is to be less sensitive to small perturbations in the sequence (S_n) to be accelerated.

Let us take the same example as in Section 2 and let us add a perturbation of magnitude less than 10^{-4} to the sequence (S_n).

Since the sequences (g_i) depend on (S_n), a perturbation of (S_n) will also modify the (g_i). Thus two different experiments have been conducted: with the (g_i) automatically modified by the perturbation of (S_n) and with unmodified (g_i). Columns R.E. in Table III contain the values of the relative errors with respect to the unperturbed case multiplied by 10000. For $n = 0$ and $m = 4$ we get the results also shown in the table. As we can verify, the ${}_4E_k^{(0)}$'s $(k < 4)$ are less sensitive to the perturbation than ${}_4E_4^{(0)} = E_4^{(0)} = 0.04$. It must be noticed that the results obtained are very sensitive to the precision on the computation of the scalar products appearing in the initializations.

ACKNOWLEDGMENTS

I am very much indebted to the two referees who reviewed this paper. The first one provided me with the numerical example showing the influence of the computer's precision, while the second gave me many valuable suggestions for improving the presentation of the paper. I also want to convey my gratitude to Prof. Å. Björck, who suggested many improvements and who, with the help of one of his assistants, modified my programs and checked them to be portable. Thanks are also due to Dr. R.J. Hanson and Prof. J.R. Rice for their numerous comments that greatly helped me to polish the paper and enhance the quality of the subroutine.

1. INTRODUCTION

ITPACK 2C is a collection of seven FORTRAN subroutines for solving large sparse linear systems by adaptive accelerated iterative algorithms. Basic iterative procedures, such as the Jacobi method, the successive overrelaxation method, the symmetric successive overrelaxation method, and the RS method for the reduced system are combined, where possible, with acceleration procedures, such as Chebyshev (semi-iteration) and conjugate gradient, for rapid convergence. Automatic selection of the acceleration parameters and the use of accurate stopping criteria are major features of this software package. While the ITPACK routines can be called with any linear system containing positive diagonal elements, they are the most successful in solving systems with symmetric positive definite or mildly nonsymmetric coefficient matrices.

For several years, we have been involved with the development and use of research-oriented programs using iterative algorithms for solving large sparse

$$Au = b$$

with positive diagonal elements. One solves for the N component unknown vector u given the $N \times N$ nonsingular coefficient matrix A and the N component right-hand side vector b. The current ITPACK software package of subroutines, version 2C, provides for the use of seven alternative iterative procedures. While these subroutines are not designed as production software, they should successfully handle industrial problems of moderate size, that is, ones that fit in high-speed

memory. This package is written in 1966 American National Standard FORTRAN code. It has been tested over a wide variety of computer systems using various FORTRAN compilers, including one which is FORTRAN-77 compatible (see Acknowledgments).

The seven iterative solution modules are based on several basic iterative procedures, such as the Jacobi method, the successive overrelaxation (SOR) method, the symmetric SOR (SSOR) method, and the RS method for the reduced system. With the exception of SOR, the convergence of these basic methods are accelerated by Chebyshev (semi-iteration, SI) or conjugate gradient (CG) acceleration. All methods are available with adaptive parameter estimation and automatic stopping tests. When using the RS method it is required that the linear system be reordered into a "red-black" system [6, 13].[1] A switch to compute, if possible, the red-black indexing, permute the linear system, and permute associated vectors is provided.

The successful convergence of iterative methods may be dependent on conditions that are difficult to determine in advance. For example, determining whether the coefficient matrix is positive definite can be as costly to check as solving the system. On the other hand, some conditions affecting convergence, such as positive diagonal elements, diagonal dominance, and symmetry are relatively easy to verify. For some applications, the theory to guarantee the convergence of an iterative method may not exist. The algorithms in ITPACK have been tested most extensively for linear systems arising from elliptic partial differential equations. The routines can be applied formally to any linear system which fits in high-speed memory. However, rapid convergence, and indeed convergence itself cannot be guaranteed unless the matrix of the system is symmetric and positive definite. Success can be expected, though not guaranteed, for mildly nonsymmetric systems. In other words, iterative methods may not converge when applied to systems with coefficient matrices which are completely general with no special properties.

This article discusses the usage of ITPACK and gives a few test results. The description of the iterative methods is given in [4]. The underlying theory on which the iterative algorithms are based is described in [6]. A survey of the iterative methods in ITPACK is presented in [12].

Throughout this paper, we adopt notation such as **SOR( )** when referring to a subroutine and **A(*)** for a single-dimensioned array. The residual vector is $b - Au$ for the linear system $Au = b$ and the pseudo-residual vector is $Gu^{(n)} + k - u^{(n)}$ for a basic iterative method of the form $u^{(n+1)} = Gu^{(n)} + k$. The smallest and largest eigenvalues of the iteration matrix G are denoted $m(G)$ and $M(G)$, respectively.

2. SPARSE MATRIX STORAGE

The sparse storage scheme used in ITPACK is a common one. It is a row-wise representation of the nonzero entries in the coefficient matrix of the linear system. For a nonsymmetric coefficient matrix, all of the nonzero values in each row are stored in a contiguous block of data in a real-valued array **A(*)**. If the matrix is symmetric, computer memory can be saved by storing only the nonzero entries in each row on and above the main diagonal. For either nonsymmetric or symmetric sparse storage, associated column numbers are stored in an integer-valued array **JA(*)** such that **JA(K)** is the column number for the value **A(K)**.

[1] In this ordering, the components of the unknown vector u are considered as either "red" or "black". A "red-black ordering" is any ordering such that every black unknown follows all of the red unknowns. This ordering of unknowns leads to a 2×2 "red-black partitioning" of the coefficient matrix; that is, a matrix of the form

$$\begin{bmatrix} A_{1,1} & A_{1,2} \\ A_{2,1} & A_{2,2} \end{bmatrix}$$

with diagonal submatrices $A_{1,1}$ and $A_{2,2}$. The original linear system may require rearrangement in order to arrive at this form.

A mapping vector **IA(*)** is used to denote the starting locations of each of the contiguous blocks. The beginning of the linear block for row **I** is given by **IA(I)**, the end by **IA(I + 1) − 1**, and its length by **IA(I + 1) − IA(I)**. Thus, **IA(*)** will contain **N + 1** elements to accommodate a linear system of order **N**. The entries for each row may be stored in any order in the contiguous block for that row.

For example, the coefficient matrix

$$\begin{bmatrix} 11. & 0. & 0. & 14. & 15. \\ 0. & 22. & 0. & 0. & 0. \\ 0. & 0. & 33. & 0. & 0. \\ 14. & 0. & 0. & 44. & 45. \\ 15. & 0. & 0. & 45. & 55. \end{bmatrix}$$

would be represented in nonsymmetric sparse storage as

A(*) = [11., 14., 15., 22., 33., 14., 44., 45., 15., 45., 55.]

JA(*) = [1, 4, 5, 2, 3, 1, 4, 5, 1, 4, 5]

IA(*) = [1, 4, 5, 6, 9, 12]

and in symmetric sparse storage as

A(*) = [11., 14., 15., 22., 33., 44., 45., 55.]

JA(*) = [1, 4, 5, 2, 3, 4, 5, 5]

IA(*) = [1, 4, 5, 6, 8, 9]

3. USAGE

The user is expected to provide the coefficient matrix and the right-hand side of the linear system to be solved. The data structure for the matrix of the system is either the symmetric or nonsymmetric sparse storage format described in the previous section. An initial guess for the solution should be provided, if one is known; otherwise, it can be set to all zero values. A series of approximations for the solution are generated iteratively until the convergence criterion is satisfied. The algorithms are performed in two work-space arrays and some control over the algorithmic procedure can be obtained from switches in two parameter arrays.

There are seven main subroutines in ITPACK, each corresponding to an iterative method. They are

SUBROUTINE	METHOD
JCG( )	Jacobi Conjugate Gradient
JSI( )	Jacobi Semi-iteration
SOR( )	Successive Overrelaxation
SSORCG( )	Symmetric SOR Conjugate Gradient
SSORSI( )	Symmetric SOR Semi-iteration
RSCG( )	Reduced System Conjugate Gradient
RSSI( )	Reduced System Semi-iteration

and the calling sequence is

CALL ⟨method⟩ (N, IA, JA, A, RHS, U, IWKSP, NW, WKSP, IPARM, RPARM, IER)

where the parameters are defined in the following. Here "input" means that the subroutine expects the user to provide the necessary input data, and "output" means that the routine passes back information in the variable or array indicated. All parameters are linear arrays, except variables **N**, **NW**, and **IER**. Moreover, all parameters may be altered by the subroutine call, except variables **N** and **NW**. (See Section 7 for additional details.)

PARAMETER	DESCRIPTION
N	Order of the linear system. [integer; input]
IA(*)	Vector of length **N + 1** used in the sparse-matrix storage format. Contains the row pointers into **JA(*)** and **A(*)**. [integer array; input]
JA(*)	Vector of length **NZ** (defined in **A(*)** below) used in the sparse-matrix storage format. Contains the column numbers for the corresponding entries in **A(*)**. [integer array; input]
A(*)	Vector of length **NZ** used in the sparse-matrix storage format. Contains the nonzero entries of the coefficient matrix with positive diagonal elements. (**NZ** is the number of nonzero entries in the upper triangular part of the coefficient matrix when symmetric storage is used and is the total number of nonzeros when nonsymmetric storage is used.) [real array; input]
RHS(*)	Vector of length **N** containing the right-hand side of the linear system. [real array; input]
U(*)	Vector of length **N** containing the initial guess to the solution of the linear system on input and the latest approximate solution on output. [real array; input/output]
IWKSP(*)	Vector of length **3 * N** used for integer work space. When reindexing for red-black ordering, the first **N** locations contain on output the permutation vector for the red-black indexing, the next **N** locations contain its inverse, and the last **N** are used for integer work space.[2] [integer array; output]
NW	On input, **NW** is the available length for **WKSP(*)**. On output, **IPARM(8)** is the actual amount used (or needed). [integer; input]
WKSP(*)	Vector used for real working space whose length depends on the iterative method being used. Must be at least **NW** entries long. (See table near end of this section for required amount of work space for each method.) [real array]
IPARM(*)	Vector of length 12 used to initialize various integer and logical parameters. Default values may be set by calling subroutine **DFAULT( )** described below. On output, **IPARM(*)** contains the values of the parameters that were changed. (Further details to follow.) [integer array; input/output]
RPARM(*)	Vector of length 12 used to initialize various real parameters on input. Default values may be set by calling subroutine **DFAULT( )** described below. On output, **RPARM(*)** contains the final values of the parameters that were changed. (Further details given later in this section.) [real array; input/output]
IER	Error flag which is set to zero for normal convergence and to a nonzero integer when an error condition is present. (See table at end of section for meaning of nonzero values.) [integer; output]

The user may supply nondefault values for selected quantities in **IPARM(*)** and **RPARM(*)** by first executing

CALL DFAULT (IPARM, RPARM)

and then assigning the appropriate nondefault values before calling a solution module of ITPACK.

[2] For the red-black ordering, the **I**th entry of a permutation array **P( )** indicates the position **J** into which the **I**th unknown of the original system is being mapped; that is, if **P(I) = J**, then unknown **I** is mapped into position **J**. The **J**th entry of an inverse permutation array **IP( )** indicates the position **I** into which the **J**th unknown of the permuted system must be mapped to regain the original ordering, that is, **IP(J) = I**.

The iterative algorithms used in ITPACK are quite complicated and some knowledge of iterative methods is necessary to completely understand them. The interested reader should consult [4] and [6] for details. Important variables in this package which may change adaptively are **CME** (estimate of largest eigenvalue of the Jacobi matrix), **SME** (estimate of the smallest eigenvalue of the Jacobi matrix), **OMEGA** (overrelaxation parameter for the SOR and SSOR methods), **SPECR** (estimate of the spectral radius of the SSOR matrix), **BETAB** (estimate for the spectral radius of the matrix LU, where L and U are strictly lower and upper triangular matrices, respectively, such that the Jacobi matrix $B = L + U$).

The integer array **IPARM(*)** and real array **RPARM(*)** allow the user to control certain parameters which affect the performance of the iterative algorithms. Furthermore, these arrays allow the updated parameters from the automatic adaptive procedures to be communicated back to the user. The entries in **IPARM(*)** and **RPARM(*)** are

POSITION	DEFAULT	MEANING OR USAGE
IPARM(1)	100	**ITMAX:** Maximum number of iterations allowed. Reset on output to the number of iterations performed.
IPARM(2)	0	**LEVEL:** Control level of output. Each higher value provides additional information. [<0: no output on unit **IPARM(4)**; 0: fatal error messages only; 1: warning messages and minimum output; 2: reasonable summary (progress of algorithm); 3: parameter values and informative comments; 4: approximate solution after each iteration (primarily useful for debugging); 5: original system]
IPARM(3)	0	**IRESET**: Communication switch. [0: implies certain values of **IPARM(*)** and **RPARM(*)** will be overwritten to communicate parameters back to the user; otherwise: only **IPARM(1)** and **IPARM(8)** will be reset.]
IPARM(4)	6	**NOUT**: output unit number.
IPARM(5)	0	**ISYM**: Sparse-storage format switch. [0: symmetric sparse storage; 1: nonsymmetric sparse storage]
IPARM(6)	1	**IADAPT**: Adaptive switch. Determines whether certain parameters have been set by user or should be computed automatically in either a fully or partially adaptive sense. [0: fixed iterative parameters used for **SME, CME, OMEGA, SPECR,** and **BETAB** (nonadaptive); 1: fully adaptive procedures used for all parameters; 2: (SSOR methods only) **SPECR** determined adaptively and **CME, BETAB,** and **OMEGA** fixed; 3: (SSOR methods only) **BETAB** fixed and all other parameters determined adaptively] (See [4, 6] for details and **RPARM(I), I = 2, 3, 5, 6, 7**, for **CME, SME, OMEGA, SPECR, BETAB**, respectively. These parameters are

set by subroutine **DFAULT( )** or by the user.)

IPARM(7) 1 **ICASE**: Adaptive procedure case switch for JSI and SSOR methods. There are two strategies, called Case I and Case II, for doing the adaptive procedure. The choice of which case to select corresponds to knowledge of the eigenvalues of the Jacobi matrix B and their estimates.

[($\neq 2$) Case I: fixed **SME** $\leq m(B)$ (general case);
($= 2$) Case II: use when it is known that $|m(B)| \leq M(B)$]

The case switch determines how the estimates for **SME** and **CME** are recomputed adaptively. In Case I, **SME** is fixed throughout and should be less than or equal to $m(B)$. In Case II, **SME** is set to **−CME**, which may adaptively change. As far as the adaptive procedure is concerned, Case I is the most general case and should be specified in the absence of specific knowledge of the relationship between the eigenvalues and their estimates. An example when Case II is appropriate occurs when the Jacobi matrix has Property A, since $m(B) = -M(B)$.[3] Also, if A is an L-matrix, then for the Jacobi matrix, we have $|m(B)| \leq M(B)$ and **SME** is always **−CME** (Case II).[4] Selecting the correct case may increase the rate of convergence of the iterative method. (See [6] for additional discussion on Cases I and II. Also, see **RPARM(I), I = 2, 3** for **CME**, **SME**, respectively.)

