Bell Laboratories

Key Words and Phrases: portability, mathematical libraries, error handling, storage management, memory allocation, machine dependencies
CR Categories: 4.4, 5.1
Language: Fortran

DESCRIPTION

The three program packages presented here provide a framework for a portable Fortran subroutine library. They were developed for the Bell Laboratories library PORT [1]. The packages are: machine-dependent constants, automatic error handling, and dynamic storage allocation using a stack. There are interdependencies among the packages in the sense that the error handling is used by both the others, and it in turn uses machine-dependent constants provided by the first. However, care is taken to avoid any actual or apparent recursion.

Two non-ANSI Standard Fortran assumptions are made in the algorithm. The first is that there is no runtime subscript range checking; the second is that variables (local to a subprogram) initialized by DATA statements, and then changed within the subprogram, keep their values from one invocation of the subprogram to the next. Appendix A of [1] discusses nonstandard usage in more detail.

Machine-Dependent Constants

The first package contains three Fortran function subprograms which can be invoked to determine basic machine or operating system dependent constants. Values are provided in commented DATA statements for the Burroughs 5700/6700/7700, the CDC 6000/7000 series, the Data General Eclipse, DEC PDP 10 (KA and KI processors), the DEC PDP 11, the Harris S220, the Honeywell 6000 series, the IBM 360/370 series, the SEL systems 85/86, the Univac 1100 series, the XEROX SIGMA 5/7/9; others can be added. When the library is moved to a new environment, only the appropriate DATA statements in these three subprograms need to be activated by removing the C's from column 1.

The three functions are: I1MACH, which delivers integer constants, R1MACH,

Received 21 July 1976 and 9 May 1977.

Authors' address: Bell Laboratories, 600 Mountain Ave., Murray Hill, NJ 07974.

which delivers single-precision floating-point (REAL) constants, and D1MACH, which delivers double-precision floating-point constants. These functions have a single integer argument indicating the particular constant desired. For example, R1MACH(2) is the largest single-precision floating-point number on the host machine, so the statement

XMAX = R1MACH(2)

sets XMAX to this largest number.

The machine-dependent values provided are defined in the listing given here. (Please note that the systems for which the machine constants are given are printed here in alphabetical order but that their corresponding sequence numbers are not in numerical order.) Details of constant specification and usage are described in [1].

ALGORITHM

[Only the PORT utility programs are included here. A Users' Guide and test programs are available upon request from the ACM Algorithms Distribution Service.]

Automatic Error Handling

The second package provides a basic mechanism for dealing with the occurrence of errors.

In the PORT library [1], for which the package was developed, calls to the general subroutines in the library do not include flags for error indication in their calling sequences. Instead, when a called subroutine detects an error, it calls the principal error-handling routine, SETERR.

The package allows for two types of error, "fatal," and "recoverable," and a parameter in the call to SETERR must be set to specify the type. Fatal errors cause an error message to be printed, the run terminated, and a call made to a dump routine. (A dummy dump routine, FDUMP, is provided here.) For recoverable errors, unless the user has specifically requested to enter the recovery mode, similar events occur, an error message is printed, and the run terminated. Thus the process is failsafe for unwary users.

When the recovery mode is in effect, any call to SETERR given within a subprogram which has detected a recoverable error has the effect only of storing the fact that an error has occurred; the run is not terminated. The user, upon return from the subprogram, is responsible for testing for the occurrence of an error. If an error has occurred, the user must turn off the error state, because additional errors might arise and the occurrence of a recoverable error while in the error state constitutes an unrecoverable error, terminating the run.

Finally, since a called subprogram, say SUBA, may, in turn, call a lower-level subprogram containing recoverable errors, SUBA must check for the occurrence of errors in the lower-level routine and reinterpret them in the context of SUBA, which the user knows about. This means that SUBA must enter the recovery mode (saving the mode previously in effect), make the call to the lower-level subprogram, then, upon return from the lower-level routine, check for errors, and, before returning to the user, restore the previous recovery mode.

An error which has caused an invocation of SETERR has an associated number, message, and type (fatal or recoverable), and the effect of the error depends on whether the recovery mode is in effect or not. The various capabilities offered in the subprograms of the package are summarized as follows.

To signal that an error has occurred:

CALL SETERR(MESSG, NMESSG, NERR, IOPT)

where MESSG and NMESSG are, respectively, a Hollerith message and the number of characters in the message, and NERR is the error number. IOPT is used to specify the type of error: IOPT = 1 for a recoverable error, and IOPT = 2 for a fatal error.

To save the recovery (or nonrecovery) mode currently in effect, and enter a new one:

```
CALL ENTSRC(IROLD, IRNEW)
```

which saves the current mode in IROLD and sets the new one to IRNEW.

To avoid having multiple errors outstanding, it is a fatal error to call SETERR or ENTSRC if the error state is on, meaning that an error has occurred but has not been recovered from.

To restore the recovery (or nonrecovery) mode which was previously saved in IROLD:

```
CALL RETSRC(IROLD)
```

where RETSRC not only restores the previous mode, but also acts as a "safety" exit gate: Since multiple errors are illegal, RETSRC checks out the situation and allows return to the calling program only if (1) an error is not outstanding, or (2) the restored mode is recovery, so that the calling program is responsible for error checking.

To test if an error has occurred, and if its number was, say, 4, a statement such as the following is used:

```
IF (NERROR(NERR) .EQ. 4) GO TO 50
```

The value of the function NERROR and the value of the argument NERR are both set to the current value of the error number by NERROR. (The double assignment may be useful and comes free since Fortran prohibits functions with no arguments.) If the error number is nonzero, it means that an error has occurred and that corrective action must be taken.

To turn off the error state:

```
CALL ERROFF
```

In summary the user subprograms are:

SETERR	turns on the error state and saves a message and an error number;
ENTSRC	at entry, sets recovery (or nonrecovery) mode, provided no error state exists;
RETSRC	before returning, checks error situation and, if no errors exist, restores prior recovery (or nonrecovery) mode;
NERROR	returns the error number;
ERROFF	turns off the error state;
EPRINT	prints the error message.

These, in turn, call on the lower-level subprograms:

E9RINT	stores or prints error message, depending on switch setting;
S88FMT	sets up FORMAT array for printing;
I8SAVE	returns error number or recovery (or nonrecovery) mode, depending on one switch, and resets or does not reset the corresponding value depending on another;
FDUMP	a dummy routine to be replaced, if possible, by a locally written symbolic dump routine.

Dynamic Storage Allocation Using a Stack

The third package provides a basic mechanism for allocating and deallocating working storage on a storage stack.

In the PORT library [1], for which the package was developed, calls to the general subroutines in the library do not include, in their calling sequences, parameters representing scratch arrays; the work space is allocated and deallocated within the called subprograms.

To implement the stack in Fortran in a portable way, it has been put in labeled COMMON as a double-precision array of length 500:

```
COMMON/CSTAK/DSTAK(500)
DOUBLE PRECISION DSTAK
```

The stack handling capabilities, which are described more fully in [1], include stack allocation and deallocation (releasing space), stack initialization to a size different from the default length of 500 double-precision locations, stack query, i.e. the ability to find out dynamically how much space is available, modification of the length of the latest allocation, and finally, the ability to ascertain certain stack statistics, such as the number of outstanding allocations, the current active length, and the maximum active length achieved.

The various capabilities are summarized as follows:

To allocate (get) N locations of type ITYPE on the stack, set

```
INDEX = ISTKGT(N, ITYPE)
```

which returns an index into the stack for the first of the N items.

To deallocate (release) the last K allocations (not locations but entire allocations):

```
CALL ISTKRL(K)
```

To initialize the stack to, say, 1000 double-precision locations, use the subroutine, ISTKIN(N, ITYPE), as follows:

```
COMMON/CSTAK/DSTAK(1000)
DOUBLE PRECISION DSTAK
                :
  CALL ISTKIN(1000, 4)
```

To find out (query) how much space of type, ITYPE, is left:

NLEFT = ISTKQU(ITYPE)

To modify the length of the current outstanding allocation to N items:

INDEX = ISTKMD(N)

which will modify the length of the allocation to N items and, as in ISTKGT, return the index of the first item of that allocation.

To obtain certain stack statistics use the

INTEGER FUNCTION ISTKST(N)

In summary the user subprograms are:

ISTKGT	allocates space on the stack;
ISTKRL	releases (deallocates) space;
ISTKIN	initializes (sets length) of stack;
ISTKQU	answers query as to space available on stack;
ISTKMD	modifies length of current allocation;
ISTKST	provides statistics on stack usage.

These, in turn, call on the lower-level subprogram:

I0TK00	initializes stack for special cases of nonstandard lengths for INTEGER, REAL, and DOUBLE PRECISION numbers.

ALGORITHM

```
      INTEGER FUNCTION ISTKGT(NITEMS,ITYPE)                              STKE0000
C                                                                        STKE0020
C  ALLOCATES SPACE OUT OF THE INTEGER ARRAY ISTAK (IN COMMON             STKE0040
C  BLOCK CSTAK) FOR AN ARRAY OF LENGTH NITEMS AND OF TYPE                STKE0060
C  DETERMINED BY ITYPE AS FOLLOWS                                        STKE0080

REMARK ON ALGORITHM 528

Framework for a Portable Library [Z]
[P.A. Fox, A.D. Hall, and N.L. Schryer, *ACM Trans. Math. Software 4*, 2 (June 1978), 177–188]

Phyllis Fox [Recd 11 September 1979]
Bell Laboratories, 600 Mountain Ave., Murray Hill, NJ 07974

In the machine-dependent constants for the PDP 10 computer with KI processor, a transcription error has been found in the double-precision value for $\log_{10} b$.

The DATA line should read as follows:

```
C  DATA LOG10(1),LOG10(2)/"177464202324, "047674776746/          MCHD1680
```

(See the complete listing of Algorithm 528, available from the ACM Algorithms Distribution Service or to be found in "Collected Algorithms from ACM.")

ACKNOWLEDGMENT

The author is grateful to Prof. Nelson Beebe of the Department of Physics, University of Utah, for detecting the incorrect value.

ALGORITHM 529
Permutations to Block Triangular Form [F1]

I. S. DUFF and J. K. REID
AERE Harwell

Key Words and Phrases: symmetric permutations, block triangular form, depth first search algorithm, sparse matrices
CR Categories: 5.0, 5.1, 5.3, 5.4
Language: ANSI Fortran

DESCRIPTION

Given the column numbers of the nonzeros in each row of a sparse matrix, this subroutine finds a symmetric permutation that makes the matrix block lower triangular. It can also be interpreted as accepting the row numbers of the nonzeros in each column and symmetrically permuting to block upper triangular form. If the user submits a matrix with zeros on the diagonal, subroutine MC13D might give a block triangular form which could be further reduced by unsymmetric permutations. To obtain the best results, the user is advised first to permute the matrix so that it has a zero-free diagonal. This can be done by Harwell subroutine MC21A (Duff [1]).

The subroutine is evoked by the Fortran statement