IPARM(8) 0 **NWKSP**: Amount of work space used. Used for output only. If **ITMAX** is set to a value just over the actual number of iterations necessary for convergence, the amount of memory for **WKSP(*)** can be reduced to just over the value returned here. This may be done when rerunning a problem, for example.

IPARM(9) −1 **NB**: Red-black ordering switch. On output, if reindexing is done, **NB** is set to the order of the black subsystem.

[For RS methods,
<0: compute red--black indexing and permute system;
≥0: skip indexing—system already in red–black form;
For other methods,
<0: skip indexing—system already in desired form;
≥0: compute red--black indexing and permute system]

[3] A matrix has Property A if and only if it is a diagonal matrix, or else there exists a rearrangement of the rows and corresponding columns of the matrix which corresponds to a red–black partitioning.

[4] An L-matrix has positive diagonal elements and nonpositive off-diagonal elements.

A negative integer value for **IPARM(9)** causes the equations to be handled in the most general way appropriate for the solution method being used. For methods other than RS methods this is the "natural order," while for RS methods it is the "red-black order." A nonnegative value produces a red-black permutation for all methods except for the RS methods, which are assumed to be in red-black order with the order of the black subsystem **NB** given. If reindexing is performed, **IPARM(9)** will contain the order of the black subsystem on output.

IPARM(10) 0 **IREMOVE**: Switch for effectively removing rows and columns when the diagonal entry is extremely large compared to the nonzero off-diagonal entries in that row. (See **RPARM(8)** for additional details.)

[0: not done; otherwise: test done]

IPARM(11) 0 **ITIME**: Timing switch.

[0: time method; otherwise: not done]

IPARM(12) 0 **IDGTS**: Error analysis switch. An analysis of final computed solution to determine accuracy.

[<0: skip error analysis
0: compute **DIGIT1** and **DIGIT2** and store in **RPARM(I), I = 11, 12, respectively;**
1: print **DIGIT1** and **DIGIT2**;
2: print final approximate solution vector;
3: print final approximate residual vector;
4: print both solution and residual vectors;
otherwise: no printing]

(If **LEVEL** $\leq$ 0, no printing is done. See **RPARM(I), I = 11, 12,** for details on **DIGIT1** and **DIGIT2**.)

ENTRY DEFAULT	DESCRIPTION
RPARM(1) 5.E−6	**ZETA**: Stopping criterion or approximate relative accuracy desired in the final computer solution. If the method does not converge in **IPARM(1)** iterations, **RPARM(1)** is reset to an estimate of the relative accuracy achieved. The stopping criterion is a test of whether **ZETA** is greater than the ratio of the Euclidean norm of the pseudo-residual vector and the norm of the current iteration vector times a constant involving an eigenvalue estimate. (See [4, 6] for details.)
RPARM(2) 0.	**CME**: Estimate of largest eigenvalue of Jacobi matrix. Changes to new estimate if adaptive procedure is used. **CME** $\leq M(B)$.
RPARM(3) 0.	**SME**: Estimate of smallest eigenvalue of Jacobi matrix for JSI method. In Case I, **SME** is fixed throughout at a value $\leq m(B)$. In Case II, **SME** is always set to **−CME** with **CME** changing in the adaptive procedure. (See **IPARM(7)** for definitions of Cases I and II.)

RPARM(4) .75 — **FF**: Adaptive procedure damping factor. Values in the interval (0., 1.] with 1. causing the most frequent parameter changes when the fully adaptive switch **IPARM(6) = 1** is used.

RPARM(5) 1. — **OMEGA**: Overrelaxation parameter for SOR and SSOR methods. If method is fully adaptive, **OMEGA** changes.

RPARM(6) 0. — **SPECR**: Estimated spectral radius for SSOR matrix. If method is adaptive, **SPECR** changes.

RPARM(7) .25 — **BETAB**: Estimate for the spectral radius of matrix LU used in SSOR methods. **BETAB** may change depending on the adaptive switch **IPARM(6)**. The matrix L is the strictly lower triangular part of the Jacobi matrix and U the strictly upper triangular part. When the spectral radius of LU is less than or equal to $\frac{1}{4}$, the "SSOR condition" is satisfied for some problems, provided one uses the natural ordering. (See [4, 5, 19] for additional details.)

RPARM(8) 100. * SRELPR — **TOL**: Tolerance factor near machine relative precision, **SRELPR**. In each row, if all nonzero off-diagonal row entries are less than **TOL** times the value of the diagonal entry, then this row and corresponding column are essentially removed from the system. This is done by setting the nonzero off-diagonal elements in the row and corresponding column to zero, replacing the diagonal element with 1, and adjusting the elements on the right-hand side of the system so that the new system is equivalent to the original one.[5] If the diagonal entry is the only nonzero element in a row and is not greater than the reciprocal of **TOL**, then no elimination is done. This procedure is useful for linear systems arising from finite-element discretizations of PDEs in which Dirichlet boundary conditions are handled by giving the diagonal values in the linear system extremely large values. (The installer of this package should set the value of **SRELPR**. See comments in subroutine **DFAULT( )** for additional details.)

RPARM(9) 0. — **TIME1**: Total time in seconds from beginning of iterative algorithm until convergence. (A machine-dependent subprogram call for returning the time in seconds is provided by the installer of this package.)

RPARM(10) 0. — **TIME2**: Total time in seconds for entire call.

RPARM(11) 0. — **DIGIT1**: Approximate number of digits using the estimated relative error with the final approximate solution. Computed as the negative of the logarithm base 10 of the final value of the stopping test. (See details below or [6].)

RPARM(12) 0. — **DIGIT2**: Approximate number of digits using the estimated relative residual with the final approximate solution. Computed as the negative of the logarithm base 10 of the ratio of the two norm of the residual vector and the two norm of the right-hand-side vector. This estimate is related to the condition number of the original linear system and therefore it will not be accurate if the system is ill-conditioned. (See details below or [6].)

[5] If the row and column corresponding to diagonal entry coef(i, i) are to be eliminated, then the right-hand side is adjusted to rhs(i) = rhs(i)/coef(i, i) and rhs(j) = rhs(j) − rhs(i) × coef(i, j) for $j \neq i$.

DIGIT1 is determined from the actual stopping test computed on the final iteration, whereas **DIGIT2** is based on the computed residual vector using the final approximate solution after the algorithm has converged. If these values differ greatly, then either the stopping test has not worked successfully or the original system is ill-conditioned. (See [6] for additional details.)

For storage of certain intermediate results, the solution modules require a real vector **WKSP(*)** and a corresponding variable **NW** indicating the available space. The length of the work-space array varies with each solution module and the maximum amount needed is given in the following table.

SOLUTION MODULE	MAXIMUM LENGTH OF WKSP(*)
JCG( )	**4 * N + NCG**
JSI( )	**2 * N**
SOR( )	**N**
SSORCG( )	**6 * N + NCG**
SSORSI( )	**5 * N**
RSCG( )	**N + 3 * NB + NCG**
RSSI( )	**N + NB**

where value of **NCG** is **2 * IPARM(1)** for symmetric sparse storage and **4 * IPARM(1)** for nonsymmetric sparse storage. It should be noted that the actual amount of work space used may be somewhat less than these upper limits since some of the latter are dependent on the maximum number of iterations allowed, **ITMAX**, stored in **IPARM(1)**. Clearly, the array **WKSP(*)** must be dimensioned to at least the value of **NW**.

Nonzero integer values of the error flag **IER** indicate that an error condition was detected. These values are listed below according to their numerical value and to the name of the routine in which the flag was set.

ERROR FLAG	MEANING
IER = 0,	Normal convergence obtained.
= 1 + Mth,	Invalid order of system, **N**
= 2 + Mth,	Work-space array **WKSP(*)** not large enough—**IPARM(8)** set to amount of required work space, **NW**.
= 3 + Mth,	Failure to converge in **IPARM(1)** iterations—**RPARM(1)** reset to last stopping value computed.
= 4 + Mth,	Invalid order of black subsystem, **NB**.
= 101,	Diagonal element not positive.
= 102,	No diagonal entry in a row.
= 201,	Red-black indexing not possible.
= 301,	No entry in row of original matrix.
= 302,	No entry in row of permuted matrix.
= 303,	Sorting error in row of permuted matrix.
= 401,	Diagonal element not positive.
= 402,	No diagonal entry in a row.
= 501,	Failure to converge in **ITMAX** evaluations.
= 502,	Function does not change sign at endpoints.
= 601,	Successive iterates not monotone increasing.

JCG( ), JSI( ), SOR( ), SSORCG( ), SSORSI( ), RSCG( ), RSSI( ) assign values to Mth of 10, 20, 30, 40, 50, 60, 70, respectively. **SBELM( ), PRBNDX( ), PERMAT( ), SCAL( ), ZBRENT( ), EQRT1S( )** are subroutines with error flags in the 100s, 200s, 300s, 400s, 500s, 600s, respectively. These routines perform the following functions: **SBELM( )** removes rows and columns, **PRBNDX( )** determines the red-black indexing, **SCAL( )** scales the system, **ZBRENT( )** is a modified IMSL routine for computing a zero of a function which changes sign in

a given interval, **EQRT1S( )** is a modified IMSL routine for computing the largest eigenvalue of a symmetric tridiagonal matrix.[6]

4. USER-ORIENTED MODULES

The array **U(*)** should contain an initial approximation to the solution of the linear system before any ITPACK module is called. If the user has no information for making such a guess, then the zero vector may be used as the starting vector. The subroutine **VFILL( )** can be used to fill a vector with a constant:

CALL VFILL (N, U, VAL)

fills array **U(*)** of length **N** with value **VAL** in each entry.

To aid the user in using the iterative methods of ITPACK, four modules for constructing the sparse-matrix storage arrays are included. The modules are

SBINI( ) called at the beginning to initialize the arrays **IA(*)**, **JA(*)**, **A(*)**, and **IWORK(*)**;

SBSIJ( ) called repeatedly to set the individual entries in the matrix and build a link-list representation of the matrix structure;

SBEND( ) called at the end to restructure the link list into final sparse storage form;

SBAGN( ) called to return again to the link-list representation if **SBEND( )** has been called but additional elements are to be added or modified.

These modules are described below.

(a) Initialization:

CALL SBINI (N, NZ, IA, JA, A, IWORK)

Initializes **IA(*)**, **JA(*)**, **A(*)**, and **IWORK(*)** for a system of order **N**. **IA(*)**, **JA(*)**, and **IWORK(*)** are integer arrays of length at least **N + 1**, **NZ**, and **NZ**, respectively. **A(*)** is a real array of length at least **NZ**.

(b) Set individual entries:

CALL SBSIJ (N, NZ, IA, JA, A, IWORK, I, J, VAL, MODE, LEVEL, NOUT, IER)

Inserts the value, **VAL**, of the **(I, J)** entry of the user's matrix into the link-list representation for that matrix. When using symmetric sparse storage, **J** must be greater than or equal to **I**. If the **(I, J)** entry has already been set, then **MODE** specifies the way in which the entry is to be treated:

MODE < 0, Current entry value is left as is;
$= 0$, Current entry value is reset to **VAL**;
> 0, **VAL** is added to the current entry value.

If **LEVEL** is less than 0, **SBSIJ( )** causes no printing. If **LEVEL** is 0, fatal error messages are written to output unit number **NOUT**; and if **LEVEL** is 1 or greater, a message is printed when **SBSIJ( )** encounters a value it has already set with the value being reset according to the value of **MODE**. **IER** is an error parameter and returns values of

ERROR FLAG	MEANING
IER = 0,	New **(I, J)** entry established.
= 700,	**(I, J)** entry already set—reset according to **MODE**.
= 701,	Improper values for either **I** or **J**.
= 702,	**NZ** too small—no room for new entry.

[6] International Mathematical and Statistical Libraries, Inc., Sixth Floor NBC Bldg., 7500 Bellaire Blvd., Houston, TX 77036.

(c) Finalization:

CALL SBEND (N, NZ, IA, JA, A, IWORK)

Restructures the link-list data structure built by **SBINI( )** and **SBSIJ( )** into the final data structure required by ITPACK.

(d) Undo finalization:

CALL SBAGN (N, NZ, IA, JA, A, IWORK, LEVEL, NOUT, IER)

Returns to link-list representation for modification or addition of elements to the system. Repeated calls to **SBSIJ( )** can then be made followed by a single call to **SBEND( )** to close out the sparse-matrix representation. If **LEVEL** is less than 0, no printing is done, and if **LEVEL** is 0 or greater, fatal error information is written to output unit number **NOUT**. **IER** is an error flag indicating

ERROR FLAG	MEANING
IER = 0,	Successful completion.
= 703,	**NZ** too small—no room for new entry.

Note that **SBINI( )** should not be called after **SBAGN( )** is called, since it would destroy the previous data.

5. EXAMPLES

Given a linear system $Au = b$ with

$$A = \begin{bmatrix} 4 & -1 & -1 & 0 \\ -1 & 4 & 0 & -1 \\ -1 & 0 & 4 & -1 \\ 0 & -1 & -1 & 4 \end{bmatrix}, \qquad b = \begin{bmatrix} 6 \\ 0 \\ 0 \\ 6 \end{bmatrix}$$