```
CALL MC13D(N,ICN,LICN,IP,LENR,IOR,IB,NUM,IW)
```

where the parameters are described in the listing given here.

The subroutine is based on Tarjan's depth first search algorithm [3], and its design is described in detail in Duff and Reid [2]. They also discuss experimental results from using this subroutine which has been tested on a wide range of both structured and randomly generated matrices.

This routine has been written in ANSI Fortran. Special comment cards have been included so that Harwell subroutine OEØ4A can be used to make an IBM Fortran version that uses half-length integers (INTEGER*2) for all the arrays except IP. This approximately halves the core requirements at the cost of restricting the order of the system to $2^{15} - 1$.

ALGORITHM 530
An Algorithm for Computing the Eigensystem of Skew-Symmetric Matrices and a Class of Symmetric Matrices [F2]

R. C. WARD and L. J. GRAY
Union Carbide Corporation, Nuclear Division

Key Words and Phrases: eigenvalues, eigenvectors, skew-symmetric matrices, symmetric matrices, matrices with constant diagonal
CR Categories: 5.14
Language: Fortran

DESCRIPTION

The set of Fortran subroutines given here is an implementation of the algorithm [3] for finding the eigenvectors x and eigenvalues λ such that $Ax = \lambda x$, where A is a real skew-symmetric matrix or a real tridiagonal symmetric matrix with a constant diagonal. The algorithm uses only orthogonal similarity transformations and is believed to be the most efficient procedure available for computing all the eigenvalues or the complete eigensystem for the indicated classes of matrices.

The three subroutines of the algorithm and their functions are described as follows:

TRIZD. A subroutine that transforms an arbitrary real skew-symmetric matrix to skew-symmetric tridiagonal form using orthogonal similarity transformations, saving the pertinent information about these transformations.

IMZD. A subroutine that computes the eigenvalues and, optionally, the eigenvectors of a symmetric tridiagonal matrix with zeros on the diagonal or of a skew-symmetric tridiagonal matrix.

TBAKZD. A subroutine that computes the eigenvectors of an arbitrary real skew-symmetric matrix by back-transforming the eigenvectors of the corresponding skew-symmetric tridiagonal matrix determined by TRIZD. Subroutines TRIZD and TBAKZD are straightforward adaptations of Fortran subroutines TRED1 and TRBAK1 [2] (originally published as Algol procedures in [1]) which accomplish similar functions for arbitrary real symmetric matrices. A detailed description of subroutine IMZD is given by Ward and Gray [3].

To determine the complete eigensystem of a full skew-symmetric matrix, the user should issue a call to TRIZD, IMZD, and TBAKZD, in that order. If only the eigenvalues are desired, then calling TBAKZD is unnecessary. To determine the complete eigensystem or only the eigenvalues of a tridiagonal skew-symmetric matrix or a tridiagonal symmetric matrix with zero diagonals, the user should only issue a call to IMZD. (If $\{\lambda_i\}$ and $\{x_i\}$ are the eigenvalues and eigenvectors of the matrix A, a tridiagonal symmetric matrix with zero diagonals, then the eigenvalues and eigenvectors of $A + \alpha I$ are $\{\lambda_i + \alpha\}$ and $\{x_i\}$.)

Subroutines TRIZD, IMZD, and TBAKZD have been tested extensively on

Received 31 March 1977 and 26 October 1977.

the IBM 360/91 computer at Oak Ridge National Laboratory using double precision arithmetic. Some of the test cases are presented in [3]. Since only orthogonal similarity transformations are used, the algorithm is numerically stable, that is, each computed eigenvalue and its corresponding eigenvector are exact for a matrix close to the original matrix.

ALGORITHM 531
Contour Plotting [J6]

WILLIAM V. SNYDER
Jet Propulsion Laboratory

Key Words and Phrases: contour plotting
CR Categories: 8.2
Language: Fortran

DESCRIPTION

Given a two-dimensional array of samples of a surface, contour values, and a subroutine to draw lines, the subroutine GCONTR determines sequences of points in the plane which may be used to draw contours through equal values of the surface.

A contour plotting algorithm may be constructed by following contours from some starting point until they either close or intersect a boundary, or by examining each cell of the grid in turn and drawing all contours found inside the cell. The advantages of contour following are that contour labeling is relatively easy and that the pen of an incremental plotter does not move about as much without writing anything. The advantages of methods which draw all contours found inside a cell are that less auxiliary storage is needed and that each cell can be completely processed before going on to the next, thereby allowing generation of contours over a much larger array than can be accommodated in main memory at one time.

GCONTR is of the type which follows contours. On a representative problem, a program using GCONTR generated about 11,000 plotter commands with about 57,000 commands generated by a program using a cellular method. For this problem, grid lines, user identification, and a table of contour values required about 36,000 additional commands.

Since the data used by contour plotting programs are presented at discrete points and since the contour values are not necessarily equal to the dependent variable values at the nodal points of the mesh, some method must be used to estimate the point at which a contour value intersects the edge of a cell. If one uses nonlinear interpolation, there is the possibility of multiple intersections of a contour with an edge and the possibility of closed contours which intersect no edges; if one wants to follow the interpolated surface faithfully, drawing the contour entails finding zeros of a nonlinear bivariate function. Linear interpolation

Received 17 June 1977 and 8 November 1977.

This work was sponsored by the National Aeronautics and Space Administration under Contract NAS 7-100; this paper presents the results of one phase of research carried out at the Jet Propulsion Laboratory. The work was carried out using a Univac 1108 computer, CalComp model 565 drum plotters, a Calcomp model 1675 Com, and Tektronix 4000 series interactive graphics terminals.
Author's address: Jet Propulsion Laboratory, California Institute of Technology, 4800 Oak Grove Drive, Pasadena, CA 91103.

has the drawback that extrema occur only at nodal points. GCONTR uses linear interpolation. If this does not produce sufficiently smooth, accurate contours, we recommend computing more function values or interpolatory subtabulation to a finer mesh. If the required storage is larger than desired, the independent variable plane is easily divided into separately processed segments. GCONTR does not provide automatic subtabulation because different methods work better for different problems. Since GCONTR uses a contour following method, any implementation of automatic subtabulation would necessarily have a higher cost than a reasonable user implementation.

Once the points of intersection of a contour with edges have been determined, one must still decide how to draw the contour line between such intersections. We recommend that straight lines be used. Most other curves can cause balloons and crossing of contours of different values.

We now discuss the features which distinguish GCONTR from the methods of Cottafava and Le Moli [1] and Crane [2]. GCONTR and the algorithms described in [1] and [2] are similar in that all are contour following methods, the data are assumed to be presented on the nodes of a topologically rectangular grid, and linear interpolation is used along the edges of a cell.

GCONTR and algorithm [2] begin following a contour as soon as an edge of a cell of the coordinate grid is found which the contour line intersects. Edges intersected by the contour are flagged in an integer array in [2] and by marks in a bitmap in GCONTR. In algorithm [1] a preliminary detection of all intersections of edges and contours is done and then the contours are drawn. The details of the bookkeeping are not described in [1].

Algorithms [1] and [2] start the contour at the first edge found while searching along rows or columns of the data array. GCONTR reduces pen-up travel by searching along a rectangular spiral starting at the current pen position. All three algorithms draw all contours which intersect boundaries before drawing any contours which do not.

Algorithm [1] treats the case of a contour intersecting all four edges of a cell in a way which depends on the fixed order of examining the edges. If a cell is approached from different directions, different contours will be drawn. Algorithm [2] forces the contours to cross inside the cell. When several different contours intersect all four edges, the resulting pattern looks like an asterisk. GCONTR examines the linear interpolate along the "top" and "bottom" edges of the cell. If the interpolate on the top edge is less than the interpolate on the bottom edge, the contour line is drawn top-to-left and bottom-to-right. Otherwise, the contour line is drawn top-to-right and bottom-to-left. This methods selects the same contours if the axes are exchanged. To show this, note that the use of linear interpolation along the edges of the unit cell implies that there is some estimated function value F_x which occurs at the same abscissa on the top and bottom edges, and some estimated function value F_y which occurs at the same ordinate on the "left" and "right" edges. It is easy to show that $F_x = F_y$. Therefore, the contour of value F_x is the only contour which crosses inside the cell, and it divides the cell into four rectangular regions. In two of these regions the esimated function value is less than F_x. In the other two, the estimated function value is greater than F_x.

Algorithms [1] and [2] consider all data in the array. GCONTR provides a means whereby the user may designate excluded elements of the array. The edges connecting excluded elements to elements not excluded are not examined. This feature has been found to be very useful in practice, as data are frequently not presented on a complete rectangular grid. When using methods which do not have this feature, one frequently finds extraneous contours drawn between the regions containing data and the regions containing no data.

The output method is not described in [1]. The output from algorithm [2] is an ordered set of points in an array which define the contour lines to be drawn. GCONTR calls a line drawing subroutine provided by the user. If the user wishes to take the risks noted above associated with using other than straight lines for

drawing the contours, points may be stored in the line drawing subroutine, and a method such as is described in [3] may be used to generate smooth contours. Transformations may be applied to the output of algorithm [2] and to the points provided by GCONTR to the line drawing subroutine for such purposes as coordinate system conversion. Note that neither algorithm [2] nor GCONTR require the grid lines to be straight or uniformly spaced.

ALGORITHM 532
Software for Roundoff Analysis [Z]

WEBB MILLER
University of California, Santa Barbara
and
DAVID SPOONER
Pennsylvania State University

Key Words and Phrases: automatic roundoff analysis, numerical stability, numerical linear algebra
CR Categories: 5.10, 5.11, 5.14
Language: Fortran

DESCRIPTION

This software package is a complement to [1] where its usage and performance are described.

C
C
C  THIS PROGRAM IS A COMPILER WHICH TAKES AS DATA A PROGRAM WRITTEN
C  IN A SIMPLE PROGRAMMING LANGUAGE ( A DESCRIPTION OF WHICH FOLLOWS)
C  AND PRODUCES AS OUTPUT A TRANSLATION OF THAT PROGRAM INTO A SERIES
C  OF ASSIGNMENT STATEMENTS.  THE STRAIGHT LINE CODE TRANSLATION IS
```

Received 21 August 1975 and 4 March 1977.