a program to solve this problem with an initial guess of $u^T = (0, 0, 0, 0)$ using **JCG( )** with symmetric sparse storage and printing the final approximate solution vector follows.

```
      INTEGER IA(5), JA(8), IPARM(12), IWKSP(12)
      REAL A(8), RHS(4), U(4), WKSP(24), RPARM(12)
      DATA A(1), A(2), A(3), A(4)/4.0, -1.0, -1.0, 4.0/
      DATA A(5), A(6), A(7), A(8)/-1.0, 4.0, -1.0, 4.0/
      DATA JA(1), JA(2), JA(3), JA(4)/1, 2, 3, 2/
      DATA JA(5), JA(6), JA(7), JA(8)/4, 3, 4, 4/
      DATA IA(1), IA(2), IA(3), IA(4), IA(5)/1, 4, 6, 8, 9/

Textbook methods such as the Jacobi (J), Gauss-Seidel (GS), successive overrelaxation (SOR—fixed relaxation factor omega), symmetric successive

Table I

Method	Use	Parameters
J	**JSI( )**	**IPARM(6) = 0, IPARM(7) = 2**
GS	**SOR( )**	**IPARM(6) = 0**
SOR—fixed omega	**SOR( )**	**IPARM(6) = 0, RPARM(5) = OMEGA**
SSOR—fixed omega	**SSORSI( )**	**IPARM(6) = 0, RPARM(5) = OMEGA**
RS	**RSSI( )**	**IPARM(6) = 0**

overrelaxation (SSOR—fixed relaxation factor omega), and the RS method can be obtained from this package by resetting appropriate parameters after the subroutine **DFAULT( )** is called but before ITPACK routines are called (see Table I). These methods were not included as separate routines because they are usually slower than the accelerated methods included in this package.

On the black unknowns, the cyclic Chebyshev semi-iterative (CCSI) method of Golub and Varga [2] gives the same result as the RSSI method. The CCSI and RSSI methods converge at the same rate, and each of them converges twice as fast as the JSI method. This is a theoretical result [6] and does not count the time involved in establishing the red-black indexing and the red-black partitioned system. Similarly, the cyclic conjugate gradient (CCG) method with respect to the black unknowns, considered by Reid [16] (see also Hageman and Young [6]), gives the same results as the RSCG method. Also, the CCG and the RSCG methods converge at the same rate, and each of them converges, theoretically, exactly twice as fast as the JCG method. Hence, the accelerated RS methods are preferable to the accelerated J methods when using a red-black indexing.

6. NUMERICAL RESULTS

The iterative algorithms in ITPACK have been tested over a wide class of matrix problems arising from elliptic partial differential equations with Dirichlet, Neumann, and mixed boundary conditions on arbitrary two-dimensional regions (including cracks and holes) and on rectangular three-dimensional regions [1]. Both finite-difference and finite-element procedures have been employed to obtain the linear systems. The two sample problems presented here, while simple to pose, are representative of the behavior of the ITPACK routines for more complex problems. The iterative algorithms make no use of the constant coefficients in these two problems or of the particular structure of the resulting linear system. Because the ITPACK code is not tailored to any particular class of partial differential equations or discretization procedure, but rather to sparse linear systems, it is felt that the package can be used to solve a wider class of problems.

We now consider two simple partial differential equations that, when discretized by finite-difference methods, give rise to large sparse linear systems. We obtain the solution of each of these systems by the seven algorithms in ITPACK 2C. These numerical results should aid the user of ITPACK in determining the amount of time required when solving more complicated sparse systems. However, one should not interpret these execution times as conclusive by themselves. Variances introduced by different compilers, computer systems, and timing functions can sometimes be significant. Moreover, the number of iterations required by an iterative method is dependent on the problem being solved, the initial estimate for the solution, the parameter estimates used, and the relative accuracy requested in the stopping criterion **RPARM(1)**. These tests were run on the CDC CYBER 170/750 at the University of Texas with the FTN 4.8 compiler (OPT = 2).

To obtain representative sparse linear systems, we discretize the following two self-adjoint elliptic partial differential equations in a region with prescribed conditions on the boundary. Here u_{xx}, u_{yy}, u_{zz} are partial derivatives and du/dn is the derivative in the normal direction.

Table II. Number of Iterations and Execution Times for Problem (1) Using Adaptive and Nonadaptive Procedures (Nonadaptive Data in Parentheses)

Routine	Ordering	Iterations	Iteration time	Total time
JCG( )	Natural	61 (61)	0.250 (0.247)	0.281 (0.271)
	Red-black	61 (61)	0.232 (0.246)	0.402 (0.413)
JSI( )	Natural	108 (95)	0.408 (0.344)	0.439 (0.375)
	Red-black	108 (95)	0.393 (0.332)	0.569 (0.498)
SOR( )	Natural	72 (54)	0.356 (0.280)	0.368 (0.307)
	Red-black	65 (47)	0.311 (0.224)	0.469 (0.411)
SSORCG( )	Natural	17 (13)	0.232 (0.173)	0.264 (0.185)
SSORSI( )	Natural	23 (22)	0.242 (0.213)	0.273 (0.244)
RSCG( )	Red-black	31 (31)	0.104 (0.117)	0.269 (0.297)
RSSI( )	Red-black	60 (48)	0.207 (0.166)	0.358 (0.344)

Table III. Number of Iterations and Execution Times for Problem (2) Using Adaptive and Nonadaptive Procedures (Nonadaptive Data in Parentheses)

Routine	Ordering	Iterations	Iteration time	Total time
JCG( )	Natural	28 (28)	0.092 (0.090)	0.107 (0.090)
	Red-black	28 (28)	0.079 (0.074)	0.191 (0.202)
JSI( )	Natural	64 (54)	0.166 (0.136)	0.196 (0.152)
	Red-black	64 (54)	0.160 (0.130)	0.268 (0.266)
SOR( )	Natural	42 (29)	0.139 (0.095)	0.150 (0.110)
	Red-black	38 (29)	0.124 (0.097)	0.236 (0.231)
SSORCG( )	Natural	15 (11)	0.136 (0.097)	0.167 (0.111)
SSORSI( )	Natural	19 (15)	0.138 (0.101)	0.153 (0.117)
RSCG( )	Red-black	15 (15)	0.032 (0.051)	0.150 (0.169)
RSSI( )	Red-black	31 (27)	0.075 (0.064)	0.186 (0.196)

$$\begin{cases} u_{xx} + 2u_{yy} = 0, & (x, y) \quad \text{in} \quad S = (0, 1) \times (0, 1) \\ u = 1 + xy, & (x, y) \quad \text{on boundary of} \quad S. \end{cases} \tag{1}$$

Using the standard 5-point symmetric finite-difference operator with $h = \frac{1}{20}$, we obtain a sparse linear system with 1729 nonzero elements and 361 unknowns.

$$\begin{cases} u_{xx} + 2u_{yy} + 3u_{zz} = 0, & (x, y, z) \quad \text{in} \quad C = (0, 1) \times (0, 1) \times (0, 1) \\ \text{On boundary of } C: & \\ \quad \begin{cases} u = 1, & (0, y, z), (x, 0, z), \quad \text{or} \quad (x, y, 0) \\ \dfrac{du}{dn} = \begin{cases} yz(1 + yz), & (1, y, z) \\ xz(1 + xz), & (x, 1, z) \\ xy(1 + xy), & (x, y, 1). \end{cases} \end{cases} \end{cases} \tag{2}$$

Using the standard 7-point symmetric finite difference operator with $h = \frac{1}{7}$, we obtain a sparse linear system with 1296 nonzero elements and 216 unknowns.

Tables II and III display the number of iterations and execution times (in seconds) for the seven methods in ITPACK 2C for the linear systems corresponding to problems (1) and (2), respectively, using symmetric sparse storage. Both the time for the iteration algorithm and the total time for the subroutine call are given. The stopping criterion was set to **5.0E−6**. To illustrate how effective the adaptive procedures are, we have included in these tables the number of iterations and the time when the optimum iteration parameters were used with no adaptive procedures.

Values corresponding to the red-black ordering with the SSOR methods are omitted from the tables since it is known that these methods are ineffective with

this ordering. Since the RS methods are defined for only the red–black ordering, the table entries for these methods with the natural ordering are not included.

7. NOTES ON USE

Before an iterative algorithm is called to solve a linear system, the values in the array **A(*)** are permuted and scaled. Afterward, these values are unpermuted and unscaled. Consequently, the values in arrays **A(*)** and **RHS(*)** may change slightly due to round-off errors in the computer arithmetic. Moreover, since entries in each row of the linear system may be stored in any order within a contiguous block of data, the locations of elements of **A(*)** and of corresponding ones in **JA(*)** may change from those given before the permuting and unpermuting was done. The same linear system is defined by the arrays **A(*)**, **JA(*)**, and **IA(*)**, whether or not corresponding elements in **A(*)** and **JA(*)** have changed locations within contiguous blocks.

Scaling of the linear system is done as follows to reduce the number of arithmetic operations. The diagonal entries of the linear system are checked for positivity and are moved to the first **N** locations of the array **A(*)**. The nonzero off-diagonal entries of the linear system $Au = b$ are scaled. The scaling involves the diagonal matrix $D^{1/2}$ of square roots of the diagonal entries of the linear system, that is,

$$(D^{-1/2}AD^{-1/2})(D^{1/2}u) = (D^{-1/2}b).$$

The algorithms iterate until convergence is reached based on the relative accuracy requested via the stopping criterion set in **RPARM(1)** for the scaled solution vector $(D^{1/2}u)$. Unscaling solves for u and returns the linear system to its original form subject to round-off errors in the arithmetic and to possible movement of entries within contiguous blocks of data.

When requested, a red–black permutation of the data will be done before and after the iterative algorithm is called. Otherwise, the linear system is used in the order it is given, which we call the "natural ordering."

The successive overrelaxation (SOR) method has been shown to be more effective with the red–black ordering than with the natural ordering for some problems [19]. In the SOR algorithm, the first iteration uses **OMEGA = 1.0** and the stopping criterion is set to a large value so that at least one Gauss–Seidel iteration is performed before an approximate value for the optimum relaxation parameter is computed.

Optional features of this package are red–black ordering, effective removal of rows and columns when the diagonal entry is extremely large, and error analysis. In the event that one is not using some of these options and needs additional memory space for a very large linear system, the relevant subroutines that can be replaced with dummy subroutines are as follows: red–black ordering [**PRBNDX( )**, **PERMAT( )**, **PERVEC( )**, **QSORT( )**], removal of rows [**SBELM( )**] , error analysis [**PERROR( )**].

The timing routines **ITICK( )** and **ITOCK( )** should call a local system routine so that they return the run time in milliseconds. **ITICK( )** is called at the beginning of a timing interval and **ITOCK( )** at the end.

The value of the machine relative precision is contained in the variable **SRELPR**, which is set in the subroutine **DFAULT( )** and in the test program. This and other default values may be permanently changed when the code is installed by changing their values in the subroutine **DFAULT( )**. **SRELPR** must be changed when moving the code to another computer. If the installer of this package does not know its value, an approximate value can be determined from a simple FORTRAN program given in the comment statements of subroutine **DFAULT( )**.

Since the amount of precision may change from computer to computer, the relative accuracy requested in the stopping criterion **ZETA** must not be less than about **500.** times the machine relative precision **SRELPR**. If a value of **ZETA** is

requested that is too small, then the code resets it to this value. The current default value for **ZETA**, **5.0E−6**, is set by the routine **DFAULT( )** into **RPARM(1)**.

The distribution tape contains the ITPACK 2C software package of 71 subprograms and a testing program **MAIN( )** together with its 27 subprograms. The routines **DFAULT( )**, **ITICK( )**, **ITOCK( )** in ITPACK and the program **MAIN( )** are the only ones requiring editing by the installer of the package. ITPACK can be made into a compiled program library, although not all of it would normally be used in a particular application.

8. ITPACK HISTORY

The 2C version of the ITPACK codes described here is the result of several years of research and development. The development of ITPACK began in the early 1970s when Professor Garrett Birkhoff suggested that general-purpose software for solving linear systems should be developed for iterative methods as well as for direct methods. Initially, prototype programs were written based on preliminary iterative algorithms involving adaptive selection of parameters and automatic stopping procedures. These programs were tested on a large set of elliptic partial differential equations over domains compatible with the subroutine **REGION( )** [8], which superimposed a square grid over the domain. These routines were designed for solving self-adjoint elliptic partial differential equations. Next a preliminary version of ITPACK was coded in standard FORTRAN. The ITPACK routines used iterative algorithms that were refined from the prototype programs. However, these routines were designed to solve large sparse linear systems of algebraic equations instead of partial differential equations. The use of three interchangeable symmetric sparse storage modes in ITPACK 1.0 [3] allowed for great flexibility and made it possible to solve a wider class of problems than the prototype programs and to study different storage modes for iterative methods. The next version, ITPACK 2.0 [4], was significantly faster than its predecessor, since it was restricted to allow only one sparse symmetric storage format. Most of the iterative algorithms utilized in the 2.0 version of this package assume that the coefficient matrix of the linear system is symmetric positive definite. As with many packages, the need to handle a slightly larger class of problems, namely, nearly symmetric systems, soon became evident. This required adapting the routines to allow a switch for either a symmetric or nonsymmetric storage mode in ITPACK 2A [5]. Moreover, a modification of the conjugate gradient algorithms was developed to handle nearly symmetric systems [13]. ITPACK has been improved in the 2B version [11] by (a) writing more efficient versions of several key subroutines, (b) incorporating basic linear algebra subprograms (BLAS) [15], and (c) improving the user interface with better printing and documentation. Some additional improvements and corrections were made in the 2C version. The algorithms in ITPACK are not guaranteed to converge for all linear systems, but have been shown to work successfully for a large number of symmetric and nonsymmetric systems that arise from solving elliptic partial differential equations [1, 14].

The numerical algorithms in ITPACK 2C correspond to those described in the appendix of technical report [4] and outlined in the book [6]. In particular, the SOR code is based on an algorithm suggested to us by L. Hageman. Various other algorithms exist for iterative methods. For example, S. Eisenstat has an implementation of the symmetric successive overrelaxation preconditioned conjugate gradient procedure.[7]

Modules based on the seven iterative routines in ITPACK have been incorporated into the elliptic partial differential equation solving package ELLPACK [17] together with all the necessary translation routines needed. The user-oriented modules described in Section 4 are not in ELLPACK. Moreover, if the ELLPACK

[7] Private communication.

system is not being used to generate the linear system for ITPACK, it is recommended that ITPACK be used as a stand-alone package apart from ELLPACK.

ACKNOWLEDGMENTS

The authors wish to thank the referee for carefully going through the code and documentation for several different versions. Test runs were made on a variety of computer systems and helpful suggestions were made by R. Boisvert, W. Coughran, J. Dongarra, W. Dyksen, S. Eisenstat, S. Fillebrown, P. Gaffney, W. Gordon, R. Hanson, R. Lynch, J. Rice, B. Ward, and others. These suggestions and comments together with those of the referee have resulted in an improved software package. ITPACK has been tested on the following computing machines: CDC 6400, 6500, 6600, 7600; CYBER 170/750, 203, 205; CRAY 1; DEC 10, 20; PDP 10; VAX 11/750, 11/780; IBM 195, 370/158, 3033; PRIME 400, 750; and others.

ALGORITHM 587
Two Algorithms for the Linearly Constrained Least Squares Problem

RICHARD J. HANSON and KAREN H. HASKELL
Sandia National Laboratories

Categories and Subject Descriptors: G.1.2. [**Numerical Analysis**]: Approximation—*least squares approximation*; G.1.6. [**Numerical Analysis**]: Optimization—*constrained optimization*; *least squares methods*; G.m [**Mathematics of Computing**]: Miscellaneous—*FORTRAN*

General Terms: Algorithms

Additional Key Words and Phrases: linear least squares solution, equality constraints, inequality constraints, nonnegativity constraints, inconsistent constraints, covariance matrix

1. INTRODUCTION

This paper discusses subroutines for computing numerical solutions of the following two linearly constrained linear least squares problems.

$$\begin{array}{lll} \textit{Problem NNLSE} & E\mathbf{x}=\mathbf{f} & \text{(equations to be exactly satisfied)} \\ & A\mathbf{x}\cong\mathbf{b} & \text{(equations to be approximately satisfied, least squares sense)} \\ & x_i\geq 0, & i=l+1,\ldots,n, \quad 0\leq l\leq n \end{array} \tag{1}$$

$$\begin{array}{lll} \textit{Problem LSEI} & E\mathbf{x}=\mathbf{f} & \text{(equations to be exactly satisfied)} \\ & A\mathbf{x}\cong\mathbf{b} & \text{(equations to be approximately satisfied, least squares sense)} \\ & G\mathbf{x}\geq\mathbf{h} & \text{(inequality constraints that the solution must satisfy)} \end{array} \tag{2}$$

In both problems the matrices E and A are real and of respective dimensions m_E by n and m_A by n. For Problem NNLSE, the variables $x_1, \ldots, x_l$ are free to have either sign. For Problem LSEI, the (real) inequality constraint matrix G is m_G by n. The right-side vectors **f**, **b**, and **h** that appear in the two problem statements have, respectively, m_E, m_A, and m_G components. The (unknown) solution vector **x** has n components.

While Problem LSEI of eq. (2) appears to be a more general problem than Problem NNLSE of eq. (1), it really is not. In fact, there are a number of ways to transform Problem LSEI into one of the forms of Problem NNLSE. Three ways of doing this are discussed in [3]. The method we have implemented is described on pages 101–102. The successful implementation of an algorithm for solving

Editing for this algorithm was supervised by Associate Editor W.J. Cody, Jr.

Problem NNLSE is the key computational process. Nevertheless, it is important for applications such as constrained curve fitting [2] to have a subprogram that solves Problem LSEI of eq. (2) directly. We provide FORTRAN subprograms **WNNLS( )** and **LSEI( )** that solve the respective problems in eqs. (1) and (2).

In Section 2 we review mathematical and numerical analysis details pertinent to solving Problem LSEI. In Section 3 we review some necessary details for understanding our methods for solving Problem NNLSE. In Section 4 we summarize some features and advantages of the codes. These features include changing tolerances, scaling of data matrices, and optional computation of the covariance matrix. Section 5 presents a test subprogram **CLSTP( )**, which is included with the package. It solves the test problem with both subprograms. Section 6 contains installation guidelines and remarks.

2. SOLVING PROBLEM LSEI

In this section, we briefly review mathematical and algorithmic details needed to solve Problem LSEI of eq. (2) [3, pp. 101–102]. The overall process consists of four main parts.

Step 1 Problem LSEI is reduced to a subproblem with possibly fewer unknown variables and with all explicitly stated equality constraints removed.

Step 2 The problem resulting from step 1 is reduced to a new problem where the least squares matrix is a simple projection matrix and the right-side vector is zero.

Step 3 The problem resulting from step 2 is solved by reposing it as a dual problem. This dual problem consists of two special cases of Problem NNLSE, eq. (1).

Step 4 The solution obtained in step 3 is transformed to the solution of the original problem using translations, matrix multiplications, and the solution of triangular linear algebraic systems.

3. SOLVING PROBLEM NNLSE

The theoretical development for solving problem NNLSE of eq. (1) is presented in [3]. The fundamental point of this method involves a numerically stable implementation of a penalty function approach. The least squares equations are each weighted by a small parameter ϵ, chosen in the subprogram **WNNLS( )**. The augmented and weighted least squares system of eq. (3) is then solved.

$$\begin{bmatrix} E \\ \epsilon A \end{bmatrix} \mathbf{x} \equiv D \begin{bmatrix} E \\ A \end{bmatrix} \mathbf{x} \cong D \begin{bmatrix} \mathbf{f} \\ \mathbf{b} \end{bmatrix} \equiv \begin{bmatrix} \mathbf{f} \\ \epsilon \mathbf{b} \end{bmatrix}$$

$$D = \operatorname{diag}(\overbrace{1, \ldots, 1}^{m_E}, \overbrace{\epsilon, \ldots, \epsilon}^{m_A}) \tag{3}$$

$$\mathbf{x} = \begin{bmatrix} \mathbf{y} \\ \mathbf{w} \end{bmatrix} \begin{matrix} \}l \\ \}n-l \end{matrix} \qquad \begin{matrix} \mathbf{y} \text{ unconstrained} \\ \mathbf{w} \geq \mathbf{0}. \end{matrix}$$

Part of the theoretical development in [3] shows that solutions of the weighted problem of eq. (3) converge to solutions of Problem NNLSE (if it is consistent) as $\epsilon \to 0$. Within the subprogram **WNNLS( )** eq. (3) is solved only once with a value of ϵ that is chosen to achieve full working accuracy in the solution. The value used in **WNNLS( )** is defined by

$$\epsilon^2 = \frac{10^{-4}\eta}{\gamma}, \tag{4}$$

where $\gamma = \| \begin{smallmatrix} E \\ A \end{smallmatrix} \|$, ($\| \cdot \|$ = subordinate matrix norm of l_∞ vector norm), and η = machine relative arithmetic precision.

The algorithm for solving eq. (3) with ϵ as defined in eq. (4) proceeds in two main steps. First we compute a (minimum-length) solution for the unconstrained

variables in terms of the constrained variables. Solving for the unconstrained variables is primarily a triangularization operation. In the second main step of the process we solve for the constrained variables. This is an iterative process, that is, it is Algorithm NNLS of [7, Chap. 23]. Certain crucial differences in numerical tests are needed because of the penalty parameter ϵ that multiplies the least squares equations. These tests are discussed in [3].

4. USAGE SUGGESTIONS AND SUBPROGRAM OPTIONS

In Sections 2 and 3 we have outlined solution methods for solving Problem LSEI of eq. (2) and Problem NNLSE of eq. (1). As shown in [3], computing the solution of Problem NNLSE can be regarded as the core computation in solving constrained linear least squares problems.

The most satisfactory method from the standpoint of accuracy and stability is to introduce slack variables into the inequality constraints of Problem LSEI [3]. This problem is then solved using subprogram **WNNLS( )**. The results of solving a bounded variable Hilbert matrix problem summarized in [3] suggest that subprogram **WNNLS( )** continues to compute acceptable solutions even as the problems become increasingly ill-conditioned.

The use of subprogram **WNNLS( )** with the slack variable formulation does have a disadvantage compared to subprogram **LSEI( )**. For most problems, **WNNLS( )** will require more computing time and storage than **LSEI( )**. This is due to the larger number of problem variables in the slack variable formulation. The advantage of efficiency with **LSEI( )** may be countered by the simultaneous occurrence of poor conditioning and rounding errors. (This can occur with a poorly conditioned least squares problem.) Owing to the poor conditioning and rounding error, the feasible constraint region can be mapped to one that is infeasible. Instances of this are shown in the results of solving the bounded variable Hilbert matrix problem summarized in [3].

The choice between the two subprograms is a time and storage versus stability trade-off. Specifically, in the case of a poorly conditioned least squares problem, **WNNLS( )** might obtain a solution when **LSEI( )** cannot. As illustrated in [3], subprogram **WNNLS( )** can also be used to extend the notion of solution for problems with infeasible constraints.

Occasionally, a user of subprogram **LSEI( )** will need the covariance matrix of the least squares solution variables of minimum length. This is returned as an output matrix if the user wants it. It is an unbiased estimate of the covariance matrix for the minimum-length solution of an equality constrained least squares problem *with no inequalities.* This is developed in [4] and [6].

When inequalities are included, certain additional mathematical problems must be considered. These have to do with the behavior of the set of inequalities chosen by the algorithm to be equalities. The question is as follows: What is the sensitivity of these equalities as the data are allowed to vary within its uncertainty? Inequalities may move from being satisfied as equalities to strict inequalities as the data are perturbed. The covariance matrix computed by **LSEI( )** is based on the assumption that the set of equalities does not change when the solution is perturbed. No comprehensive theory is known to the authors for determining the matrix when the set of equalities does change. The user must keep these facts in mind when interpreting the covariance matrix for Problem LSEI with inequalities.

The remainder of this section describes parameters within **LSEI( )** and **WNNLS( )** which can optionally be changed by the user. These options fall into the three following groups.

(A) Computation of the covariance matrix.
(B) Column scaling of the data matrix.
(C) Redefinition of tolerances used for determining ranks of problem matrices.

Changes to any number of these parameters can be specified as the linked-list input in the array **PRGOPT(*)**. Precise instructions for defining **PRGOPT(*)** are found in the usage prologues for **LSEI( )** and **WNNLS( )**. If the user is satisfied with the nominal subprogram features, it is only necessary to set **PRGOPT(1)=1.**

Remarks about A: Nominally the covariance matrix is not computed by **LSEI( )**.

Remarks about B: Column scaling of the form $\mathbf{x} = D\mathbf{y}$ is always performed by **LSEI( )** and **WNNLS( )**. Nominally D is the identity matrix. Another option here is a choice for D such that each nonzero column of the entire scaled data matrix has length one. The user can also specify an arbitrary D.

Remarks about C: The user can change tolerances t_E and t_A in **LSEI( )** and tolerance t_W in **WNNLS( )**. The nominal values of t_E, t_A, and t_W are $\eta^{1/2}$, where η is the relative arithmetic precision of the machine. The parameter t_E is used in approximating the rank of the equality constraint matrix E of eq. (2). Its role is discussed near the end of [3, Sec. 1].

The parameter t_A is used in approximating the rank of the least squares matrix that results from eliminating the equality constraints from eq. (2). It is used to compute the factor τ, which is t_A times the norm of this reduced least squares matrix. Then τ is used in Algorithm HFTI [7, Chap. 14].

The parameter t_W is used by **WNNLS( )** to compute the rank of the row-scaled least squares matrix as discussed in [3, Sec. 3.1].

5. REMARKS ON THE TESTING SUBPROGRAM CLSTP( )

The subprogram **CLSTP (KLOG, COND, ISTAT)** constructs and solves a constrained least squares problem that has a known solution and known condition numbers [7, Chap. 9]. The problem generated is stated in eq. (2). The matrices A, E, and G are computed using formulas

$$A = U_1 S_1 V_1^{\mathrm{T}}$$

$$E = U_2 S_2 V_2^{\mathrm{T}}$$

and

$$G = U_3 S_3 V_3^{\mathrm{T}}.$$

The problem dimensions are specified by using five integer parameters k_A, k_E, k_G, k_I, and k_n to compute $m_A = 2^{k_A}$, $m_E = 2^{k_E}$, $m_G = 2^{k_G}$, and $n = 2^{k_n}$. The integer $m_I = 2^{k_I}$ denotes the number of inequality constraints that are to be satisfied as strict inequalities. These five integers are passed to **CLSTP( )** in the array **KLOG(*)** in the order indicated. If any of the values k_A, k_E, k_G, k_I, or k_n are less than zero, the respective values m_A, m_E, m_G, m_I, or m_n are set to zero. No computation is performed if $n = 0$.

Arrays within **CLSTP( )** currently have fixed dimensions that require k_A, k_E, k_G, k_I, and k_n to all be less than or equal to 5. Instructions for increasing the array dimensions are given as comments within **CLSTP( )**.

The matrices U_J and V_J are symmetric orthogonal Hadamard matrices of dimension $n = 2^k$ generated by the recursion

$n := 1$

$U := 1$

For $l = 1, \ldots, k$

$$U := \begin{bmatrix} U & : & U \\ U & : & -U \end{bmatrix}$$

$n := n + n$

End For

$$U := n^{-1/2}U$$

The matrices S_J, $J = 1, 2, 3$, are rectangular diagonal matrices. The extreme diagonal terms are κ_i and 1, where $\kappa_J \equiv$ **COND(J)**. The intermediate diagonal terms are generated in the open interval $(1, \kappa_J)$ using the random number generator **RAN( )**. The output value of $t =$ **RAN(ISEED)** satisfies $0 < t < 1$. The intermediate diagonal terms are successively computed as $1 + t(\kappa_J - 1)$. Initially, **ISEED** is set to 100001 in **CLSTP( )**.

The n-vector $\hat{\mathbf{x}} = (1, \ldots, 1)^T$ is used to generate the vectors

$$\mathbf{f} = E\hat{\mathbf{x}}$$

$$\hat{\mathbf{b}} = A\hat{\mathbf{x}}$$

and

$$\hat{\mathbf{h}} = G\hat{\mathbf{x}}.$$

We add a vector $\tilde{\mathbf{b}}$ to $\hat{\mathbf{b}}$ that is orthogonal to the column space of A. This is given by

$$\tilde{\mathbf{b}} = U_1(0, \ldots, 0, g_{n+1}, \ldots, g_{m_A}),$$

where

$$g_i = \textbf{RAN(ISEED)} \cdot \| \hat{\mathbf{b}} \| \cdot \sigma, \qquad i = n + 1, \ldots, m_A.$$

The value of σ is specified by the variable **ANSR** in **CLSTP( )**. It is currently set to 0.01. The right-side vector for the least squares equations in eq. (2) is $\mathbf{b} \equiv \hat{\mathbf{b}} + \tilde{\mathbf{b}}$.

The right-side vector for the inequality constraints is constructed by making the first m_I constraints strict inequalities. This is done by defining the right-side vector as $\mathbf{h} = \hat{\mathbf{h}} - \tilde{\mathbf{h}}$, where

$$\tilde{\mathbf{h}} = (h_1, \ldots, h_{m_I}, 0, \ldots, 0^T),$$

$$h_i = \textbf{RAN(ISEED)} \cdot \| \hat{\mathbf{h}} \|, \qquad i = 1, \ldots, m_I.$$

These techniques for generating problems with known solutions are similar to those discussed in [9, pp. 6–9]. One might obtain different sets of test problems on machines with differing arithmetic characteristics. Part of this is due to a different sequence of numbers generated by **RAN( )**.

We have found that column scaling is sometimes required for solving eqs. (1) and (2). In particular, when using 32-bit floating-point arithmetic, problems generated by **CLSTP( )** using the published test data occasionally failed to pass the tests when no column scaling was done. Thus the option array input for calls to both **LSEI( )** and **WNNLS( )** are set so that unit length column scaling is performed on all the tests.

After subprogram **LSEI( )** has computed an approximate solution $\mathbf{x}'$ for this particular form of eq. (2), and subprogram **WNNLS( )** has solved for an approximate solution $\mathbf{x}''$ of the system

$$E\mathbf{x} = \mathbf{f}$$

$$A\mathbf{x} \cong \mathbf{b}$$

$$G\mathbf{x} - \mathbf{h} = \mathbf{w}$$

for the unknown $(\mathbf{x}^T, \mathbf{w}^T)^T$, we compute the differences $\mathbf{dx}_1 = \mathbf{x}' - \hat{\mathbf{x}}$ and $\mathbf{dx}_2 = \mathbf{x}'' - \hat{\mathbf{x}}$. A test is made on the value of $\| \mathbf{dx}_i \|$ to ensure that $\mathbf{x}'$ or $\mathbf{x}''$ is as accurate as it deserves to be. The test of the subprogram has failed if the corresponding $\| \mathbf{dx}_i \|$ is too large. Otherwise the test has passed and $\mathbf{x}'$ or $\mathbf{x}''$ is an acceptable approximation of $\mathbf{x}$. With

$$\rho = \| \tilde{\mathbf{b}} \| / \| \hat{\mathbf{b}} \|$$

$$\kappa = \kappa_1 = \text{condition number of } A$$

η = relative arithmetic precision

$\mu = \max(m_A, n)$

$\nu = \min(m_A, n)$

$\phi = 100$

each test has passed if and only if

$$\frac{\| \mathbf{dx}_i \|}{\| \hat{\mathbf{x}} \|} \leq \kappa(1 + \kappa\rho)\eta[(6\mu - 3\nu)\nu]\phi.$$

The output value of **ISTAT** is set as follows:

ISTAT = 1 means both **LSEI( )** and **WNNLS( )** failed.
= 2 means **WNNLS( )** passed but **LSEI( )** failed.
= 3 means **LSEI( )** passed but **WNNLS( )** failed.
= 4 means both **LSEI( )** and **WNNLS( )** passed.

This measure for $\| \mathbf{dx}_i \|$ is based on combining the estimate for the norm of the matrix H of the nearby problem that $\mathbf{x}'$ solves (without constraints), $(A + H)\mathbf{x}' \cong \mathbf{b}$, [7, Chap. 13], together with the perturbation bounds of [7, Chap. 9].

It may be necessary to increase the value of ϕ slightly on some machines.

A short main program, **CLSTST**, is provided with the algorithm. Also provided are 11 data cards that are read by **CLSTST** from FORTRAN unit = 5. Each pair of the first 10 cards specifies a distinct test case. The last (eleventh) card terminates the program execution.

The subprogram **CLSTP( )** prints the computed values of the least squares residual vector length and the vectors $\mathbf{dx}_i$ for both **WNNLS( )** and **LSEI( )**. Also printed in **CLSTP( )** are the computed ranks of the equality constraint and reduced least squares matrices returned by **LSEI( )**. The arrays **KLOG(I), I = 1 to 5**, and **COND(I), J = 1 to 3**, and the value of **ISTAT** returned from **CLSTP( )** are printed by **CLSTST**. Printing is done on FORTRAN unit = 6.

6. INSTALLATION GUIDELINES AND REMARKS

This section contains information for installing subprograms **LSEI( )** and **WNNLS( )**.

Included in the package are seven groups of subprograms.

(1) **LSEI, LSI, LPDP**
(2) **WNNLS, WNLSM, WNLIT**
(3) **HFTI, H12, DIFF** from [7]
(4) **SDOT, SSCAL, SASUM, SAXPY, SNRM2, SCOPY, SSWAP, ISAMAX, SROTM, SROTMG** from [8]. (For double-precision usage **DDOT, DSCAL, DASUM, DAXPY, DNRM2, DCOPY, DSWAP, IDAMAX, DROTM, DROTMG**.)
(5) **XERROR, XERRWV, XERABT, XERCLR, XERCTL, XERDMP, XERMAX, XERPRT, XERSAV, XGETF, XGETUA, XGETUN, XSETF, XSETUA, XSETUN, FDUMP, J4SAVE, S88FMT, NUMXER** from [5]. (The subprogram **NUMXER** is included for completeness but is not used in this package.)
(6) **I1MACH** based on [1]
(7) **CLSTST, CLSTP, RAN** (test package)

All of the subprograms are written in 1966 American National Standard portable FORTRAN. The only machine-sensitive subprogram is **I1MACH( )**. It provides two environmental parameters required by the error-handling subprograms **XERROR( )** and **XERRWV( )**. This will require modification of **I1MACH( )** at each host site. FORTRAN **DATA** statements defining the values of all the required constants are available for many machines in comments within the subprogram. The appropriate set of commented statements must be activated. If the values for your machine are not there, they should be provided in the order