This work was supported in part by NSF Grants GJ-42968 and MCS 76-13561A01.
Authors' addresses: W. Miller, Department of Mathematics, University of California, Santa Barbara, Santa Barbara, CA 93106; D. Spooner, Department of Computer Science, 303 Whitmore Laboratory, Pennsylvania State University, University Park, PA 16802.

```
C  PRINTED IN A READABLE FORM FOR THE COMPILER USER AND ALSO PUNCHED
C  IN  A CODED FORM FOR USE AS INPUT TO ANY OF SEVERAL ROUNDOFF ERROR
C  ANALYSIS PROGRAMS OF WEBB MILLER.
C  THE MAIN ROUTINE OF THE COMPILER IS AN LL-1 PARSING ROUTINE.  IT
C  CALLS THE LEXICAL ANALYZER TO PRODUCE INTERNAL TOKENS BY SCANNING
C  THE SOURCE CODE.  THE PARSER ALSO CALLS THE ROUTINE CODGEN WHICH
C  PRODUCES INTERMEDIATE CODE FOR THE INTERPRETER AND WHICH PERFORMS
C  SOME SYNTAX CHECKING AND OTHER PERIPHERAL FUNCTIONS NECESSARY
C  FOR PARSING.
C  WHEN THE ENTIRE INPUT HAS BEEN SCANNED AND PARSED, THE INTERPRETING
C  ROUTINES ARE ACTIVATED.  THESE INTERPRET THE INTERMEDIATE CODE AND
C  GENERATE THE FINAL STRAIGHT LINE PRINTED AND PUNCHED OUTPUT.  DURING
C  INTERPRETATION, ALL INTEGER EXPRESSIONS ARE ACTUALLY EVALUATED IN
C  ORDER TO PERFORM THE CORRECT NUMBER OF ITERATIONS OF EXPLICIT FOR-
C  LOOPS AND OF FOR-LOOPS IMPLICIT IN SUMMATION EXPRESSIONS, AND TO
C  INTERPRETIVELY PERFORM IF-THEN TESTS.  IN CONTRAST, NO ACTUAL
C  REAL ARITHMETIC COMPUTATION IS DONE.  THROUGHOUT, ALL REAL
C  VARIABLES ARE TREATED SYMBOLICALLY AS BEING THE N-TH INPUT VALUE,
C  INTERMEDIATE VALUE, OR REAL CONSTANT.
C  BOTH THE LEXICAL ANALYZER AND THE INTERPRETER COMPRISE SEVERAL SUB-
C  ROUTINES.IN ADDITION THERE ARE COLLECTIONS OF SYMBOL TABLE ROUTINES,
C  ERROR ROUTINES AND ROUTINES TO PRINT AND PUNCH THE COMPILER'S
C  OUTPUT.
C  IF ANY ERRORS ARE ENCOUNTERED DURING PARSING, THE PARSER CONTINUES
C  TO CHECK FOR SYNTAX ERRORS, BUT NO FURTHER INTERMEDIATE CODE WILL BE
C  GENERATED, AND NO INTERPRETATION WILL TAKE PLACE.  SIMILARLY, IF
C  EXECUTION ERRORS ARE IDENTIFIED DURING INTERPRETATION, NO STRAIGHT
C  LINE CODE WILL BE EITHER PRINTED OR PUNCHED.

C            *                                      *
C            ****************************************
C
C
C       THE LANGUAGE TO BE COMPILED IS A SIMPLE LANGUAGE DESIGNED FOR
C  CODING NUMERICAL ALGORITHMS.  IT BASICALLY INCLUDES REAL ASSIGN-
C  MENT STATEMENTS, DIMENSION STATEMENTS AND SOME BLOCK STRUCTURE
C  IMPOSED BY FOR-LOOPS, AND IF-THEN TESTS. THERE ARE NO MIXED-MODE
C  ARITHMETIC EXPRESSIONS, AND NO STATEMENT LABELS.  INTEGER EXPRESSIONS
C  AND VARIABLES ARE USED ONLY FOR DIMENSIONING REAL ARRAYS, FOR
C  DEFINING BOUNDS IN FOR-LOOPS AND SUMMATION EXPRESSION LOOPS, AND FOR
C  VARIABLES TO BE TESTED IN IF-THEN STATEMENTS.
C         THE CARD FORMAT IS SIMILAR TO FORTRAN.  STATEMENTS APPEAR
C  IN COLUMNS 7-72, AND A 1 IN COLUMN 6 INDICATES CONTINUATION.  A
C  C IN COLUMN 1 INDICATES A COMMENT.
C         THERE ARE SEVEN STATEMENT TYPES, BRIEFLY DESCRIBED BELOW:
C
C  1. THE TEST STATEMENT
C
C     USE:  TO ASSIGN VALUES TO INTEGER VARIABLES WHICH WILL THEMSELVES
C           BE USED TO DIMENSION REAL ARRAYS.
C
C     FORM: TEST(I1,I2,I3,...)
C
C           WHERE EACH I IS AN ASSIGNMENT STATEMENT OF THE FORM
C           INTEGER VARIABLE = INTEGER CONSTANT.
C
C  2. THE DIMENSION STATEMENT
C
C     USE:  TO ASSIGN DIMENSIONS TO ARRAYS.  THE ARRAY NAME MAY BE
C           EITHER A DEFAULT REAL OR INTEGER IDENTIFIER.  ITS USE IN
C           THE DIMENSION STATEMENT CONSTITUTES AN IMPLICIT REAL
C           DECLARATION.
C
C     FORM: DIMENSION(D1,D2,D3 ..)
C
C           WHERE EACH D IS OF ONE OF THE FOLLOWING FORMS:
C           IDENTIFIER(I)
C           IDENTIFIER(I1,I2)
C           AND EACH I IS AN INTEGER VARIABLE OR INTEGER CONSTANT.
C
C  NOTE: DIMENSION AND TEST STATEMENTS ARE NON-EXECUTABLE AND MUST
C        PRECEED ALL EXECUTABLE STATEMENTS.  IN ADDITION, AN INTEGER
```

```
C        VARIABLE APPEARING IN A DIMENSION STATEMENT MUST BE ASSIGNED A
C        VALUE IN A PRECEEDING TEST STATEMENT.
C
C  3.  THE INPUT/OUTPUT STATEMENTS
C
C     USE:  TO NOTIFY THE COMPILER THAT CERTAIN VALUES WILL BE SUPPLIED
C           BY THE PROGRAMMER AS INITIAL VALUES FOR REAL VARIABLES WHEN
C           THE STRAIGHT LINE CODE IS USED AS INPUT FOR A ROUNDOFF ERROR
C           ANALYSIS; OR THAT CERTAIN REAL VARIABLES ARE EXPECTED TO
C           RECEIVE VALUES AS A RESULT OF RUNNING THE PROGRAM BEING
C           COMPILED.
C
C     FORM: INPUT(D1,D2,D3,...)
C           OUTPUT(D1,D2,D3,..)
C
C           EACH D IS EITHER THE NAME OF A REAL SCALAR, A SINGLE ARRAY
C           ELEMENT, OR AN ENTIRE ARRAY.  IN THE LATTER CASE THE ARRAY
C           WILL BE INPUT(OUTPUT) IN COLUMN MAJOR ORDER.
C           NOTE THAT ONLY VALUES WHICH ARE THE RESULT OF A
C           COMPUTATION MAY BE OUTPUT.  CONSTANTS OR DATA VALUES
C           MAY NOT BE OUTPUT.
C
C  4. THE REAL ASSIGNMENT STATEMENT
C
C     USE:  TO ASSIGN A VALUE TO A REAL VARIABLE
C
C     FORM: REAL VARIABLE = REAL EXPRESSION
C
C           WHERE THE REAL VARIABLE IS EITHER A REAL SCALAR OR SINGLE
C           ARRAY ELEMENT.  REAL EXPRESSIONS ARE MADE UP OF REAL
C           VARIABLES AND CONSTANTS COMBINED WITH THE BINARY OPERATORS
C           +, -, * AND / AND THE UNARY OPERATORS UNARY - AND SQRT.
C           (THE OPERAND OF THE SQRT MUST APPEAR IN PARENTHESES.)
C           (NOTE THAT THERE IS NO REAL EXPONENTIATION ALLOWED.)
C           OPERATOR PRECEDENCE IS AS IN STANDARD FORTRAN. IN ADDITION
C           THERE IS A SUMMATION OPERATION ON ARRAY VECTORS, IN EFFECT,
C           A BUILT-IN INNER PRODUCT.  A SUMMATION EXPRESSION CAN APPEAR
C           IN A REAL EXPRESSION AND IS OF THE FORM:
C
C           SUMMATION(D1 * D2, SUMMATION-VARIABLE = INTEXP1 TO INTEXP2)
C
C           WHERE INTEXP IS AN INTEGER EXPRESSION, THE SUMMATION
C           VARIABLE IS ANY INTEGER IDENTIFIER NAME, AND WHERE D1 AND D2
C           ARE EACH OF ONE OF THE FORMS:
C               ARRAY NAME(SUMMATION-VARIABLE)
C               ARRAY NAME(SUMMATION-VARIABLE,SUMMATION-VARIABLE)
C               ARRAY NAME(SUMMATION-VARIABLE,INTEXP)
C               ARRAY NAME(INTEXP,SUMMATION-VARIABLE)
C
C           A SUMMATION EXPRESSION WILL BE INTERPRETED AS AN IMPLICIT
C           FOR-LOOP. ANY USE OF THE SUMMATION VARIABLE IN THE INTEGER
C           EXPRESSIONS BOUNDING THE SUMMATION LOOP WILL BE FLAGGED AS
C           AN ERROR.
C
C  5.  THE FOR STATEMENT
C
C     USE:  AS A MEANS OF INDICATING THAT A BLOCK OF STATEMENTS IS TO BE
C           ITERATIVELY EXECUTED A SPECIFIED NUMBER OF TIMES.
C
C     FORM:  FOR INTEGER-VARIABLE = INTEXP1 TO INTEXP2 BY INCREMENT
C
C           WHERE INTEXP STANDS FOR INTEGER EXPRESSION, AND INCREMENT IS
C           WRITTEN AS EITHER +1, -1 OR 1.
C
C     INTERPRETATION:  ALL STATEMENTS UP TO THE END STATEMENT MATCHING
C           THIS FOR STATEMENT (SEE BELOW FOR DISCUSSION OF END
C           STATEMENTS) WILL BE ITERATIVELY INTERPRETED AS IN A FORTRAN
C           DO LOOP, EXCEPT THAT NEGATIVE INCREMENTS ARE ALLOWED AND IN
C           THIS CASE, THE LOOP VARIABLE TEST IS DONE AT THE TOP OF THE
C           LOOP.  THUS, EMPTY LOOPS ARE POSSIBLE, THAT IS THOSE WHICH
C           WILL NOT BE EXECUTED AT ALL.  (NOTE THE SAME IS TRUE OF THE
C           IMPLICIT FOR-LOOP IN A SUMMATION EXPRESSION.)
C
C  6. THE IF-THEN STATEMENT
C
C     USE:  TO ALLOW SELECTIVE EXECUTION OF A BLOCK OF STATEMENTS
```

```
C           DEPENDING ON THE OUTCOME OF A COMPARISON OF THE VALUES OF
C           TWO INTEGER EXPRESSIONS.
C
C     FORM: IF INTEXP1 .R. INTEXP2 THEN
C
C           WHERE INTEXP STANDS FOR INTEGER EXPRESSION AND R IS ONE OF
C           THE RELATIONS WRITTEN EQ,NE,GT,LT,LE OR GE WITH THE
C           STANDARD FORTRAN DENOTATION. NOTE THAT THERE ARE NO
C           PARENTHESES AROUND THE RELATIONAL EXPRESSION.
C
C     INTERPRETATION: IF THE TEST SUCCEEDS, THAT IS IF THE TWO INTEGER
C           EXPRESSIONS ARE RELATED IN THE INDICATED WAY AT THE TIME OF
C           INTERPRETATION, THEN ALL THE STATEMENTS UP TO THE NEXT END
C           STATEMENT WILL BE INTERPRETED.  OTHERWISE, THE FIRST
C           EXECUTABLE STATEMENT FOLLOWING THE NEXT END STATEMENT WILL
C           BE THE NEXT STATEMENT INTERPRETED.
C
C  7. THE END STATEMENT
C
C     USE:  TO DEFINE THE ENDS OF BLOCKS OF STATEMENTS BEGINNING WITH
C           FOR STATEMENTS OR IF-THEN STATEMENTS.
C
C     FORM1:    END
C     FORM2 :   END(INTEGER-VARIABLE)
C
C     MEANING:  WHEN FORM 1 IS USED THE EFFECT IS TO CLOSE THE BLOCK OF
C           STATEMENTS  BEGINNING AT THE NEAREST PRECEEDING FOR OR
C           IF-THEN STATEMENT.
C           WHEN FORM2 IS USED THE EFFECT IS TO CLOSE THE FOR BLOCK
C           WHOSE LOOP VARIABLE MATCHES THE END STATEMENT VARIABLE.  IN
C           ADDITION, ANY FOR OR IF-THEN BLOCKS WHICH BEGIN BETWEEN THIS
C           END STATEMENT AND ITS MATCHING FOR STATEMENT ARE CLOSED.
C           THIS INTERPRETATION IMPOSES STANDARD FORTRAN LIKE NESTING
C           CONVENTIONS ON FOR AND IF-THEN BLOCKS.  THAT IS, A SEQUENCE
C           OF STATEMENTS
C                           FOR K = IE1 TO IE2 BY 1
C                           .
C                           .
C                           FOR I = IE3 TO IE4 BY 1
C                           .
C                           .
C                           END(K)
C                           .
C                           END(I)
C           WILL RESULT IN AN ERROR MESSAGE WHEN THE END(I) STATEMENT
C           IS ENCOUNTERED, BECAUSE BOTH FOR STATEMENTS WILL HAVE BEEN
C           CLOSED BY THE PARSER WHEN THE END(K) STATEMENT WAS PARSED.
C
C  NOTE:    ADDITIONAL RESTRICTIONS ON BLOCK STRUCTURES:
C           1) AT MOST EIGHT FOR AND/OR IF-THEN BLOCKS CAN BE BEGUN
C              BEFORE AN END STATEMENT OCCURS.
C           2) A FOR LOOP VARIABLE CANNOT BE USED AGAIN AS AN EXPLICIT
C              FOR LOOP VARIABLE WITHIN ITS ORIGINAL LOOP. IT CAN BE
C              REUSED AS A SUMMATION VARIABLE, HOWEVER.
C
C  8. THE STOP STATEMENT
C
C     USE:  TO DENOTE THE END OF THE PROGRAM
C
C     FORM:  *STOP
C
```