corresponding to the description near the beginning of **I1MACH( )**. Machines for which these constants are provided are Honeywell 600/6000, IBM 360/370, Xerox Sigma, CDC 6000/7000, PDP-10 (KA and KI processors), PDP-11 (16- and 32-bit arithmetic), Burroughs 5700/6700/7700, UNIVAC 1100, Data General Eclipse, Harris, VAX, and CRAY. In addition, the user must open or declare the FORTRAN unit, designated in **I1MACH(4)**, where any error messages will be written.

We strongly recommend that calls to the error-handling subprograms **XERROR( )** and **XERRWV( )** be left intact. If the size or complexity of the error-handling package presents a problem on a particular machine, we suggest that the subprograms **XERROR( )** and **XERRWV( )** be replaced by shorter, machine-sensitive versions. These replacements should, minimally, print the character string comprising the error message and the specified data values. Usage of the full error-handling package is discussed in [5].

To convert the package for double-precision usage, follow the editing instructions at the beginning of each subprogram in groups 1, 2, 3, and 7 above. Use the double-precision version of the BLAS in group 4. No conversion is required for subprograms in groups 5 and 6.

ACKNOWLEDGMENTS

We thank two anonymous referees for providing suggestions that clarified the presentation of this algorithm.

ALGORITHM 588
Fast Hankel Transforms Using Related and Lagged Convolutions

WALTER L. ANDERSON
U.S. Geological Survey

Categories and Subject Descriptors: F.2.1 [**Analysis of Algorithms and Problem Complexity**]: Numerical Algorithms and Problems—*computation of transforms*; G.1.2 [**Numerical Analysis**]: Approximation—*linear approximation*; G.m [**Mathematics of Computing**]: Miscellaneous—*FORTRAN*

General Terms: Algorithms

Additional Key Words and Phrases: Hankel transforms of integer order, Bessel functions of the first kind, convolution integrals, linear digital filters

DESCRIPTION

Subprogram **HANKEL( )**, for evaluating complex Hankel transforms, is a complement of [1], where the algorithm is discussed in more detail. A double-precision real version, subprogram **DHANKL( )**, is also provided. The calling sequence for **DHANKL( )** is ordered the same way as is described below for **HANKEL( )**, except all **REAL** and **COMPLEX** declarations in **HANKEL( )** are declared **DOUBLE PRECISION** in **DHANKL( )**.

ALGORITHM 589
SICEDR: A FORTRAN Subroutine for Improving the Accuracy of Computed Matrix Eigenvalues

JACK J. DONGARRA
Argonne National Laboratory

Categories and Subject Descriptors: G.1.3 [**Numerical Analysis**]: Numerical Linear Algebra—*eigenvalues*; G.m [**Mathematics of Computing**]: Miscellaneous—*FORTRAN*
General Terms: Algorithms
Additional Key Words and Phrases: Matrix eigensystems, iterative method; eigensystem improvement

1. INTRODUCTION

SICEDR is a FORTRAN subroutine for improving the accuracy of a computed real eigenvalue and improving or computing the associated eigenvector. It is first used to generate information during the determination of the eigenvalues by the Schur decomposition technique. In particular, the Schur decomposition technique results in an orthogonal matrix Q and an upper quasi-triangular matrix T, such that

$$A = QTQ^{\mathrm{T}}. \tag{1.1}$$

Matrices A, Q, and T and the approximate eigenvalue, say λ, are then used in the improvement phase. **SICEDR** uses an iterative method similar to iterative improvement for linear systems to improve the accuracy of λ and improve or compute the eigenvector x in $O(n^2)$ work, where n is the order of the matrix A. The method used in **SICEDR** is described in [1, 5].

2. USAGE

For a description of the calling sequence, see the listing presented at the end of this paper.

SICEDR factors the matrix into its Schur decomposition, and this is termed the pre-**SICE** phase. A modification of the EISPACK routine **HQR2** is used for this purpose (see [4, pp. 100–101] for details).

During the improvement phase (or **SICE** phase), **SICEDR** is called with matrices A, T, and Q and the approximate eigenvalue W. On return from **SICEDR** the improved eigenvalue is stored in W and the improved or computed eigenvector in X. W and X contain the corrected eigenpair produced by the method at the next to last iteration. A still more accurate eigenpair can be formed if on return from **SICEDR** the user adds W to CW and X to CX in double

Author's address: Argonne National Laboratory, 9700 South Cass Avenue, Argonne, IL 60439.

precision and saves the results in double precision, where CW and CX contain the corrections to W and X, respectively, at the final iteration when the method terminates.

The routine **SICEDR** is provided as a driver to simplify usage. **SICEDR** performs both the pre-**SICE** phase (reduction to upper form) and the **SICE** phase (improvement).

In addition to the EISPACK package, the LINPACK [2] routine **STRSL** and the BLAS [3] package are used to perform fundamental operations.

To produce a double-precision version of **SICEDR** in addition to making the obvious changes, such as changing variables to double precision and using double-precision intrinsic functions, it is necessary to replace routine **STRSL** by **DTRSL** and use the double-precision version of the BLAS. In addition, there are two critical parts of the calculation which *must* be performed in an extended precision. In the single-precision version, the routine **SDDDOT** and **SDADD** perform double-precision accumulations. In a double-precision version, they must be replaced by, say **DQQDOT** and **DQADD**, the extended precision counterparts. These extended precision routines would accumulate in quadruple precision, a nonstandard FORTRAN construct. Such routines are not included here, but can be constructed from the BLAS routines **DQDOTI** and **DQDOTA.**

3. SUMMARY OF THE ALGORITHM

We begin with a brief discussion of the basic algorithm as described in [1].

If λ, x is an approximate eigenpair, and $\lambda + \mu$, $x + \tilde{y}$ is a neighboring eigenpair, then

$$A(x + \tilde{y}) = (\lambda + \mu)(x + \tilde{y}), \tag{3.1}$$

this relation being exact. We assume that x is normalized so that $\| x \|_\infty = 1 = x_s$, and we remove the degree of arbitrariness in $\tilde{y}$ by requiring that $\tilde{y}_s = 0$. Rearranging this equation, we have

$$(A - \lambda I)\tilde{y} - \mu x = \lambda x - Ax + \mu\tilde{y}, \tag{3.2}$$

where the last term on the right will be of second order in the errors of λ, x. The equation above may be simplified by the introduction of a vector y defined by

$$y^{\mathrm{T}} = (y_1, y_2, \ldots, y_{s-1}, \mu, y_{s+1}, \ldots, y_n), \tag{3.3}$$

so that y gives the full information on both μ and $\tilde{y}$. The above equation then becomes

$$By = r + y_s\tilde{y}, \tag{3.4}$$

where $r = \lambda x - Ax$ is the residual vector corresponding to λ, x and B is the matrix $A - \lambda I$ with column s replaced by $-x$.

When the original approximate eigenpairs have been found by Francis' double QR algorithm, we have an orthogonal matrix Q and a quasi upper triangular matrix T, such that

$$A = QTQ^{\mathrm{T}}. \tag{3.5}$$

T is triangular apart from possible 2×2 diagonal blocks corresponding to complex conjugate eigenvalues. We solved a succession of linear systems of the form (3.4) with varying right-hand sides g. It will be convenient to introduce the generic notation $Z - \lambda I = Z_\lambda$ and $(Z - \lambda I)e_s = Z_\lambda e_s = z_{\lambda s}$. We may then rewrite eq. (3.4) in the form

$$[A_\lambda - (x + a_{\lambda s})e_s^{\mathrm{T}}]y = (A_\lambda + ce_s^{\mathrm{T}})y = g, \tag{3.6}$$

where

$$c = -x - a_{\lambda s}.$$

Using the orthogonal factorization, we have

$$Q[T_\lambda + Q^T c e_s^T Q]Q^T y = g,$$

giving

$$(T_\lambda + df^T)Q^T y = Q^T g, \tag{3.7}$$

where

$$d = Q^T c, \qquad f^T = e_s^T Q \qquad \text{and} \qquad g = r + y_s \tilde{y}.$$

The matrix df^T is a rank one modification of the quasi-triangular matrix T_λ. To solve this system, we need to retriangularize $T_\lambda + df^T$. Accordingly, we premultiply the system by two orthogonal matrices Q_1 and Q_2, giving

$$Q_2 Q_1 (T_\lambda + df^T)Q^T y = Q_2 Q_1 Q^T g, \tag{3.8}$$

where Q_1 and Q_2 are products of elementary plane rotations determined as follows.

The matrix Q_1 is such that

$$Q_1 d = (P_2 P_3 \cdots P_n)d = \gamma e_1 \qquad \text{where} \quad \gamma = \| d \|_2 \tag{3.9}$$

and P_i is a rotation in the $(i-1, i)$ plane designed to annihilate the ith component of $P_{i+1}P_{i+2} \cdots P_n d$. We have

$$Q_1(T_\lambda + df^T) = Q_1 T_\lambda + \gamma e_1 f^T, \tag{3.10}$$

where $Q_1 T_\lambda$ is upper Hessenberg, while $\gamma e_1 f^T$ is null except in the first row. Hence the right-hand side is also an upper Hessenberg matrix H. H may now be reduced to upper triangular form, $\bar{T}_\lambda$, by premultiplication with Q_2 defined by

$$Q_2 = P_n' \cdots P_3' P_2', \tag{3.11}$$

where the premultiplication by P_i' annihilates the element $(i, i-1)$ of the current matrix by a rotation in the $(i-1, i)$ plane. Hence, the triangular system remains to be solved

$$\bar{T}_\lambda Q^T y = Q_2 Q_1 Q^T g. \tag{3.12}$$

A system with the matrix B may thus be solved in $O(n^2)$ operations.

By its nature, eq. (3.2), which leads to eq. (3.12), is mildly nonlinear. Thus we repeat the process with $x + \tilde{y}$ and $\lambda + \mu$ as the new approximations. The convergence theorem for this iterative procedure can be found in [1]. Since an orthogonal triangularization of A is available, it becomes practical to update the matrix B at each stage of the iteration, using the current approximation to the eigenpair. Accordingly, we treat the $(p+1)$th step of the iteration as though it were the first step in the basic iteration starting with values $\lambda^{(p)}$ and $x^{(p)}$. Since we treat each iterate as if it were the first, the term $\mu\tilde{y}$ in eq. (3.2) is zero. Thus $g = \lambda x - Ax$. The algorithm then becomes

$$(A - \lambda^{(p)} I)\tilde{y}^{(p)} - y_s^{(p)} x^{(p)} = r^{(p)} = (\lambda^{(p)} I - A)x^{(p)} \tag{3.13}$$

where

$$x^{(p+1)} = x^{(p)} + \tilde{y}^{(p)}, \qquad \lambda^{(p+1)} = \lambda^{(p)} + y_s^{(p)}.$$

We may rewrite this as

$$B^{(p)} y^{(p)} = r^{(p)}, \tag{3.14}$$

where

$$B^{(p)} = A - \lambda^{(p)} I + c^{(p)} e_s^T, \qquad c^{(p)} = -x - a_{\lambda s}^{(p)}.$$

We now write

$$B^{(p)} = Q(T_\lambda^{(p)} + Q^T c^{(p)} e_s^T Q)Q^T$$

$$= Q(T_\lambda^{(p)} + d^{(p)}f^T)Q^T \tag{3.15}$$

and solve (3.14) by the triangular system

$$\bar{T}_\lambda^{(p)}Q^T y^{(p)} = Q_2^{(p)}Q_1^{(p)}Q^T r^{(p)}. \tag{3.16}$$

Convergence is detected by examining successive values for the correction to the eigenvalue. When the previous correction is smaller by a factor of 2 than the current correction, the iteration is stopped.

Note that Q and f will be independent of p if s is not changing from one iteration to the next. The rotations involved in $Q_1^{(p)}$ and $Q_2^{(p)}$, on the other hand, differ from one iteration to the next; but because the number of operations in each retriangularization is $O(n^2)$ and since some $\frac{1}{2}n^2$ multiplication and additions are necessarily involved in the solution of a triangular system, this is quite acceptable.

If we examine the number of operations for the reduction to quasi-triangular form, the *pre*-**SICE** phase, we see that there are roughly $10n^3 + 30n^2$ operations involved (here, an operation means a multiplication followed by an addition). For the **SICE** phase there are approximately $13n^2$ operations per iteration. Assuming 3 iterations to improve an eigenpair, the total count is approximately $39n^2$ operations.

ACKNOWLEDGMENT

I would like to thank the referees for their valuable suggestions, which have improved the quality of the software.

1. DESCRIPTION

A reliable and widely available method to compute the generalized eigenvalues of an $n \times n$ real regular (i.e., invertible) pencil $\lambda B - A$ is the so-called QZ-algorithm [1, 3]. This algorithm constructs orthogonal row and column transformations Q_1 and Z_1 such that the transformed pencil

$$\lambda B_1 - A_1 = Q_1(\lambda B - A)Z_1 \tag{1}$$

is in "quasi-triangular" form, that is, with B_1 in upper triangular form and A_1 in block triangular Hessenberg form with 1×1 and 2×2 diagonal blocks, as illustrated below:

$$B_1 = \begin{bmatrix} x & x & x & x & x & x \\ & x & x & x & x & x \\ & & x & x & x & x \\ & & & x & x & x \\ & & & & x & x \\ & & & & & x \end{bmatrix}, \qquad A_1 = \begin{bmatrix} x & x & x & x & x & x \\ & x & x & x & x & x \\ & x & x & x & x & x \\ & & & x & x & x \\ & & & & x & x \\ & & & & x & x \end{bmatrix}. \tag{2}$$

The 1×1 diagonal pencils of $\lambda B_1 - A_1$ contain the real generalized eigenvalues of the pencil $\lambda B - A$, and the 2×2 diagonal pencils of $\lambda B_1 - A_1$ contain the complex generalized eigenvalues, a conjugate pair to each 2×2 pencil.

The FORTRAN subroutines **DSUBSP** and **EXCHQZ** allow one to update the decomposition (1) by postmultiplying Z_1 by Z_2 and premultiplying Q_1 by Q_2 such that

$$\lambda B_2 - A_2 = Q_2 Q_1(\lambda B - A)Z_1 Z_2 \tag{3}$$

Author's present address: Philips Research Laboratory, Avenue Van Becelaere 2, Box 9, B-1170, Brussels, Belgium.

is still in quasi-triangular form, but in addition, a specific ordering of generalized eigenvalues is obtained in this form. This is important in several applications [6, 7]. Indeed, when the generalized eigenvalues $\lambda_1, \ldots, \lambda_n$ are ordered such that $\lambda_1, \ldots, \lambda_k$ are inside a region Γ and $\lambda_{k+1}, \ldots, \lambda_n$ are outside this region, then the space spanned by the first k orthonormal columns of $Z = Z_1 Z_2$ is the deflating subspace [4] of $\lambda B - A$ corresponding to the spectrum inside Γ. In several applications, deflating subspaces have to be computed for different regions Γ. Of course, Γ has to be symmetric with respect to the real axis, since complex pairs of eigenvalues have to be categorized both outside or inside Γ in order for this deflating subspace to be real. No further assumptions have to be imposed on Γ: it can be open or not, connected or not.

The user has to provide a function describing the region Γ by testing whether the generalized eigenvalues of a 1×1 or 2×2 (diagonal) pencil lies inside or outside the region Γ. This function must be of the type

INTEGER FUNCTION FTEST (LSIZE, ALPHA, BETA, S, P)

with parameters:

LSIZE An integer containing the size of the considered pencil (1 or 2).

ALPHA,BETA Two real variables. In case **LSIZE**=1, the generalized eigenvalue of the considered pencil is given by **ALPHA/BETA**, which may be infinite when **BETA**=0.

S, P Two real variables. In case **LSIZE**=2, they contain the sum and product of the two complex conjugate generalized eigenvalues of the considered pencil.

FTEST The function value, which is put equal to 1 when the generalized eigenvalue(s) of the considered pencil is (are) inside the specified region Γ, and equal to --1 otherwise.

Simple examples for such routines are given by the functions **FIN**, **FOUT**, **FOLHP**, and **FCRHP**, describing the regions inside and outside the unit circle, the open left half-plane, and the closed right half-plane, respectively. Their listings are included below as templates for the user.

This routine is then used as parameter for the subroutine **DSUBSP**, which reorders the 1×1 and 2×2 diagonal pencils of the quasi-triangular form $\lambda B_1 - A_1$ such that those with generalized eigenvalues inside Γ appear first. The calling sequence for **DSUBSP** is

CALL DSUBSP (NMAX, N, A, B, Z, FTEST, EPS, NDIM, FAIL, IND)

with (parameters preceded by an asterisk are altered by the subroutine):

NMAX An integer containing the first dimension of the arrays **A**, **B**, and **Z**.

N An integer containing the current order of **A**, **B**, and **Z**.

;axA,*B Doubly subscripted real arrays containing the pencil to be reordered. On return, $\lambda B - A$ contains the final quasi-triangular pencil, rearranged with respect to the region Γ specified by **FTEST**.

***Z** A doubly subscripted real array into which the reducing column transformation is postmultiplied.

FTEST The integer function provided by the user to describe the region Γ of interest.

EPS A real number used as the convergence criterion. Maximal accuracy is obtained when **EPS** is set equal to relpr $\times \max\{\|\mathbf{A}\|_2, \|\mathbf{B}\|_2\}$, where relpr is the relative precision of the computer used. Smaller values of **EPS** will increase the amount of work without significantly improving the accuracy.

***NDIM** An integer giving the dimension of the computed deflating subspace.

***FAIL** A logical variable that on normal return is **.FALSE.** If the iterative part of the algorithm does not converge, **FAIL** is set to **.TRUE.**.

*IND An integer working array of dimension at least **N**.

DSUBSP is to be used together with the EISPACK programs **QZHES**, **QZIT**, and **QZVAL** [1] to reduce a full pencil $\lambda B - A$ to quasi-triangular form with the eigenvalues inside the contour Γ appearing first on diagonal. (For the explanation of the parameters **EPS1**, **IERR**, **ALPHAR**, **ALPHAI**, and **BETA** in these routines, see [1].):

```
CALL QZHES (NMAX, N, A, B, .TRUE., Z)
CALL QZIT (NMAX, N, A, B, EPS1, .TRUE., Z, IERR)
CALL QZVAL (NMAX, N, A, B, ALPHAR, ALPHAI, BETA, .TRUE., Z)
CALL DSUBSP (NMAX, N, A, B, Z, FTEST, EPS, NDIM, FAIL, IND)
```

Besides the function **FTEST**, describing the region Γ of interest, **DSUBSP** also uses the subroutines **EXCHQZ**, **GIV**, and **SROT**. **EXCHQZ** is a FORTRAN subroutine to interchange two adjacent (1×1 and/or 2×2) pencils of a quasi-triangular form. Specifically, it is supposed that A has a block of order $l1$ starting at the lth diagonal element, and a block of order $l2$ starting at the $(l + l1)$th diagonal element (illustrated below for $n = 5$, $l = 2$, $l1 = 2$, $l2 = 1$):

$$B = \begin{bmatrix} x & x & x & x & x \\ & x & x & x & x \\ & & x & x & x \\ & & & x & x \\ & & & & x \end{bmatrix}, \quad A = \begin{bmatrix} x & x & x & x & x \\ & x & x & x & x \\ & & x & x & x \\ & & & x & x \\ & & & & x \end{bmatrix}. \tag{4}$$

EXCHQZ constructs orthogonal row and column transformations V and W such that $V(\lambda B - A)W$ has consecutive blocks of order $l2$ and $l1$ at the lth diagonal element (illustrated for the example above):

$$VBW = \begin{bmatrix} x & x & x & x & x \\ & x & x & x & x \\ & & x & x & x \\ & & & x & x \\ & & & & x \end{bmatrix}, \quad VAW = \begin{bmatrix} x & x & x & x & x \\ & x & x & x & x \\ & & x & x & x \\ & & & x & x \\ & & & & x \end{bmatrix}. \tag{5}$$

The generalized eigenvalues associated with each diagonal block are interchanged along with the blocks. The column transformation W is postmultiplied into the array **Z**; the row transformation V is not stored since it is not required in the computation of bases of deflating subspaces.

The calling sequence for **EXCHQZ** is