Contents of program comparing rounding error in a single algorithm with perturbations of the problem: MAIN1(372), F(64), ROUND(116), GETRHO(64), OMEGA(76)

ALGORITHM 533
NSPIV, A Fortran Subroutine for Sparse Gaussian Elimination With Partial Pivoting [F4]

ANDREW H. SHERMAN
The University of Texas at Austin

Key Words and Phrases: sparse Gaussian elimination, sparse linear systems, linear equations, partial pivoting algorithms
CR Categories: 5.14
Language: Fortran

DESCRIPTION

1. Introduction

NSPIV is a Fortran subroutine which solves a sparse system of linear equations

$$Ax = b$$

by sparse Gaussian elimination with partial pivoting. More precisely, it performs Gaussian elimination with column interchanges on the nonsingular $N \times N$ matrix A to effectively obtain a factorization of the form

$$AQ = LU,$$

where L is lower triangular, U is unit upper triangular, and Q is a permutation matrix corresponding to the column interchanges. To conserve storage, only the factor U is retained, so during elimination, operations are performed on the right-hand side to obtain the solution y of the system.

$$Ly = b.$$

Once U has been obtained, x is computed by solving the upper triangular system

$$UQ^{\mathrm{T}}x = y.$$

This algorithm discusses the usage of NSPIV and gives a few test results. The method used in NSPIV is described in [7], where it is called "run insertion"; [7] also includes extensive test results which show NSPIV to be more efficient than other currently available software for sparse Gaussian elimination with pivoting.

Received 17 June 1977 and 8 November 1977.

This work was supported in part by the National Science Foundation under Grant NSF DCR 73-07998, in part by the Energy Research and Development Administration under Grant US ERDA E(11-1) 2383, and in part by Yale University under a grant subcontracted from the United States Air Force Office of Scientific Research.
Author's address: Department of Computer Sciences, Painter 328, The University of Texas at Austin, Austin, TX 78712.

2. Usage

For a description of the calling sequence and matrix storage schemes used, see the listing presented here.

The actual numerical computations are performed in an internal subroutine NSPIV1, which is written to perform all computations in single precision. Conversion to double precision may be accomplished simply by changing REAL declarations to DOUBLE PRECISION declarations in both NSPIV and NSPIV1, and by changing the calls to ABS into calls to DABS.

It is well known that the initial ordering of the rows of A greatly affects the overall performance of a subroutine like NSPIV (cf. [1, 7]). To provide initial row and column orderings to NSPIV, the user must set the arrays R, C, and IC so that $R(I)$ is the number of the Ith row in the row ordering, $C(I)$ is the number of the Ith column in the column ordering, and $IC(C(I)) = I$ for all I. (Notice that no modifications are required to the arrays, IA, JA, and A.) It is always assumed by NSPIV that the user has provided initial row and column orderings; if the orderings are unchanged from those of A, then the user should set $R(I) = C(I) = IC(I) = I$.

Often, sparse linear systems arise with a natural band structure in which all of the nonzeros of A are clustered near the main diagonal. On such problems, with a poor initial ordering, NSPIV may perform worse than some widely available subroutines for band Gaussian elimination with partial pivoting. However, for a sparse matrix A with a given row ordering, NSPIV will often require less storage and not too much more computation time than a band subroutine. Moreover, it is usually possible to find easily computed row orderings for which NSPIV is substantially more efficient than a band subroutine would be with a good band-reducing ordering.

To illustrate these remarks, we consider a sample problem which could arise in the numerical solution of partial differential equations. Here A is a 10×10 block tridiagonal matrix

$$A = \begin{pmatrix} C & D & & & \\ B & C & D & & \\ & B & \ddots & \ddots & \\ & & \ddots & \ddots & D \\ & & & B & C \end{pmatrix}$$

with the 10×10 blocks given by

$$C = \begin{pmatrix} 3. & -.5 & & & \\ -1.5 & 3. & -.5 & & \\ & -1.5 & \ddots & \ddots & \\ & & \ddots & \ddots & -.5 \\ & & & -1.5 & 3. \end{pmatrix}, \quad B = D = \begin{pmatrix} -1. & & & \\ & -1. & & \\ & & \ddots & \\ & & & -1. \end{pmatrix}$$

We solved this problem using NSPIV with three different initial row orderings: the natural ordering (NO) in which the problem was presented, the so-called alternate diagonal ordering (ADO) (cf. Price and Coats [6]), and an ordering in which the sparsest rows are ordered first (SO). We also solved the problem using the subroutine LEQT1B from the IMSL library ([4]) using the natural ordering to produce the smallest possible bandwidth for this problem (cf. George [3]).

Table I

Subroutine	Ordering	Solution Time*	Total Storage
NSPIV	SO	.799	4785
NSPIV	ADO	.146	2453
NSPIV	NO	.283	3181
LEQTIB	NO	.244	3300

* Times are in seconds. Programs were run on a CDC-6600 computer using the MNF Fortran compiler.

Our results are summarized in Table I. With the SO ordering, NSPIV required much more storage and time than LEQT1B did with the natural ordering. With identical orderings, LEQT1B was slightly faster than NSPIV, but NSPIV required less storage and also saved both the input matrix A and the right-hand side b in their original forms. (LEQT1B does save both triangular factors, however.) Finally, with the ADO ordering, NSPIV used substantially less storage and computation time than LEQT1B. It should be noted in passing that the SO ordering apparently works quite well on problems without the natural band structure present in this example (cf. [1, 7]), even though it did not do well here. Also, experiments indicate that more complex orderings such as the minimum degree or modified Markowitz orderings (cf. Sherman [8]) may be used to good advantage with NSPIV.

APPENDIX A

The code in this appendix illustrates the use of NSPIV. The linear system is of the form

$$Ax = b$$

where A is a 10×10 block tridiagonal matrix with 10×10 blocks. Specifically, This example is chosen for its simplicity; it does not exercise the algorithm, since A is a strictly diagonally dominant matrix.

$$A = \begin{pmatrix} C & D & & & \\ B & C & D & & \\ & B & \ddots & \ddots & \\ & & \ddots & \ddots & D \\ & & & B & C \end{pmatrix}$$

with

$$B = \begin{pmatrix} -1 & & & \\ & -1 & & \\ & & \ddots & \\ & & & -1 \end{pmatrix}, \quad C = \begin{pmatrix} 4 & & & \\ -1 & 4 & & \\ & -1 & \ddots & \\ & & \ddots & 4 \end{pmatrix}$$

$$D = \begin{pmatrix} -1.5 & & & \\ & -1.5 & & \\ & & \ddots & \\ & & & -1.5 \end{pmatrix}.$$

ALGORITHM 534
STINT: STiff (differential equations) INTegrator [D2]

JOEL M. TENDLER
IBM Poughkeepsie Laboratories
THEODORE A. BICKART
Syracuse University
and
ZDENEK PICEL

Key Words and Phrases: stiff differential equations, stiffly stable methods, composite multistep methods, cyclic methods, numerical integration, ordinary differential equations, initial value problems, multistep formulas, numerical integration program, Fortran code STINT
CR Categories: 5.16, 5.17
Language: Fortran

DESCRIPTION

The algorithm given here is a complement to [1] where the theoretical development and test results are described.

ALGORITHM 535
The QZ Algorithm To Solve the Generalized Eigenvalue Problem for Complex Matrices [F2]

BURTON S. GARBOW
Argonne National Laboratory

Key Words and Phrases: eigenvalues, generalized eigenvalue problem
CR Categories: 5.14
Language: Fortran

DESCRIPTION

Three Fortran subroutines are provided that implement a complex form of the QZ algorithm for finding λ and z such that $Az = \lambda Bz$, where A and B are complex N by N matrices. The subroutines are complex analogs of those for the corresponding real problem included in the EISPACK eigensystem package [1]; the original QZ algorithm is described in [3] and [4]. The complex QZ algorithm shares the fundamental property of the real QZ algorithm in being unaffected by singularity or near singularity of B.

Subroutine CQZHES implements the first step of the algorithm wherein A and B are simultaneously reduced by unitary transformations to upper Hessenberg and upper triangular form, respectively. Subroutine CQZVAL implements an iterative process that reduces A to upper triangular form while maintaining the triangular form of B. At the completion of this step, the eigenvalues are derivable from the corresponding diagonal elements of the reduced A and B. Finally, if eigenvectors are desired, subroutine CQZVEC applies the accumulated transformations from the two earlier steps onto the eigenvectors of the triangular problem.

No facility is provided for obtaining just a few eigenvectors; a subroutine employing inverse iteration might be included for this purpose, proceeding from the Hessenberg A, the triangular B, and an approximate eigenvalue of the problem. Inverse iteration could be expected to save time, but it might be somewhat less accurate and reliable, especially in the presence of close eigenvalues.

Also, no facility is included for balancing A and B. Optimally scaled matrices could result in further improvement of accuracy obtainable with unitary transformations, but no automatic scaling technique is known at this time.

The subroutines can be invoked with consecutive statements:

```
CALL CQZHES (NM, N, AR, AI, BR, BI, MATZ, ZR, ZI)
CALL CQZVAL (NM, N, AR, AI, BR, BI, EPS1, ALFR, ALFI, BETA, MATZ, ZR, ZI,
  IERR)
```

Received 18 May 1977; revised 10 November 1977.
This work was performed under the auspices of the U.S. Department of Energy.

Fig. 1

and, if IERR is zero and eigenvectors are desired:

CALL CQZVEC (NM, N, AR, AI, BR, BI, ALFR, ALFI, BETA, ZR, ZI)

where parameter usage is explained in the algorithm that follows.

In timing the subroutines on the IBM 370/195, it was found that they run between two and three times slower than the corresponding real subroutines for systems of the same order. This is felt to be a quite favorable result and is attributable chiefly to two factors: (1) double shifts used with real systems to avoid complex arithmetic can be replaced by more efficient single shifts here, and (2) the amount of complex arithmetic itself can be reduced by choosing one of the defining elements of each 2×2 unitary transformation to be real.

The subroutines provide an alternative to the LZ algorithm developed by Kaufman [2] for the solution of the complex generalized eigenproblem. The elementary transformations employed in the LZ algorithm, even though stabilized, do not preclude possible numerical growth with consequent loss of accuracy; the unitary transformations employed in the QZ algorithm, on the other hand,

are stable. Although unitary transformations require more arithmetic than elementary transformations, speed comparisons between the algorithms are complicated by the fact that the LZ algorithm employs complex operands while the QZ algorithm employs programmed complex arithmetic on real operands. With certain CDC compilers, for example, it has been demonstrated that formal complex arithmetic is more efficient than programmed complex arithmetic, thereby strengthening the advantage of the LZ algorithm; in contrast, with the H compiler on the IBM 370/195, the reverse is true: the complex QZ algorithm actually runs faster than does the LZ algorithm.

A long precision IBM version of the subroutines was first written and tested on the 370/195 at Argonne National Laboratory; the standard single precision Fortran version was then derived from it and also tested on the 370/195. There are no machine-dependent constants in the subroutines, so the standard version should run directly on different machines.

The example chosen for illustration is the same as that used in [2] and appears here as Figure 1. The quantities labeled RESIDUAL are computed as

$$\| \beta_i A z_i - \alpha_i B z_i \|_1 / (\| z_i \|_1 * [\beta_i \| A \|_1 + \| \alpha_i \| \| B \|_1])$$

where β_i = BETA(I), α_i = CMPLX(ALFR(I), ALFI(I)), and z_i = CMPLX(ZR (*, I), ZI (*, I)).