```
CALL EXCHQZ (NMAX, N, A, B, Z, L, LS1, LS2, EPS, FAIL)
```

with (parameters preceded by an asterisk are altered by the subroutine):

NMAX An integer containing the first dimension of **A, B**, and **Z**.

N An integer containing the current order of **A, B**, and **Z**.

***A,*B** Doubly subscripted real arrays containing the pencil to be reordered.

***Z** A doubly subscripted real array into which the updating column transformation is postmultiplied.

L An integer containing the leading diagonal position of the first block to be interchanged.

LS1 An integer containing the size of the first block.

LS2 An integer containing the size of the second block.

EPS A convergence criterion (cf. **EPS** in the calling sequence of **DSUBSP**).

***FAIL** A logical variable that on normal return is **.FALSE.**. If the iterative part of the algorithm does not converge, **FAIL** is set to **.TRUE.**.

EXCHQZ requires the subroutines **GIV** and **SROT**, which are elementary routines that construct and perform Givens rotations on column or rows. **SROT** is a BLA subroutine and **GIV** is a modification of **SROTG** of the BLAS package [2] in order to allow a more compact code for **EXCHQZ**, which contains several calls to these routines.

2. METHOD AND PROGRAMMING DETAILS

The subroutine **DSUBSP** makes a first pass through the diagonal blocks of the quasi-triangular form $\lambda B - A$ in order to determine the sizes of the diagonal blocks and the locations of their generalized eigenvalues with respect to Γ. During this pass the integer vector **IND(•)** is created with entries ± 1 or ± 2. Here **sign [IND(I)]** refers to the location of the generalized eigenvalues of block **I** with respect to Γ (+ for inside Γ, − for outside Γ) and **abs[IND(I)]** indicates the size of this block. The entries of this vector are then rearranged such that the plus signs appear first. This is done using a "bubble sort," that is, each time a plus sign follows a minus sign, it is moved in front of all its preceding minus signs via consecutive permutations. Each permutation, of course, involves an interchanging of two consecutive blocks using the subroutine **EXCHQZ**.

EXCHQZ works in a fashion similar to the routine **EXCHNG**, developed for the reordering of the standard eigenvalue problem [5] (this is also the reason why an apparent parallelism with that paper has been pursued here). To interchange two consecutive blocks where at least one of them has order 1, a shift is performed to the real eigenvalue of a 1×1 block (in [5], this was only done for the interchange of two 1×1 blocks). Givens rotations are then constructed in a straightforward manner to interchange the shifted zero eigenvalue to the other block. The construction of the Givens transformations needed for the exchange of the blocks is done in such a way as to ensure backward stability.

In the case of two 2×2 blocks, an arbitrary QZ-step is performed on both blocks in order to eliminate the uncoupling between them. Then a sequence of QZ-steps using a previously determined shift is performed on both blocks. A decoupling with the blocks in the desired order is usually obtained with a few steps (rarely more than two). If within 30 iterations no decoupling is obtained, the subroutine gives an error return. The criterion used is that the coupling element of the two blocks in the Hessenberg form of A is smaller than **EPS**. Since it does not make sense to force this coupling element to be smaller than the errors in the rest of the pencil, one should not choose **EPS** smaller than relpr $\times$ $\max\{\|A\|_2, \|B\|_2\}$, where relpr is the relative precision of the computer used. A good choice for **EPS** is the "estimated" absolute precision of the (sometimes measured) data in A and B. Since the pencils used here are of dimension 4×4, the QZ steps are implemented with Givens transformations instead of Householder transformations, which turns out to be economical. More details are given in [7], where a proof of the backward stability of the method is also given.

EXCHQZ uses the routines **GIV** and **SROT**, which construct a 2×2 Givens rotation to zero out an element of a 2-vector, and perform it, respectively, on two columns or rows of a specified matrix.

ALGORITHM 591
A Comprehensive, Matrix-Free Algorithm for Analysis of Variance

WILLIAM J. HEMMERLE
University of Rhode Island

Categories and Subject Descriptors: G.3 [**Mathematics of Computing**]: Probability and Statistics—*statistical computing*; *statistical software*; G.m **[Mathematics of Computing]**: Miscellaneous—*FORTRAN*

General Terms: Algorithms

Additional Key Words and Phrases: Linear models, analysis of variance, unbalanced data, missing cells, estimation, hypothesis testing, storage-efficient algorithm, iterative improvement, balanced data operators, algebraic-model specification, rank computations, G-inverse solution.

1. INTRODUCTION

Some of the work to be described is reminiscent of **AARDVARK** [5], an analysis-of-variance package, at Iowa State University in the early 1960s. This program was used for most of the large number of analyses processed at Iowa State at that time; however, the program was definitely not transportable, being written in a mix of assembler and FORTRAN for a nonstandard IBM 7074. Subsequent versions, lacking some of its initial capabilities but adding others, were prepared for other machines, including the IBM 360 (see for example [7]). One distinctive feature of the program that greatly aided in its usability was algebraic specification of the statistical model by the user [14], [18]. This facility has now become common in statistical packages.

The initial **AARDVARK** relied principally on balanced analysis-of-variance (AOV) algorithms and approximate statistical methods were applied to treat unbalanced data. An iterative AOV algorithm was later developed by Hemmerle [12], which permits using balanced analysis-of-variance algorithms to obtain exact statistical results for unbalanced data. This algorithm along with subsequent work will be exploited in our development of a comprehensive analysis-of-variance algorithm for balanced or unbalanced data.

Balanced analysis-of-variance algorithms frequently represent a level of elegance of logic that is difficult to surpass. One fine example is the algorithm due to H. O. Hartley [3], which obtains a complete factorial decomposition. Another is Wilkinson's recursive algorithm [23]. Unfortunately, these algorithms are also frequently difficult to explain using straightforward notation; they are likely to involve matrices with complicated structures implicitly rather than explicitly.

Author's address: Department of Computer Science and Experimental Statistics, University of Rhode Island, Kingston, RI 02881.

Balanced analysis-of-variance algorithms normally do not require the coding of indicator variables, either externally or internally by the program. They possess the virtue of efficiency, both with respect to the number of operations performed and the amount of storage required.

Data, on the other hand, are frequently unbalanced and are likely to have missing cells. Both theoretically and computationally, the order of complexity of analysis-of-variance problems increases down the following categories:

(1) balanced data;
(2) unbalanced data with no missing cells;
(3) unbalanced data with missing cells.

In some cases, the unbalanced data arise from a balanced design in which some of the observations are missing as a result of the experiment. Computationally, there are a number of missing data algorithms, notably Healy and Westmacott's iterative algorithm [4] and Rubin's noniterative algorithm [16], which essentially fill in the missing values for use with balanced algorithms. One could also use dummy covariates for each missing cell and then compute a balanced analysis of covariance. These approaches have the disadvantage that, in general, they require balancing all of the data (including the missing observations) to have equal cell frequencies.

Almost all algorithms which seek to process unbalanced data with any degree of generality in an analysis-of-variance situation, including those in statistical packages, are matrix-oriented least squares or regression algorithms. These involve the creation of indicator variables, to cast the analysis-of-variance model as a regression model, and the formation of the design matrix X_0 or the coefficients matrix of the normal equations $X_0'X_0$. The normal equations are then solved using either orthogonalization or elimination methods. In some cases, SAS Procedure GLM [1], for example, an explicit G-inverse is obtained for $X_0'X_0$. One problem with the matrix-oriented approach is that the dimensions of X_0 or $X_0'X_0$ can be overwhelming for moderate to large analysis-of-variance problems. This approach is also extremely inefficient when the data are balanced.

2. FEATURES AND DESIGN OBJECTIVES

In what follows, we describe a global algorithm for the analysis of variance with the following features.

(1) Balanced data, unbalanced data, and unbalanced data with missing cells are all processed by the algorithm. This is accomplished without losing the operational efficiencies obtainable from balanced data and without applying approximate statistical methods to the unbalanced data.

(2) The algorithm is very general with respect to the kind of problems it can handle. Specifically, it bases its calculations upon an algebraically specified analysis-of-variance model of the type discussed in Searle [19]. This includes models with crossed factors, nested factors, and interactions between factors. This general model, along with the facility to handle missing cells, also includes such designs as incomplete blocks, lattices, and Latin squares.

(3) Very large problems may be processed using a relatively small amount of computer storage. With one minor exception, no matrices are stored and no explicit matrix operations are performed. In particular, neither X_0 nor $X_0'X_0$ is stored or computed. An exact G-inverse solution to the normal equations is obtained without ever computing a G-inverse. The rank of the design matrix X_0 is obtained from the pattern of missing cells without explicit operations on X_0.

(4) The algorithm provides a heuristic optimum of maximizing analysis-of-variance capabilities while minimizing lines of source code. Since a principal attribute of the algorithm is its limited demands for array storage, an effort was made to also constrain program storage through a judicious selection of functional capabilities and the production of tight code. Consequently, the algorithm should be well suited for use on small computers.

(5) The user is given reasonable facilities in specifying his analysis-of-variance problem algebraically and various options alphanumerically in an essentially format-free manner.

(6) The algorithm is well suited to interactive usage. It was developed using **CALL/OS** at the University of Rhode Island and **TSO** (time-sharing option) at North Carolina State. It may, of course, also be used as a batch program. A mode parameter, interactive or batch, determines the nature of prompting, I/O, and error returns.

(7) The program has been written in American National Standard Basic FORTRAN for portability. The program has been verified by the Bell Laboratories PFORT verifier [17] and should run on any computer supported with a FORTRAN 66 compiler. With the exception of using the Hollerith data type in DATA statements, the program is also compatible with FORTRAN 77.

Along with the effort to constrain program storage, steps were taken to reduce the number of *lines* of source code. Lines of source (including **COMMENT** statements) can be a limiting factor with respect to file storage in interactive systems. Most of the following measures served to reduce program storage as well as lines of source code: limiting the number of specification statements, **WRITE** statements, **FORMAT** statements, and unnecessary **CONTINUE** statements; limiting the amount of constant alphanumeric information in **FORMAT** statements; using selective, concise **COMMENT** statements; accepting trivial operational inefficiencies which reduce lines of source code; avoiding modularity not contributing to operational efficiency or storage reduction; and using single-character identifiers when possible. The portability objective essentially limits one to storage of a single alphanumeric character per alphanumeric constant or array location. Rather than use additional code to interpret multiple-character identifiers, for such things as specified options, we limit these to one character.

As a consequence of these measures, the complete program for the global algorithm consists of 836 FORTRAN statements exclusive of **COMMENT** statements. The object code produced by the **WATFIV** compiler was contained in 36,656 bytes. In addition, the program was written in such a manner that several of the functional capabilities may easily be deleted, if necessary, to relax program storage.

3. CONSTITUENT ALGORITHMS

We have called the algorithm under discussion a global algorithm, since it encompasses the use of several independent algorithms. The principal independent algorithms, which comprise the global algorithm, are the following.

3.1 The Iterative AOV Algorithm

This algorithm iteratively applies expectation and residual operators (E/R operators) for balanced data to obtain exact results for unbalanced data. In other words, stated simply, the algorithm computes an analysis of variance for unbalanced data by successive computation of balanced analyses. Since the algorithm uses balanced E/R operators to obtain its results, there is no need to create indicator variables or form the design matrix X_0 or $X_0'X_0$. The algorithm operates upon a vector of cell sums and a vector of cell frequencies rather than upon a (potentially large) matrix so that array storage requirements are minimal. Missing cells are handled routinely and convergence of the algorithm is guaranteed [12]. A useful monotonic property serves to limit iteration when testing hypotheses. A balanced analysis of variance is a special case requiring only one iteration.

The basic algorithm [12] is very general and applies to any analysis of variance; however, one must know or determine the balanced E/R operators. It is in this context that one can apply much of the algorithmic lore associated with balanced analyses. An initial implementation using a relatively comprehensive class of balanced E/R operators was discussed by Hemmerle and Piette [6]. Many of the features of the global algorithm were included in this implementation; however,

certain unnecessary rank restrictions were placed upon the design matrix X_0. The latter restrictions were subsequently removed by Hemmerle [10], who showed that with proper parameter selection the iterative AOV algorithm would obtain a G-inverse solution to the normal equations for any design matrix. An improved iterative approximation, which halves the number of iterations in testing hypotheses, is also given in [10] and is used here.

An iterative analysis of covariance algorithm was also developed by Hemmerle [11] as an extension of the iterative AOV algorithm. Although this covariance algorithm adapts well to the logic of the global algorithm and is array storage efficient, covariance capabilities were excluded here principally because of the additional program storage requirements.

3.2 An Iterative Rank Algorithm

With unbalanced data, including missing cells, the ranks of the design matrix and restricted design matrix must be computed to determine degrees of freedom for F statistics. Algorithms have been included (Section 3.5) to determine rank noniteratively from the pattern of missing cells for a given model when possible. When this cannot be accomplished, a recent adaptation of the iterative AOV algorithm is used to compute rank in one of two ways, depending upon the number of missing cells. Either way will produce monotonically increasing convergence to the integer rank value. For a small number of missing cells we use some matrix storage (the exception cited earlier) and obtain monotonically increasing quadratic convergence. Both methods are outlined in a subsequent section. A complete discussion is given in [9].

3.3 A Balanced Factorial Decomposition Algorithm

The technique for computing a balanced analysis of variance based upon a factorial decomposition of linear combinations of classifications means dates back to H. O. Hartley [3].

We use the algorithm described in Hemmerle [13, pp. 180–185] to obtain this decomposition. A one-to-one correspondence is maintained between the distinct arrays in this decomposition and the locations of an E/R list which we shall discuss shortly.

3.4 A Pooling Algorithm

In order to construct the E/R operators needed for the iterative AOV algorithms, we must "pool" (add together in the proper manner) distinct arrays in the factorial decomposition as dictated by the particular analysis-of-variance model. The complete factorial decomposition will be stored in a single linear, one-dimensional array, and we must be able to map one of the distinct arrays within this decomposition into another. We use essentially the same algorithm described in Schlater and Hemmerle [18] to do the mapping and pooling; however, we pool arrays of the decomposition rather than classification means, as do the latter.

3.5 Algorithms to Recognize Balance and Restructure Data

A balanced analysis of variance is a special case for the iterative AOV algorithm. When properly executed, final results will be obtained on the first iteration. Furthermore, iterative rank computations are unnecessary. With unbalanced data, there are also frequent situations in which some of the results may be obtained noniteratively. An example would be a full factorial model; the rank of the design matrix, the sum of squares for error (SSE), the sum of squares for regression (SSR), and a G-inverse solution to the normal equations may all be obtained from a balanced analysis of variance on cell means [12]. Also, when testing an hypothesis involving unbalanced data, the data structure for the model restricted by the hypothesis frequently has fewer dimensions than it has for the full model. A simple restructuring of the data may facilitate obtaining results without iterating. Essentially, this involves creating a surrogate vector of cell

frequencies based upon reduced dimensions for the same data; however, duplicate entries are made in this surrogate vector to maintain a proper one-to-one correspondence with the original vector of cell sums. Several algorithms have been incorporated into the global algorithm to recognize balance and restructure data, when appropriate, to avoid unnecessary iteration. The related theory and a description of the algorithms will be found in [8].

3.6 An E/R List Construction Algorithm

Numeric calculations in the global algorithm are driven by what we have called an E/R list. If there are n factors in the full analysis-of-variance model, then the E/R list will have 2^n entries corresponding to the 2^n terms (mean, main effects, and interactions) in a full factorial model. The E/R list is constructed by scanning or parsing an algebraic model statement. Numeric entries are made in the list which uniquely describe the model. Following the procedure suggested by Hemmerle [14], decreasing powers of 2 are assigned as numerical values to factor symbols and their associated subscripts, with unity for the last factor and its associated subscript.

The sum of the numerical values of the factor symbols (plus one) is computed for each term in the model. For crossed factors or interactions between crossed factors, this sum is entered in the corresponding location of the E/R list. For nested factors or interactions involving nested factors, multiple entries are made in the E/R list. The sum is entered into each location of the E/R list which corresponds to an array in the factorial decomposition which must be pooled (see [13, pp. 174–176]). The algorithm determines these locations from the numerical values of the factor symbols and subscripts in the model term. Examples will be given later in the sequel.

An hypothesis statement indicates those terms in the full model which should be deleted in forming the reduced model. As this statement is parsed, the E/R list entries for the model terms in the statement are made negative. The R operator is then always formed by pooling the arrays in the factorial decomposition associated with zero or negative E/R list entries.

4. STATISTICAL FOUNDATIONS AND COMPUTATIONS

Analysis-of-variance models tend to create confusion because of the fact that in the form they are usually written, these models are overparameterized. For example, the two-way classification with interaction is usually written as

$$y_{ijk} = \mu + a_i + b_j + ab_{ij} + e_{ijk},$$
$$i = 1, \ldots, I, \quad j = 1, \ldots, J, \quad k = 1, \ldots, n_{ij}. \quad (4.1)$$

With e_{ijk} distributed $N(0, \sigma^2)$ and σ^2 unknown. None of the parameters μ, a_i, b_j, or ab_{ij} in (4.1) are estimable (for any i or j), even though the data may be balanced. That is, although the normal equations for (4.1) are consistent, there is no unique solution for these equations. We may obtain a unique solution by imposing constraints or side conditions upon the solution. These conditions have no effect upon what is estimable from the data for the model; however, they do have a bearing upon the hypothesis that is tested by applying the same applicable conditions to a reduced model.

Speed and Hocking [22] discuss the resulting difference in the application of Searle's R ( ) notation [19] to the initial, overparameterized model as opposed to a reparameterized model obtained by imposing conditions on the original model. They refer to the latter as R* ( ) or procedure 2. Speed et al. [21] survey the hypotheses being tested by current computational methods and computer programs. A significant by-product of this work is that, when using procedure 2, the unweighted summation constraints (e.g., $\sum_i a_i = \sum_j b_j = \sum_i ab_{ij} = \sum_j ab_{ij} = 0$) yield the most likely hypotheses of interest, the classical Yates hypotheses [24].

The global algorithm uses procedure 2 with the unweighted summation conditions. In matrix form, the full reparameterized model is given by

$$y = X_0\beta + e \tag{4.2}$$

where y is a vector of N observations; X_0 is an $N \times p$ matrix of -1, 0, 1 indicator variables consistent with the unweighted summation conditions; β is a vector of p parameters; and the elements of e are distributed $N(0, \sigma^2)$.

Note that the p parameters in β will be linear combinations of the parameters appearing in the overparameterized model. As an example, consider the two-way classification *without* interaction. We have that

$$\beta' = (\mu + a. + b., a_1 - a., \ldots, a_{I-1} - a., b_1 - b., \ldots, b_{J-1} - b.) \tag{4.3}$$

with the dot notation denoting a mean. If X_0 has full rank, then all of the elements of β are linearly independent estimable functions. A fact that sometimes causes confusion is that $a_I - a.$ and $b_J - b.$ are also estimable in the above example; however, they are not linearly independent of the elements in β. We mention this fact here since the global algorithm yields a G-inverse solution for the initial overparameterized model as well as a G-inverse solution for (4.2). These solutions are the same, except for the inclusion of additional nonlinear independent elements in the former solution.