Remark on Algorithm 535

The QZ Algorithm to Solve the Generalized Eigenvalue Problem [B.S. Garbow, *ACM Trans. Math. Softw. 4*, 4 (Dec. 1978), 404–410]

B.S. Garbow [Received 10 June 1982; accepted 10 June 1982]

Applied Mathematics Division, Argonne National Laboratory, 9700 S. Cass Avenue, Argonne, IL 60439.

Replace the single card with sequence label **VAL 153**:

IF (BI (L, L) .EQ. 0.0) GO TO 98

with

IF (B11 .EQ. 0.0) GO TO 98

The error that this change corrects results occasionally in eigenvalues with the wrong sign.

ALGORITHM 536
An Efficient One-Way Enciphering Algorithm [Z]

H. D. KNOBLE
The Pennsylvania State University

Key Words and Phrases: one-way security transformation, password, encipher, decipher, multiprecision integer arithmetic
CR Categories: 3.15, 4.49
Language: Fortran

DESCRIPTION

This algorithm is a Fortran implementation of the procedures developed in [1]. Its purpose is to serve as a machine independent model for studying the evaluation of polynomials mod P and for the implementation of more efficient machine dependent system utility programs for enciphering passwords.

ALGORITHM 537
Characteristic Values of Mathieu's Differential Equation [S22]

WALTER R. LEEB
Technische Universität Wien, Austria

Key Words and Phrases: Mathieu's differential equation, wave equation, characteristic values, eigenvalues, separation constants, Mathieu functions, ordinary Mathieu functions, modified Mathieu functions, elliptic cylinder functions, hyperbolic cylinder functions
CR Categories: 5.14, 5.17
Language: Fortran

DESCRIPTION

The algorithm calculates the characteristic values b of Mathieu's differential equation

$$d^2y/dx^2 + (b - S\cos^2 x)\,y = 0 \qquad (1)$$

for solutions $y(x)$ of periodicity π or 2π. In this case b is a function of S and belongs to a countably infinite set of values for every S [2]. The knowledge of b is a prerequisite for calculating ordinary and modified Mathieu functions.

The program has been tested for real S-parameters between zero and 1000, and for a number of characteristic values of up to 24, depending on the value of S. (For negative S, simple equations exist which relate the corresponding b to those for positive S [2, p. xvii]). The calculated b are correct to at least 9 decimal places. Within the calculated finite subset of b, the characteristic values are arranged with increasing magnitude, the first value being the smallest of the infinite set. The algorithm uses a library subroutine to find the eigenvalues of a real symmetric tridiagonal matrix.

Four types of solutions $y(x)$ can be distinguished: An odd and an even solution with period 2π, and an odd and an even solution with period π. The corresponding characteristic values b are called bo_{2r+1}, be_{2r+1}, bo_{2r+2},[1] and be_{2r}. ($r = 0, 1, 2, \ldots$; within each of the four sets, the smallest index is used for the smallest value of b.) Upon insertion of $y(x)$ in the form of Fourier series into eq. (1), a system of homogeneous, linear equations for the Fourier coefficients is obtained [2]. The determinant of the resulting square coefficient matrix of infinite order has to equal zero for nontrivial $y(x)$. This characteristic equation determining the

[1] Note the difference in the index notation for bo_{2r+2} compared with [2], where this set of characteristic values is called bo_{2r}. We have thus avoided unequal starting values for r among the four sets.

Received 27 December 1976, 6 January 1978, and 22 May 1978.

Author's address: Institut für Hochfrequenztechnik, Technische Universität Wien, Gusshausstrasse 25, A-1040 Wien, Austria.

characteristic values b may be written as

$$|\beta I - A| = 0, \tag{2}$$

where $\beta = b - S/2$ and I is the identity matrix. In the case of y being odd with a periodicity of 2π, the elements of the matrix A are found to be

$$a_{11} = 1 - S/4;\ a_{i-1,i} = a_{i,i-1} = S/4,\ a_{ii} = (2i-1)^2 \quad \text{for} \quad i \geq 2,$$

and all the other a_{ij} are equal to zero. Therefore, after adding $S/2$, the eigenvalues of the real symmetric tridiagonal matrix A (of unrestricted order) yield the characteristic values bo_{2r+1}.

Correspondingly, one can show that the be_{2r+1}, bo_{2r+2}, and be_{2r} are given by the eigenvalues of matrices which we call B, C and D, respectively. The nonzero elements of all four matrices have been compiled in Table I. When proceeding the way outlined above, the matrix D' determining the characteristic values be_{2r}

Table I. Nonzero Elements for Calculation of Characteristic Values

Characteristic value	Matrix elements
bo_{2r+1}	$a_{11} = 1 - S/4$; $a_{i-1,i} = a_{i,i-1} = S/4$ and $a_{ii} = (2i-1)^2$ for $i \geq 2$
be_{2r+1}	$b_{11} = 1 + S/4$; $b_{i-1,i} = b_{i,i-1} = S/4$ and $b_{ii} = (2i-1)^2$ and $i \geq 2$
bo_{2r+2}	$c_{ii} = 4t^2$ for $i \geq 1$; $c_{i,i-1} = c_{i-1,i} = S/4$ for $i \geq 2$
be_{2r}	$d_{12} = d_{21} = S/(8^{1/2})$; $d_{22} = 4$
	$d_{ii} = 4(i-1)^2$ and $d_{i-1,i} = d_{i,i-1} = S/4$ for $i \geq 3$

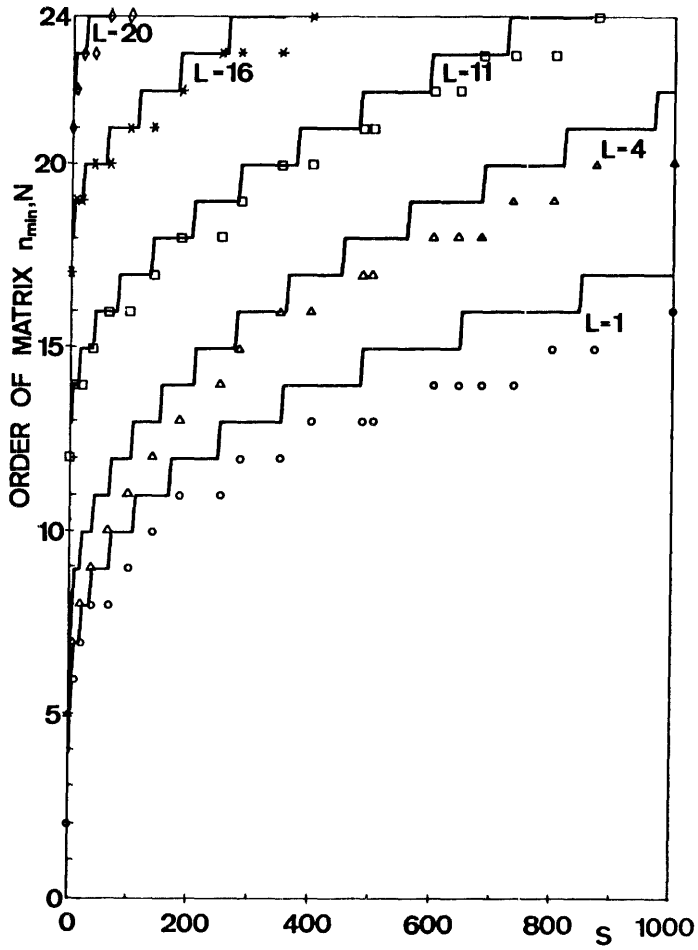

Fig. 1. Order of matrix (A, B, C, or D) necessary to give the first L characteristic values b correct to nine decimal places. Data points (○, △, □, *, and ◇) represent numerically found n_{min} in case of matrix D, while the full lines represent the function $N(S, L)$ according eq. (3). For clarity, only five values of L are presented.

turns out to be tridiagonal but unsymmetric. The only reason for unsymmetry is that $d'_{12} = S/4$ is unequal $d'_{21} = S/2$. Proper similarity transformation produces a symmetric tridiagonal matrix D with $d_{12} = d_{21} = S/(8^{1/2})$ and all other elements remain unchanged. This allows the use of one and the same library subroutine for determining the eigenvalues of all four matrices.

Next, one has to establish the minimum order $n_{\min}$ of the matrix A (or B, C, D) such as to yield a number L ($L < n_{\min}$) of characteristic values with given accuracy. In a modification of the program presented here, and using a trial and error method, we determined $n_{\min}$ as a function of both S and L for a b-accuracy of 9 decimal places. This was done for some discrete values of S and for integer L in the domain $0 \leq S \leq 1000$ and $0 \leq n_{\min} \leq 24$. The results are shown in Fig. 1 for some selected values of L. Then an analytic function $N(S, L)$ was developed which closely approximates $n_{\min}$, but ensures $N \geq n_{\min}$:

$$N(S, L) = \text{int}((0.17 + 2.1 \exp(-0.24\, L))S^{(0.77-5/(9.5+L)} + L + 2.8). \qquad (3)$$

The function $N(S, L)$ is presented in Fig. 1 as full line for the same parameters L as the numerically evaluated $n_{\min}(S, L)$. There are only minor differences in $n_{\min}$ required for A, B, C, and D, and eq. (3) has been determined as to fulfill $N \geq n_{\min}$ for all four matrices; therefore, it will be used for all four sets of characteristic values.

EXAMPLES

Find bo_1, $bo_3, \ldots$, bo_{29} for $S = 2$, also be_1, $be_3, \ldots$, be_7 for $S = 1000$; in addition, bo_2, $bo_4, \ldots$, bo_{38} for $S = 100$, and be_0, $be_2, \ldots$, be_{18} for $S = 0.1$. The results computed with a CDC CYBER/16 are given in Table II. Part of these results can be compared with tabulated values [2] and show agreement.

ACKNOWLEDGMENT

Thanks are due to the Computer Center of the Technische Universität Wien, which provided free computer time, and to R. Welser for his assistance.

ALGORITHM 538
Eigenvectors and Eigenvalues of Real Generalized Symmetric Matrices by Simultaneous Iteration [F2]

PAUL J. NIKOLAI
U.S. Air Force Flight Dynamics Laboratory

Key Words: and Phrases: eigenvalue, eigenvector, sparse matrix, diagonable matrix, simultaneous iteration, Fortran program
CR Categories: 4.6, 5.14
Language: Fortran

DESCRIPTION

The program presented here is an implementation of the simultaneous iteration algorithm [2] for calculating the eigenvalues largest in magnitude and corresponding eigenvectors of a real matrix symmetric relative to a prescribed inner product. Let $\mathrm{ip}(n, w, z)$ denote an inner product in the space of real column n-tuples and let the real n-square matrix C satisfy $\mathrm{ip}(n, Cw, z) = \mathrm{ip}(n, w, Cz)$. Then C is *symmetric relative to* ip, and if the n-square positive definite matrix B satisfies $\mathrm{ip}(n, w, z) = w^{\mathrm{T}}Bz$ then C is *B-symmetric*. The equation $BC = C^{\mathrm{T}}B$ characterizes the B-symmetry of C. Given an optional set of p initial approximate eigenvectors of a real n-square B-symmetric matrix C corresponding to p eigenvalues of C largest in magnitude, the program calculates em eigenvalues and em corresponding eigenvectors, $0 \leqq em < p \leqq n$, to a precision dependent on the structure of C and on a prescribed tolerance eps. The matrix B is presented to the program as an independently prepared real function subprogram which calculates $\mathrm{ip}(n, w, z) = w^{\mathrm{T}}Bz$ given column n-vectors w and z. The matrix C is presented as an independently prepared subroutine subprogram $\mathrm{op}(n, z, w)$ which when given an n-vector z computes its image $w = Cz$. The program is an outgrowth of a literal Fortran translation [5] of the Algol procedure *ritzit* [8] to which it is substantially equivalent when $C = C^{\mathrm{T}}$ and $\mathrm{ip}(n, w, z) = w^{\mathrm{T}}z$, the standard inner product. But depending on the choice of B and C, the present program enables the direct treatment of a wide variety of symmetric eigenproblems.

Let $A = A^{\mathrm{T}}$ and $B = B^{\mathrm{T}}$ denote n-square real matrices and let σ be real. If B is positive definite then the matrix $C = B^{-1}(A - \sigma B)$ is B-symmetric, and the program computes eigenvalues farthest from σ of the eigenproblem $Au = \lambda Bu$ and corresponding eigenvectors. Implementation of $\mathrm{op}(n, z, w)$ here consists in providing for the appropriate solution for w of the linear system $Bw = (A - \sigma B)z$. Alternatively, selection of op to solve the system $(A - \sigma B)w = Bz$ for w enables

Author's address: Department of the Air Force, Applied Mathematics Group, Analysis and Optimization Branch, Structural Mechanics Division, Wright-Patterson Air Force Base, Ohio 45433.

the calculation by simultaneous inverse iteration of the eigenvalues nearest to σ and their eigenvectors. Implications for large sparse systems for which the Cholesky factorization [6] of B is impractical are clear. The user may wish to supplement the following outline of the operation of the program by consulting the description of the Algol procedure *ritzit* in [8] or [10] as well as a review of the mathematical foundations of simultaneous iteration in [4] and [7].

Let the eigenvalues $d_1, \ldots, d_p, d_{p+1}, \ldots, d_n$ of C be arranged in order of descending absolute value and let E_p denote the direct sum of the distinct eigenspaces corresponding to $d_1, \ldots, d_p$. Let X_0 denote an n-by-p matrix having a p-dimensional column space not orthogonal relative to ip to any eigenvector in E_p. Simultaneous iteration is based on the observation that if $|d_p| > |d_{p+1}|$, the columns of the matrix $X_{k+m} = C^m X_k$ tend to a basis of E_p as $ks = k + m$ increases. But in practice all of the columns of X_{ks} tend toward the eigenspace E_1 causing loss of information concerning the residual eigenvectors. To counter this tendency, set

$$X_{k+m} = C^m X_k R_{k+m}^{-1} \tag{1}$$

where the p-square upper triangular matrix R_{ks} is constructed together with X_{ks} by the Gram-Schmidt process to render the columns of X_{ks} orthonormal relative to ip. Now the ith column vector of X_{ks} converges to the ith eigenvector of C at a rate proportional to $\max_{2 \leqq i \leqq p}(|d_i/d_{i-1}|, |d_{i+1}/d_i|)$. Clearly this convergence will be delayed in the presence of eigenvalue clustering. But if $|d_p|/|d_{p+1}|$ is not too small, the column space of X_{ks} will contain a good approximation to the ith eigenvector even when ks is small.

In order to recover this approximation, a modified Rayleigh-Ritz process is employed. Let Q_{ks} denote an orthogonal matrix which diagonalizes the p-square symmetric matrix $R_{ks}R_{ks}^{\mathrm{T}}$. Then the ith column vector of

$$X_{k+1} = CX_k R_{k+1}^{-1} Q_{k+1} \tag{2}$$

converges to the ith eigenvector of C at a rate proportional to $|d_{p+1}/d_i|$ while the entries of the diagonal matrix computed with Q_{ks} and properly ordered offer close approximations to $d_1^2, \ldots, d_p^2$. The true signed eigenvalues need only be computed at termination by diagonalizing the leading $(p-1)$-square principal submatrix of $X_{ks}^T BCX_{ks}$, the eigenproblem for C projected on E_{p-1} relative to ip.

The program determines a strategy for employing the devices (1) and (2) based on the distribution of the leading p eigenvalues of C upon which the convergence rate ultimately depends. The selection of values m in eq. (1) is particularly important in this regard in that $C^m X_k$ is replaced by the mth Chebychev polynomial on the interval $[-e, e]$ evaluated by a special three-term recurrence relation and permitting accelerated convergence when values of m are continually large; e is the current value of d_p. As a result the convergence quotient lies between $|d_p/d_{em}|$ and $\exp(-\text{arc cosh}\,|d_{em}/d_p|)$. It is nearer to the first value if $|d_1/d_{em}|$ is large and nearer to the second if the latter quotient is close to 1.

As the iteration proceeds through a maximum of $|km|$ iteration steps (km is a program parameter), acceptance tests for the eigenvalues and eigenvectors are conducted following each of the Rayleigh-Ritz steps (2). As soon as the relative increase of $|d_{h+1}|$ is smaller than eps/10, then d_{h+1} is accepted and h, the number of previously accepted eigenvalues, is increased by 1. Eigenvectors are accepted in groups of one or more corresponding to clusters of accepted eigenvalues nearly equal in magnitude. If g eigenvectors have already been accepted, let $d_{g+1}, \ldots, d_l$ denote such a cluster. For all j, $g + 1 \leqq j \leqq l$, denote by y_j the projection relative to ip of the image Cx_j of the tth column x_j of X_{ks} on the linear closure of $x_1, \ldots, x_l$. Set $f_i = \max_j \| Cx_j - y_j \| / \| Cx_j \|$ for $i = g + 1, \ldots, l$ where the indicated norm is the Euclidean norm or 2-norm relative to ip. If $|d_l| f_l/(|d_l| - e)$ is smaller than eps then all the $x_j, j = g + 1, \ldots, l$, are accepted as eigenvectors and g is increased to l. The error quantities f_i are systematically discounted in accordance with the convergence properties of the algorithm to permit convergence in the presence of excessive roundoff error or in case the parameter eps is prescribed unrealistically

small. Having determined g eigenvectors, the iteration continues with $p - g$ remaining columns of X_{ks} until either *em* eigenvectors have been calcuated or $|km|$ has been exceeded. The program may reduce *em* if it detects either no progress in convergence of eigenvectors corresponding to smaller eigenvalues or lack of stability in the behavior of larger eigenvalues.

We list the principal differences between *ritzit* and the program given here.

(1) The procedure *inprod* for calculating standard inner products was removed and the procedure ip was introduced where appropriate.

(2) The procedure *jacobi* for calculating the solutions of the eigenproblem for $(p - g)$-square and $(p - 1)$-square symmetric matrices was replaced by calls to the EISPACK [9] subroutines TRED2 and IMTQL2, primarily to save space.

(3) The procedure *random* for calculating random column n-vectors of the matrix X_{ks} was replaced by in-line code which references a Fortran function RANF. RANF returns uniformly distributed random REAL values from the interval (0, 1), one per function reference, given any one argument of any type. It is provided by the user.

(4) The procedure *orthog* to perform Gram-Schmidt orthogonalization of the columns of X_{ks} was replaced by internally linked in-line code. In attempting to control potential underflow within *orthog* in a machine independent fashion, *ritzit* calculates the machine precision *mc* but assumes in usage that out-of-range values underflow gracefully to zero, a machine dependent characteristic. The present program utilizes a single REAL machine dependent constant MT, the ratio of the smallest Fortran representable positive value to the machine precision, to test for this condition and upon its detection to take appropriate measures.

(5) In its Algol implementation *ritzit* requires approximately $(p + 3)n + 2p^2 + 5p$ storage locations in excess of those required by the program. Economies resulting in part from (2) above [3] have reduced this requirement to $(p + 2)n + p^2 + 4p$ in the program presented here. All working storage is confined to a single array of $2n + p^2 + 3p$ locations.

(6) The value of *km* as an input parameter, set to $|km|$ during program execution, is finally replaced by the value of *ks* as an output parameter, the number of iteration steps used in the calculation of *em* eigenvectors.

(7) The program given here retains unchanged the reference to a user supplied procedure inf as a window on program execution. However, the one variable involving eps is periodically redefined to enable effect control of eps from inf or from ip or op should this prove desirable.

The testing procedures developed for the present Fortran program parallel its evolution from a research tool, which conformed closely to its Algol parent, to present form. Early testing was concentrated on duplicating the tests furnished with *ritzit* and in eliminating errors in interpretation and translation of the Algol code. This was done for the most part on the CDC 6600 using Fortran Extended, Version 3, under the SCOPE 3.3 operating system. Upon completion of this first phase, the resulting program was distributed as SUBROUTINE RITZIT with a locally developed library of Fortran linear algebra routines [5]. This same program served as a basis of *ritzit* translations for IBM 360/370 processors [1, 3] whose preparation uncovered several bugs in the RITZIT code and suggested worthwhile modifications. A second phase of testing involved the development of a package of auxiliary Fortran programs for use with SUBROUTINE RITZIT to solve the eigenvalue problem $Au = \lambda Bu$ through methods depending on Cholesky factorization where A and B may either be full matrices or sparse and banded. This phase was conducted on the CDC 6600 using Fortran Extended, Version 4, under SCOPE 3.4.

Systematic testing of the present program, SUBROUTINE SIMITZ, has been accomplished in part with the aid of driver program TESTB which generates a symmetric band matrix A and a lower triangular band matrix T of prescribed order n and bandwidths whose relevant entries are randomly generated integer values from a prescribed interval. The band matrix B is TT^{T}, and the program

calculates the maximal eigenvalues of $Au = \lambda Bu$. For the sequence of values of p, $p = 2, \ldots,$ min([$n/5$], 10), TESTB exercises SIMITZ for successive values of em, $em = 1, \ldots, p - 1$. For each value of i, $i = 1, \ldots, em$, TESTB computes the residuals $Ax_i - d_iBx_i$ and their Euclidean norms relative to the standard inner product. Each norm is normalized by the difference $|d_1| - e$, and for each value of em the quantity $\max_{1 \le i \le em} \|Ax_i - d_iBx_i\|/(|d_1| - e)$, the value k of i for which the maximum occurs, and the corresponding geometric mean with unit weights are listed. Also listed are the relevant nonzero diagonals of A and T and the final eigenvalues computed for $em = p - 1$.

Figure 1 shows an output listing from the executable program TESTB on the CDC 6600 under the NOS/BE operating system and Fortran Extended, Version 4. Here A and B are of order 30 and each of bandwidth 7 having relevant entries between −99 and +99. Listed are the main diagonal and the three adjacent lower diagonals of T and A beginning with the entries in the first column. Here eps = 10^{-10} and km = 100. Note how the relative nearness in magnitude of the first three eigenvalues inhibits the convergence of the second eigenvector when $p = 3$ and $em = 2$ resulting in acceptance of the first eigenvector only. The fourth eigenvalue, however, is in absolute value far enough away from this cluster to permit successful convergence when $p = 4$ and $em = 1$, 2, and 3. This phenomenon points to a procedure for pursuing a solution when p is initially chosen too small. SIMITZ may be reentered with X containing the approximate eigenvectors calculated for the smaller value of p as initial approximations for use with p increased in size. Significant processor time may often be saved in this fashion.

ALGORITHM 539
Basic Linear Algebra Subprograms for Fortran Usage [F1]

C. L. LAWSON
Jet Propulsion Laboratory
R. J. HANSON
Sandia Laboratories, Albuquerque
D. R. KINCAID
The University of Texas, Austin
and
F. T. KROGH
Jet Propulsion Laboratory

Key Words and Phrases: linear algebra, utilities
CR Categories: 4.49, 5.14
Language: Fortran, assembly language

DESCRIPTION

This package complements [1], where further details are given.

REFERENCES

1. LAWSON, C.L., HANSON, R.J., KINCAID, D.R., AND KROGH, F.T. Basic linear algebra subprograms for Fortran usage. *ACM Trans. Math. Software 5*, 3 (September 1979), 308–323.