In order to consider hypothesis testing, we partition the design matrix X_0 for the full model as $[X_{01} \mid X_{02}]$, where X_{01} is $N \times k$, and write the model (4.2) as

$$y = X_{01}\beta_1 + X_{02}\beta_2 + e. \tag{4.4}$$

The global algorithm will attempt to test the hypothesis

$$H_0 : \beta_2 = 0 \tag{4.5}$$

by fitting the reduced model

$$y = X_{01}\beta_1 + e. \tag{4.6}$$

The hypothesis statement specifies the model terms which are to be deleted from the full model in forming the reduced model (4.6). For balanced data or unbalanced data with no missing cells, these are the same hypotheses tested, with F statistics, in a standard balanced analysis-of-variance table. A rule is given in [9] to determine whether or not the equivalent balanced data hypothesis is testable for unbalanced data with missing cells. For a model with all factors crossed, this rule is simply: the equivalent balanced data hypothesis is testable if and only if the rank of the full model minus the rank of the reduced model equals the degrees of freedom one would use for the hypothesis with balanced data. It is the author's opinion that when the equivalent balanced data hypothesis is not testable, those hypotheses that are testable are usually very difficult to interpret in a meaningful way.

Some designs which are considered to be balanced designs will require iteration because the residual operator used applies to a more general model. An example of this is a Latin square which the algorithm treats as a missing cell problem. Iteration will be necessary to obtain SSE for the full model; however, as a result of data restructuring, iteration is not required in testing the relevant hypotheses.

The following statistics may be obtained from the algorithm, most of them on an optional basis:

(1) cell sums, frequencies, and means;
(2) classification sums, frequencies, and means;
(3) rank (X_0);
(4) SSE (full model) $= y'[I - X_0(X_0'X_0)^-X_0']y$ (invariant);
(5) SSR (full model) $= y'X_0(X_0'X_0)^-X_0'y$;
(6) a G-inverse solution to $X_0'X_0\hat{\beta} = X_0'y$; $\hat{\beta} = (X_0'X_0)^-X_0'y$;
(7) estimates of expected cell means $= X_0\hat{\beta}$ (invariant);
(8) rank (X_{01});

(9) SSE (reduced model) $= y'[I - X_{01}(X'_{01}X_{01})^{-}X'_{01}]y$;

(10) SSR (reduced model) $= y'X_{01}(X'_{01}X_{01})^{-}X'_{01}y$;

(11) $$F = \frac{(\text{SSR(full)} - \text{SSR(reduced)})/(\text{rank}(X_0) - \text{rank}(X_{01}))}{\text{SSE(full)}/(N - \text{rank}(X_0))};$$

(12) probability values; Prob$\{F \mid H_0\}$.

We indicated earlier that a G-inverse solution is obtained for the overparameterized model as well. It should be clear that the rank of X_0 is the same as the rank of the design matrix of the overparameterized model formed using 0, 1 indicator variables.

5. LOGICAL COMPONENTS

The program for the global algorithm consists of a main program and eight subroutines. The principal function of these components is described below.

MAINA processes the factor, level statement; computes cell sums, cell frequencies, and $y'y$ as it reads the data; processes the options statement and contains much of the code to execute the A (cell means) and C (classification means) options.

SCAN processes the model and hypothesis statement to construct (or modify) the E/R list; computes parameters needed in restructuring data; computes the degrees of freedom applicable to data with no missing cells.

IGET is used by the main program and subroutine **SCAN** to sequentially retrieve characters (other than blank, plus, or comma) from the input buffer.

PART1 restructures the data (cell frequencies) when appropriate; checks for balance and alternative noniterative computations; computes rank noniteratively if possible or iteratively otherwise when the R (rank) option is specified.

PART2 is the principal numeric computational component; with the use of the remaining four subroutines, it computes SSE, SSR, estimates of expected cell means, a G-inverse solution to the normal equations, F statistics, and probability values.

STEP performs one basic step of the iterative AOV algorithm [12] using the improved approximation for SSR given in [10]. This basic step consists of the following substeps.

(1) $A \leftarrow (Y - D \cdot V)/c$
(2) $V \leftarrow V + A$
(3) $B \leftarrow B + A$
(4) $A \leftarrow R[A]$
(5) $V \leftarrow V - A$
(6) $S \leftarrow 2 \cdot Y'V - V'DV$

where

Y is the vector of cell sums, D is the diagonal matrix of cell frequencies stored as a vector, and c is an algorithm constant set to assure convergence and, in hypothesis testing, to assure monotonicity of the approximation S to SSR;

A, B, and V are work vectors of size n_c, with n_c being the number of cells. An additional work vector large enough to contain the factorial decomposition cited earlier is also required; however, vector A will occupy the first n_c locations of this additional vector;

$R[A]$ is the residual operator applied to vector A. Substep (4) above consists of a factorial decomposition of vector A, followed by pooling the appropriate arrays of the decomposition back into A.

The vectors B and V must be initially set to zero. Upon completion, perhaps after many steps, estimates of the expected cell means will be contained in V, and a G-inverse solution is obtained by applying the E operator to the vector B.

Substep (1) above is modified slightly for iterative rank computations and for restructured data. In computing rank, this takes the form

$$A \leftarrow (Y - \Delta V),$$

where Δ is a diagonal matrix with unit diagonals for filled cells and zero diagonals for missing cells. Operations with Δ are handled implicitly and this matrix is never stored. In performing noniterative calculations (a single step) on restructured cell frequencies, substep (1) is modified to

$$A \leftarrow (D2^{-} \cdot Y - V)$$

where $D2^{-}$ is a diagonal G-inverse of the diagonal matrix of restructured cell frequencies [8].

Substep (6) above must also be modified in computing rank iteratively with Δ replacing D. Furthermore, in rank computations, the vector Y contains a dummy unit vector; cell sums have been temporarily stored elsewhere in a vacant vector.

DECOMP obtains a factorial decomposition of a given vector; determines the classification frequencies needed in **PART1** to restructure data; computes classification means for the C option in **MAINA**.

POOL either moves the secondary array into the primary array, duplicating entries where needed, or it pools the secondary array into the primary array by addition.

LABEL calculates the array of coefficients for the array map needed in pooling; produces output labels for classification means and for the G-inverse solution.

Of these logical components, all of **PART1** may be deleted to further reduce program storage without making **PART2** inoperable; however, this would make the program less efficient owing to unnecessary iteration and full rank would be assumed by default for X_0 or X_{01}. Almost all of **SCAN** can also be deleted, provided the user constructs and inputs the required E/R list.

6. ARRAY STORAGE

We previously emphasized the storage efficiency of the algorithm for moderate to large problems. Fundamentally, this efficiency is attributable to the use of the iterative AOV algorithm; however, array storage economy was also stressed in constructing the global algorithm. The following is a brief description of all of the arrays included.

LSTFI is the array discussed in [13] and [18], which is used in formation and subsequent manipulation of the arrays in the factorial decomposition; this is an array of size 2^n, where n is the number of factors.

LER is the E/R list that is also of size 2^n.

LE is an alphanumeric array for factor symbols of size n.

LS is an alphanumeric array of associated subscripts of size n.

LV is an array of the numerical values assigned to the factor symbols and their associated subscripts; it also has size n.

LLIM contains the number of levels for each factor and is of size n.

LT is a temporary work array of size n.

LP is also a work array; however, its size is 10, the maximum number of factors handled by the program.

LD is an alphanumeric array of size 10 containing the digits 0–9; this array is used to convert alphanumeric input, such as the number of levels for a factor, to numeric.

LO is an alphanumeric array of size 10 containing the single-character option identifiers.

IA is an alphanumeric input buffer—a card image--which is used in processing the factor, levels, options, model, and hypothesis statements and also for storage

Table I. Options

Identifier	Function of option	Default
S(d)	Significant digits in results	$d = 5$
T($l \times 10^4$)	Test level	$l = 0.05$
I(m)	Iteration maximum	$m = 100$
R	Rank computations (iterative)	off
V	Estimates of expected cell means	off
G	G-inverse solution to normal equations	off
P	Probability values for F statistics	off
Z	Intermediate output	off
A	Cell sums, frequencies, and means	off[a]
C	Classification sums, frequencies, and means	off[a]

[a] These switches do not change their status each time the option is specified.

of a variable **FORMAT** statement for input data. (The model and hypothesis statements have continuation facilities.)

Q is the only two-dimensional array. It is used exclusively for rank computations and its size, in relation to the number of missing cells, determines the rank algorithm applied. If the dimension of **Q** were fixed at 10 × 10, then the quadratically convergent rank algorithm would be used only if there were no more than 10 missing cells.

QT is a vector whose size is the same as one of the dimensions of **Q**; it is used in conjunction with **Q** in computing rank.

W is a linear array that is used for all the numeric computations. This array logically consists of six contiguous vectors. The implicit names of these vectors coincide with those used in describing a step of the iterative AOV algorithm; they are ordered in storage as

Y, D, D2, V, B, A.

The first five of these vectors have size n_c, where n_c is the number of cells. The sixth vector is the size of the factorial decomposition for the problem. For example, with two factors we have n_c = **I•J**, while the vector **A** has size **(I + 1)(J + 1)**. Ordinarily, the array **W** would be allocated all of the remaining computer storage; the implicit variable dimensioning of **W** maximizes the number of analysis-of-variance problems that can be processed within a given amount of storage.

7. THE FACTOR, LEVELS STATEMENT

The factor, levels statement creates entries for the arrays **LE, LS, LV,** and **LLIM.** The array **LSTFI** is then formed from **LLIM.** Factor symbols, subscript symbols, and factor levels are included in the statement; the number of factors and their numerical values are determined. As an example of a factor, levels statement, consider an analysis involving 3 factors with levels 5, 10, and 15. If we decide to name the factors **R, C, T** with subscripts **I, J, K,** then the statement would be written (typed/punched) on one line as

F(R, C, T), L(I(5), J(10), K(15))

All of the commas above are cosmetic, as are blanks and pluses; the same statement could be written as

F(RCT)L(I(5)J(10)K(15))

8. OPTIONS AND THE OPTIONS STATEMENT

A list of option identifiers and default values is given in Table I. The first three identifiers include an argument enclosed within parentheses which are used to modify a parameter. The remaining seven identifiers trigger on/off switches; with the exception of the A and C option, these switches change their status each time the option is specified.

The S option sets the relative iterative tolerance for SSR by forming the test constant $0.05 \times 10^{-d} \times (y'y)$. Iteration ceases when two successive approximations to SSR differ in magnitude by less than this test constant. This approach in practice seems to provide at least the requested accuracy in results obtained iteratively. A specification of $d = 0$ results in the skipping of all calculations in **PART2** and thus provides an option for independent rank calculations.

The T option sets the probability level at which F tests will be conducted. When iterative calculations are necessary for hypothesis testing, the constant c of the iterative AOV algorithm [12] is selected such that the sequence of approximations to the F statistic will be monotonically decreasing. The approximation given in [20] is used to compute the probability level for the F approximation. Whenever this value falls below the level specified, iteration ceases due to lack of significance. In the event that this value stays above the level specified, iteration continues until two successive F approximations differ by less than 0.005. When the P option is specified, iteration is continued for nonsignificant F's as well, in order to also obtain final probability levels for these statistics.

The R option must be in on status to compute rank *iteratively*. Noniterative rank computations in **PART1** are not affected by this option. The terminal iterative approximation to rank need not be highly accurate since the approximations converge monotonically to an integer; furthermore, absolute rather than relative cutoff tolerances may be used. Although the preset values for these tolerances may be modified, they have been tested to obtain the correct rank with minimal iteration.

The method best suited to a relatively small number of missing cells involves computing powers of a matrix whose order is the number of missing cells. The initial matrix is formed noniteratively. Successive powers, 1, 2, 4, 8, . . . , of this matrix are formed in the array **Q**. The trace of the matrix in **Q** converges quadratically and monotonically to the rank of X_0. In this case, we cease iteration when successive traces differ by less than 0.1. The rank is taken as the next integer. The method best suited to a large number of missing cells applies the iterative AOV algorithm to dummy unit vectors for each filled cell with D replaced by Δ. The sum of the SSRs obtained for each unit vector will equal the rank of X_0. In this case, we cease iteration when two successive approximations to SSR for a given unit vector differ by less than $0.1/n_f$ where n_f is the number of filled cells. This method will be expensive timewise when n_f is large.

When the Z option is on, the following intermediate output is produced when applicable: the current E/R list; the successive traces of the matrix in array **Q** or the cumulative sum of the SSRs for unit vectors in computing rank; the approximations to SSR for the full model; the approximations to SSR for the reduced model of the hypothesis.

Although the A and C options may appear to be somewhat mundane, these options require no additional array storage and they require little additional code; furthermore, it is likely that they would be requested as part of an analysis of variance.

An option statement is written on one line as a string of selected identifiers enclosed in parentheses and preceded by an O. The identifers may be in any order. For example, with the R and Z options in off status, to specify eight significant digits of accuracy, iterative rank computations, and intermediate output, the options statement may be written as

O(R, S(8), Z)

where the commas are again cosmetic.

9. MODEL AND HYPOTHESIS STATEMENTS

Examples of the model and hypothesis statements for three factors are given in Table II along with the E/R list entries that would be produced for these statements. These examples assume that factor symbols A, B, C, and subscript symbols I, J, K were used in the factor, levels statement. The analysis-of-variance

Table II. Model and Hypothesis Statements

$(y_{ijkl} = \mu + a_i + b_j + ab_{ij} + c_{ijk} + e_{ijkl})$	ABC	AB	AC	A	BC	B	C	M
M + A(I) + B(J) + AB(IJ) + C(IJK)	2	7	2	5	2	3	2	1
H AB(IJ), C(IJK)	−2	−7	−2	5	−2	3	−2	1

model, as it is usually written, appears above each model statement in Table II. Notice that the variate y_{ijkl} and the error term e_{ijkl} do not appear in the model statement. The additional subscript l is also implicit; that is, the number of observations in the (i, j, k) cell depends upon the data. The rules for constructing the model statement basically parallel those used in [14] and [18]: the associated subscript of a factor must always appear along with the factor symbol in a model term; if a factor is nested, it must be nested within a factor or factors appearing to the left of it in the factor, levels statement; the ordering of the associated subscripts in the factor, levels statement must correspond with the ordering of the data. As indicated earlier, pluses, blanks, and commas serve only to improve the appearance of these statements; these characters are ignored in parsing. Should either the model or hypothesis statement require more than one line (or card), continuation to the next line is indicated by placing a slash (/) after the last model term in the current line. For example, the fourth model statement in Table II could be written as

M + A(I) + B(J) + AB(IJ)/

+ C(IJK)

As a convenience, a full factorial model may be specified as M*, an asterisk following M. Hypothesis statements are then written normally using the same symbols appearing in the factor, levels statement. The E/R list construction algorithm includes the logic necessary to detect invalid models or hypotheses incorrectly specified. During interactive use, corrections can be made when an error is detected.

Any number of models may be applied experimentally to a given set of data. This includes models with fewer factors than appear in the factor, levels statement; the data will automatically be restructured for such models.

10. FLOW OF CONTROL

Flow of control proceeds in the following manner:

(1) factor, levels statement,
(2) variable **FORMAT** statement,
(3) data,
(4) blank line (card),
(5) options statement/model statement/hypothesis statement/blank line/E.

The data are prepared with one observation per line and cell indicators preceding the observation; the variable **FORMAT** statement must reflect this order. Cell

indicators are the factor levels for the observation. There is no indicator for within cell replication and no entries are made for missing cells. A check on lexicographical ordering of indicators is included; however, this check is easily deleted if inconvenient.

Once the data have been entered, control is centered upon (5). Any number of options, model, or hypothesis statements may be entered in any order (except that a model statement must precede any hypothesis statements). Entering a blank line returns control to (1); entering the character E, for end, will terminate processing.

11. EXAMPLE

We present here a simple example, processed in batch mode, to illustrate many of the features of the global algorithm. There are three factors A, B, and C with levels of 3, 2, and 2, respectively; this information is conveyed in the initial factor, levels statement. The data are unbalanced and three cells—cells (1, 1, 2), (2, 1, 2), and (2, 2, 1)—are empty.

After the data have been read, the first option statement is entered requesting intermediate output and specifying the A, C, and R options. Summary statistics, computed immediately for the A and C options, are printed followed by the current status of the options, including default values. A model statement representing a model with three crossed factors A, B, and C and an interaction between factors A and B is entered; the corresponding E/R list is printed as intermediate output. Intermediate output of rank computations for the design matrix for the full model follows, with each iteration displaying the trace of the matrix in **Q**, until the rank of 7 has been determined. SSR for the model is next computed iteratively to approximately five significant digits with intermediate output printed for each iteration.

An hypothesis statement is entered to test the significance of factor C. The algorithm determines the rank of the design matrix for the reduced model to be six noniteratively; it also restructures the data and computes SSR noniteratively for the reduced model. The computed F statistic is found to be not significant at the 5 percent level. Another hypothesis statement is entered to test the hypothesis of no AB interaction. Again the algorithm determines rank noniteratively; however, it must iterate to determine SSR for the reduced model. Intermediate output of the monotonically increasing approximation to SSR is printed until the corresponding approximation for F falls below the 5 percent level on the second iteration.

Another options statement is entered which suspends intermediate output and specifies the V and G option; again the status of the options is printed. A model statement representing the two-way classification without interaction for factors A and B is entered. All of the remaining computations are noniterative. Estimates of expected cell means are printed followed by a solution to the normal equations in response to the V and G options. Unfortunately, this example does not convey the algorithm's facility to handle large data sets and diverse models.

12. SUMMARY

We have described a comprehensive algorithm for analysis of variance which has the facility to handle large problems involving unbalanced data on small computers. At the same time, the computational efficiencies common to balanced data are realized. Array storage economy is achieved by virtue of the fact that the algorithm performs vector operations as opposed to matrix operations. Neither the design matrix of indicator variables X_0 nor the matrix $X_0'X_0$ is ever formed or stored. Ancillary computations and output amenities have been deliberately limited to conserve program storage; however, the facility for algebraic problem specifications has been included.

For some data sets and models requiring iteration, the algorithm may converge slowly so that it will be expensive timewise to achieve a high degree of accuracy; however, performance studies of the iterative AOV algorithm given in [10] and [6] indicate that the algorithm is likely to outperform matrix-oriented algorithms timewise on large problems with unbalanced data. It should always outperform these algorithms timewise when the data are balanced. Subsequent to submission of this algorithm, other authors [2], [15] have suggested using the conjugate gradient method rather than iterative improvement for the basic iterative step. The monotonicity properties of the algorithm are preserved with the conjugate gradient method, and performance should be improved whenever iteration for SSR is necessary. Subroutine step may be modified relatively easily to reflect using this method.

ACKNOWLEDGMENTS

The author wishes to acknowledge three former research assistants: Donald Piette, Clifford Pelletier, and James Petrarca. Their work in implementing the iterative AOV algorithm and extensions of this algorithm to covariance and multivariate analysis contributed to this ultimate design of the algorithm presented here. The author appreciates the efforts of Karen Hemmerle Hodge related to editing, documenting, and verifying the program.