ALGORITHM

[The contents of this package consists of four files. The first file contains Fortran versions for the BLAS (38 subprograms), programs for testing the BLAS (13 modules), and 18 subprograms from Brent's multiple precision package that are used in the implementation of the extended precision inner products. The remaining 3 files contain Fortran callable assembly language versions for 3 different machines: IBM 360/370 series, CDC 6000 series, and Univac 1100 series. Printed here are the 38 BLAS subprograms. The complete listing is available from the ACM Algorithms Distribution Service.]

Received 13 July 1977.

The work of the first and fourth authors was supported by the National Aeronautics and Space Administration under Contract NAS 7-100. The work of the second author was supported by the U.S. Energy Research and Development Administration (ERDA) under Contract AT (29-1)-789 and (at Washington State University) by the Office of Naval Research under Contract NR 044-457.

REMARK ON ALGORITHM 539

Basic Linear Algebra Subprograms for Fortran Usage [C.L. Lawson, R.J. Hanson, D.R. Kincaid, and F.T. Krogh, *ACM Trans. Math. Softw. 5*, 3 (Sept. 1979), 324–325]

David S. Dodson and Roger G. Grimes [Received 11 May 1982; revised 25 August 1982; accepted 17 September 1982]

Boeing Computer Services Company, Mail Stop 9C-01, 565 Andover Park West, Tukwila, WA 98188.

The companion [5] to Algorithm 539 (the BLAS) contains two errors which we discovered in the preparation of [1].

The more serious error occurs in the mathematical specifications for subroutines **SROTG** and **DROTG**, which construct Givens plane rotations. For convenience of reference, we include the relevant specifications from [5].

Given a and b, each of these subroutines computes

$$\sigma = \begin{cases} \operatorname{sgn}(a) & \text{if } |a| > |b|, \\ \operatorname{sgn}(b) & \text{if } |b| \geq |a|, \end{cases} \qquad r = \sigma(a^2 + b^2)^{1/2}, \qquad \text{(1a,b)}$$

Table I. Status of BLAS Implementations

Source	SROTG and DROTG		
	Reference	Documentation	Code
Boeing Computer Services	[1]	Correct	Correct
Dongarra et al.	[2]	Incorrect	Incorrect
Floating Point Systems	[3]	Incorrect	Incorrect
IMSL	[4]	Incorrect	Correct
Lawson et al.	[5]	Incorrect	Correct
Petersen	[6]	Correct	Incorrect

$$= \begin{cases} a/r & \text{if } r \neq 0, \\ 1 & \text{if } r = 0, \end{cases} \qquad s = \begin{cases} b/r & \text{if } r \neq 0, \\ 1 & \text{if } r = 0, \end{cases} \tag{1c,d}$$

$$z = \begin{cases} s & \text{if } |a| > |b|, \\ 1/c & \text{if } |b| \geq |a| \quad \text{and} \quad c \neq 0, \\ 1 & \text{if } c = 0. \end{cases} \tag{1e}$$

If the user later wishes to reconstruct c and s from z, it can be done as follows:

If $z = 1$ set $c = 0$ and $s = 1$.

If $|z| < 1$ set $c = (1 - z^2)^{1/2}$ and $s = z$. (2)

If $|z| > 1$ set $c = 1/z$ and $s = (1 - c^2)^{1/2}$.

The problem occurs in the computation of z. In particular, when $a = b = 0$, (1a–e) yield the results $r = 0$, $c = 1$, $s = 0$, and $z = 1$. However, when c and s are reconstructed from z using (2), the incorrect values $c = 0$ and $s = 1$ result. This discrepancy can be resolved only by changing the computation of z, as $z = 1$ can result both when $c = 0$ (when $a = 0$ and $b \neq 0$) and when $c = 1$ (when $a = b = 0$).

Stewart [7] intended that z represent the smaller in magnitude of c and s and that it indicate which one of c and s is the smaller, since the magnitude of the larger can be reconstructed stably from the smaller. He expressly omitted consideration of the point $a = b = 0$, which is the only point at which (1e) fails. We propose that z be computed directly from c and s. Two observations simplify matters. First, the larger in magnitude of c and s is positive: $|s| < |c|$ implies $c > 0$ and $0 < |c| \leq |s|$ implies $s > 0$. Second, if $c = 0$, then $s = 1$. Thus the value z can be redefined as follows:

$$z = \begin{cases} s & \text{if } |s| < c \quad \text{or} \quad c = 0, \\ 1/c & \text{if } 0 < |c| \leq s. \end{cases} \tag{3}$$

This definition of z in (3) differs from (1a–e) only at the single point $a = b = 0$, where $z = 0$ results. For $z = 0$, the reconstruction formulas (2) give the correct values, $c = 1$ and $s = 0$.

Even though the original mathematical specifications for subroutines **SROTG** and **DROTG** are incorrect, the FORTRAN and assembly language versions of **SROTG** and **DROTG**, available from the ACM Algorithm Distribution Service as part of Algorithm 539, do conform to the correct mathematical specification, as given in this Remark.

BLAS documentation has appeared in several publications, and BLAS code is available for use or distribution from several sources. Table I lists the status of some of these BLAS implementations.

A second error, more innocuous than the above, involves the dimensions of the arrays passed to the BLAS. In several places, the length is incorrectly specified as max(**1, N*|INCX|**). The correct length is max(**1, 1+(N − 1)*|INCX|**). This error occurs near the beginnings of Sections 5 and 7, and would be unobtrusive if Section 7 did not contain the word "precisely."

ACKNOWLEDGMENT

We thank Dr. C. L. Lawson for his helpful comments, which have led to a redefinition of z that is superior to what we had originally suggested.

Language: Fortran

DESCRIPTION

1. Introduction

The basic purpose of this paper is to describe and discuss PDECOL, which is a new computer software package for numerically solving coupled systems of nonlinear partial differential equations (PDE's) in one space and one time dimension. The package implements finite element collocation methods based on piecewise polynomials for the spatial discretization techniques. The time integration process is then accomplished by widely acceptable procedures [7] which are generalizations of the usual methods for treating time dependent partial differential equations.

PDECOL is unique because of its flexibility both in the class of problems it addresses and in the variety of methods it provides for use in the solution process. High order methods (as well as low order ones) are readily available for use in both the spatial and time discretization procedures. The time integration methods used feature automatic time step size and integration formula order selection so as to efficiently solve the problem at hand and yet achieve a user specified time integration error level.

PDECOL consists of a collection of 19 subroutines written in reasonably standard Fortran, and therefore is quite portable and can be readily used on almost any capable computer with a Fortran compiler. No special hardware features are required.

Received 25 June 1976 and 1 August 1977.

This work was performed under the auspices of the U.S. Energy Research and Development Administration under Contract W-7405-Eng-48.
Authors' present addresses: N.K. Madsen, Lawrence Livermore Laboratory, Livermore, CA 94550; R.F. Sincovec, Boeing Computer Services, Co., Energy Technology Applications, Mail Stop 9C-01, P.O. Box 24346, Seattle, WA 98124.

PDECOL is designed to solve broad classes of difficult systems of partial differential equations that describe physical processes. This package should be of interest to almost anyone involved in scientific and engineering simulations, calculations, and model development. It should also be of interest to those involved in mathematical software development and, in particular, to those concerned with software development for partial differential equations.

One of our main objectives in producing PDECOL was to make available a package which will allow users to try out a variety of collocation techniques on a variety of problems with little program development required. As is mentioned in the text, there are over 3000 different potentially useful PDE methods in PDECOL. Basically, we are relying on others to produce the final judgments as to the overall effectiveness of collocation for their problems. We feel from our experience that collocation looks attractive enough to warrant serious consideration by others—hence, the package PDECOL.

2. Class of Problems

PDECOL is designed to solve the general system of *NPDE* nonlinear partial differential equations of at most second order on the interval $[x_L, x_R]$ for $t \geq t_0$ which is of the form

$$\frac{\partial \mathbf{u}}{\partial t} = \mathbf{f}(t, x, \mathbf{u}, \mathbf{u}_x, \mathbf{u}_{xx}), \tag{2.1}$$

where

$$\begin{aligned} \mathbf{u} &= (u_1, u_2, \ldots, u_{NPDE}), \\ \mathbf{u}_x &= \left(\frac{\partial u_1}{\partial x}, \frac{\partial u_2}{\partial x}, \ldots, \frac{\partial u_{NPDE}}{\partial x}\right), \\ \mathbf{u}_{xx} &= \left(\frac{\partial^2 u_1}{\partial x^2}, \frac{\partial^2 u_2}{\partial x^2}, \ldots, \frac{\partial^2 u_{NPDE}}{\partial x^2}\right). \end{aligned} \tag{2.2}$$

Each u_k is a function of the scalar quantities t and x, $k = 1, 2, \ldots, NPDE$. In (2.1) $\mathbf{f}$ represents an arbitrary vector valued function whose *NPDE* components define the respective partial differential equations of the PDE system. As there is no explicit requirement that $\mathbf{f}$ actually depends on $\mathbf{u}_x$ and/or $\mathbf{u}_{xx}$, any particular equation in (2.1) may actually be an ordinary differential equation (ODE), a first-order PDE, or a second-order PDE.

Depending on the particular type of equation, 0, 1, or 2 boundary conditions may be required for each equation in the system (2.1). These are imposed at x_L and/or x_R (or not imposed at all in the case of no condition) and must be of the form

$$\mathbf{b}(\mathbf{u}, \mathbf{u}_x) = \mathbf{z}(t), \tag{2.3}$$

where $\mathbf{b}$ and $\mathbf{z}$ are arbitrary vector valued functions with *NPDE* components and $\mathbf{u}$, $\mathbf{u}_x$, and t are as above. We make the basic assumption that these boundary conditions (2.3) must be consistent with the initial conditions (2.4) which are described next.

Each solution component u_k is assumed to be a known function of x at the initial time $t = t_0$. That is,

$$u_k(t_0, x) = \phi_k(x), \qquad k = 1, 2, \ldots, NPDE, \tag{2.4}$$

where each $\phi_k,(x)$ is a known function of x. The initial condition functions must be consistent with the boundary conditions (2.3), (i.e. the initial condition functions must satisfy the boundary conditions for $t = t_0$).

We assume that all functions are continuous in t and at least piecewise continuous in x. With some understanding of the internal workings of the package, it is possible to solve problems with inconsistent boundary and initial conditions

or problems with jump discontinuities in the boundary conditions with respect to t.

It is obvious that the possible PDE problems described above are sufficiently general to include many systems for which solutions may not exist or may not be unique. *It must be, of course, the user's responsibility to define a mathematically meaningful PDE problem.*

3. Defining the PDE Problem

The PDE system described above is completely specified if one defines: *NPDE*; the interval $[x_L, x_R]$; the initial time t_0; the vector functions **f**, **b**, and **z**; and the initial condition functions $\phi_k(x)$, $k = 1, 2, \ldots,$ *NPDE*. The PDE problem can be properly defined for solution by PDECOL by constructing a main program and three subprograms, F, BNDRY, and UINIT, which specify the above-mentioned quantities.

Main Program. The construction of the main program that a user is required to supply is usually straightforward. The main program serves four basic purposes. First, initialization of the calling arguments for PDECOL must be performed. Second, the main program must call the package. Third, it should provide logic to detect possible error returns from PDECOL. Fourth, the main program should perform the desired output of the computed results. A typical main program is shown in a later section for one numerical example.

Required User Supplied Subroutines. The user is required to construct three subroutines which define the form of the PDE problem. Stated briefly, the purposes of these routines, F, BNDRY, and UINIT, are as follows. For given input values of t and x and corresponding input values of $\mathbf{u}$, $\mathbf{u}_x$, and $\mathbf{u}_{xx}$ which are associated with this time and spatial position: subroutine F is to compute appropriate values for the functions f_k in (2.1); subroutine BNDRY is to compute appropriate values for the derivatives of the boundary condition functions b_k and z_k in (2.3) at the left or right boundary as determined by the value of x (see (4.3) and (4.4)); and subroutine UINIT is to compute initial condition function values (2.4).

The subroutines F, BNDRY, and UINIT are usually easily constructed and an example showing these routines is contained in a later section. More specific comments are given in the Algorithm at the end of this paper.

4. Methods Used

The software package PDECOL is based on the method of lines [7, 8, 11] and uses a finite element collocation procedure (with piecewise polynomials as the trial space) for the discretization of the spatial variable x. The collocation procedure reduces the PDE system to a semidiscrete system (actually an initial-value ODE system), which then depends only on the time variable t. The time integration is then accomplished by use of slightly modified standard techniques [5, 6, 7], which will be discussed briefly in a later section.

Piecewise Polynomials. The user has the opportunity to specify the piecewise polynomial space which is to be used to compute his approximate solution. In selecting this space the order, *KORD*, of the polynomials to be used must first be specified (*KORD* = polynomial degree + 1). Next, the number of pieces (intervals), *NINT*, into which the spatial domain $[x_L, x_R]$ is to be divided is chosen. The *NINT* + 1 distinct breakpoints of the domain must be defined and set into the array *XBKPT* in strictly increasing order, i.e.

$$x_L = XBKPT(1) < XBKPT(2) < \cdots < XBKPT(NINT + 1) = x_R.$$

The approximate solution at any time, t, will be a polynomial of order *KORD* in each subinterval $[XBKPT(i), XBKPT(i + 1)]$, $i = 1, 2, \ldots,$ *NINT*. The number of continuity conditions, *NCC*, to be imposed on the polynomial pieces across all of the interior breakpoints is the last piece of user supplied data which is required

to uniquely determine the desired piecewise polynomial space. For example, *NCC* = 2 would require that the approximate solution (made up of the separate polynomial pieces) and its first spatial derivative be continuous at the breakpoints and hence on the entire domain $[x_L, x_R]$. *NCC* = 3 would require in addition that the second spatial derivative be continuous. The dimension of this linear space is known and finite and is $NCPTS = KORD*NINT - NCC*(NINT - 1)$. The well-known B-spline basis [2] for this space is used by PDECOL and it consists of *NCPTS* known piecewise polynomial functions $\Phi_i(x)$, $i = 1, 2, \ldots, NCPTS$, which do not depend on the time variable t. Use of the B-spline basis results in banded (in contrast to full) matrix problems to be solved in the package. The computer program requires $3 \le KORD \le 20$, $1 < NCC < KORD$, and $NINT \ge 1$.

Collocation over Piecewise Polynomials. The basic assumption made is that at any given time t, each approximate solution component, u_k, is a piecewise polynomial in the user specified space and hence can be written in terms of the B-spline basis functions as

$$u_k(t, x) = \sum_{i=1}^{NCPTS} c_{i,k}(t)\, \Phi_i(x), \qquad k = 1, 2, \ldots, NPDE. \tag{4.1}$$

The unknown coefficients $c_{i,k}$ depend only on the time t, and the *known* basis functions Φ_i depend on x. The semidiscrete equations (actually ordinary differential equations) which determine these coefficients, $c_{i,k}$, for $i = 1, 2, \ldots, NCPTS$ and $k = 1, 2, \ldots, NPDE$, are obtained by collocating, i.e. by requiring the approximate $u_k(t, x)$ in (4.1) to satisfy the PDE's (2.1) and the boundary conditions (2.3) exactly, at a set of *NCPTS* collocation points.

To be more specific, we choose *NCPTS* collocation points such that

$$x_L = \xi_1 < \xi_2 < \cdots < \xi_{NCPTS} = x_R$$

and $\Phi_i(\xi_i) \neq 0$ for $i = 1, 2, \ldots, NCPTS$. Then, substituting (4.1) into (2.1) and requiring (2.1) to be valid at the interior collocation points gives

$$\sum_{i=1}^{NCPTS} \Phi_i(\xi_j) \frac{dc_{i,k}}{dt} = f_k(t, \xi_j, \mathbf{u}(t, \xi_j), \mathbf{u}_x(t, \xi_j), \mathbf{u}_{xx}(t, \xi_j)),$$
$$j = 2, 3, \ldots, NCPTS - 1, \quad k = 1, 2, \ldots, NPDE. \tag{4.2}$$

To determine the equations corresponding to $j = 1$ and $j = NCPTS$, we form equations which depend on the type of boundary condition. It will suffice to show the technique we use for the left boundary, $x = x_L$ where $j = 1$, since those for the right boundary, $x = x_R$ where $j = NCPTS$, are completely analogous.

Normally, we form an ODE corresponding to the point $x = x_L$ by differentiating the boundary conditions (2.3) with respect to t, which gives

$$\sum_{j=1}^{NPDE} \left\{ \frac{\partial b_k}{\partial u_j} \frac{\partial u_j}{\partial t} + \frac{\partial b_k}{\partial u_{x_j}} \frac{\partial u_{x_j}}{\partial t} \right\} = \frac{dz_k}{dt}. \tag{4.3}$$

Substituting (4.1) into (4.3) and using the facts [1, 3] that $\Phi_1(x_L) \neq 0$, $\Phi_i(x_L) = 0$, $i = 2, 3, \ldots, NCPTS$, and that $\Phi_1'(x_L) \neq 0$, $\Phi_2'(x_L) \neq 0$, $\Phi_i'(x_L) = 0$, $i = 3, 4, \ldots, NCPTS$ gives the appropriate ODE:

$$\sum_{j=1}^{NPDE} \left\{ \frac{\partial b_k}{\partial u_j} \Phi_1(x_L) + \frac{\partial b_k}{\partial u_{x_j}} \Phi_1'(x_L) \right\} \frac{dc_{1,j}}{dt} + \sum_{j=1}^{NPDE} \left\{ \frac{\partial b_k}{\partial u_{x_j}} \Phi_2'(x_L) \right\} \frac{dc_{2,j}}{dt} = \frac{dz_k}{dt}. \tag{4.4}$$

In the special case when no boundary condition is desired for the $k = k_0$ equation, we simply collocate in the usual manner at the boundary point and obtain (4.2) with $j = 1$ and $k = k_0$ for our equation corresponding to the point $x = x_L$.

Combining the boundary condition equations with (4.2) yields a semidiscrete system of $N = NPDE*NCPTS$ time dependent ordinary differential equations which have the form

$$A\frac{d\mathbf{c}}{dt} = \mathbf{g}(t, \mathbf{c}). \tag{4.5}$$

The matrix A in (4.5) and the Jacobian matrix of $\mathbf{g}$, $\partial\mathbf{g}/\partial\mathbf{c}$, are matrices with a maximum bandwidth of $2*(KORD-1)*NPDE-1$ except when $KORD=3$ and an equation with no boundary condition at one endpoint exists. Except for the first and last block rows, all of the entries of A are simply basis function values at the collocation points. The first and last block rows of A consist of the appropriate boundary condition equation coefficients from (4.4) or (4.2). Since at any point at most *KORD* basis functions have nonzero values, each block row of A consists of *KORD NPDE* by *NPDE* matrices.

We remind the reader that the unknowns in (4.5) which are actually computed by PDECOL are the *basis function coefficients* in (4.1) and *not* the actual approximate solution values. However, with a knowledge of these coefficients, we can then easily evaluate the approximate solution values by using (4.1).

Accuracy Considerations. There are two sources of error in the approximate solutions generated by PDECOL. The first is due to the time discretization methods used and the second is due to the collocation spatial discretization technique. PDECOL attempts to control the time discretization error and to maintain it below a user specified level by dynamically selecting appropriate time step sizes and time integration formulas. We refer the reader to the package documentation for the details on how this is accomplished. Control of the error introduced by the spatial discretization is a more difficult problem, and we make the following observations.

Piecewise polynomials of order *KORD* have the approximation property [13] that sufficiently smooth functions can be approximated by these polynomials such that the spatial errors in the approximation are proportional to h^{KORD}, where $h=\max_i[XBKPT(i+1)-XBKPT(i)]$. Derivatives of order j of these smooth functions are also approximated with spatial errors which are proportional to h^{KORD-j}. We can use these approximation properties to estimate the expected orders of accuracy (for the *spatial* discretization) of the collocation techniques implemented in PDECOL. In particular, when using a piecewise polynomial space of order *KORD*, since eq. (2.1) involves second-order spatial derivatives, we expect PDECOL to generate approximate solutions with *spatial* errors which are proportional to h^{KORD-2}. However, for the special spaces with $KORD>3$ and $NCC=2$, a special choice of collocation points (Gauss-Legendre quadrature points in each subinterval) generates approximate solutions with *spatial* errors which are proportional to h^{KORD} for certain classes of PDE problems [4].

We emphasize that the piecewise polynomial space used in PDECOL (*which is selected by the user*) will determine the magnitude of the spatial discretization errors in the computed approximate solution. *The package has no control over errors introduced by the user's choice of the piecewise polynomial space.*

5. Limitations and Use of PDECOL

Of course, it goes without saying that no one program such as PDECOL will solve all PDE problems. There are several reasons for this, and we will enumerate them.

First, in order to be "solvable" a PDE problem should be properly posed in a mathematical sense. There is nothing that PDECOL can do to insure or detect that a user's problem is properly posed and so we reiterate that this responsibility must fall back to the user. Discussion of what constitutes a properly posed problem is beyond the scope and intent of this paper and we refer the interested reader to any good PDE textbook.

Second, PDECOL (and almost any general purpose software package) imposes certain restrictions on the classes of problems it allows. These restrictions are enumerated in Section 2. Perhaps the most unpleasant of these restrictions is the form of the boundary conditions (2.3) and the fact that the boundary conditions must be consistent with the initial conditions. Maintaining high order approxi-

mations at the boundary is a difficult problem in solving PDE's, and the above restrictions result from our approach to accomplish this.

All problems do not fit these restrictions. For example, certain hyperbolic systems of PDE's require (for stability) that the boundary conditions be imposed through the use of characteristic transformations at the boundary. We know of no way to implement the use of characteristic variables for the boundary conditions with the current structure of PDECOL. Another limitation is that PDECOL is restricted to problems in at most one space dimension. The extension to higher dimensions of the method of lines approach with either collocation or finite differences is conceptually quite simple. The basic difficulty arises from the fact that this basic approach yields a *fully implicit* discretization method. This, of course, implies that a possibly very large matrix problem must be solved. We feel certain that there are classes of PDE problems where fully implicit methods will be necessary, and for these problems extensions of these current techniques would prove fruitful. For other classes of problems, splitting or alternating direction implicit techniques may be much more efficient.

If a user's problem does not fit the prescription of the package, he has the following options: (a) find another package, (b) modify the existing package to suit his needs, or (c) modify or transform the problem to fit the package. The complexity of PDECOL and the limit of space precludes presenting details on how to modify PDECOL to accommodate problems which may not satisfy the above restrictions.

Third, the methods implemented in a program may not be adequate for a particular problem. Collocation methods (as implemented in PDECOL) will not work for all problems. For example, some PDE problems are quite sensitive to a particular conservation law being satisfied by the discrete approximation (conservation of mass, energy, particles, etc.). Collocation techniques are inherently nonconservative and difficulties can be expected if such sensitivities exist for a problem.

Summarizing, our experience in using general purpose software such as PDECOL over several years has led us to believe that general purpose software is somewhat more difficult to use because of its generality. Therefore, the probability for errors and misuse is greater and so its primary advantage (its general nature) also becomes a disadvantage. We have found that users have difficulties primarily for three reasons: (1) their problem is not well posed, (2) the methods in the general package will not work for their problem, and (3) the user has made programming errors or misused the package. Perhaps 99 percent of all difficulties fall into the third category.

6. Structure of PDECOL

Since the methods in PDECOL are based on the method of lines, PDECOL is structured much like some of the recently developed integrators for ordinary differential equations. This structure includes a driver subroutine, a core integrator which advances the time by a single time step, and miscellaneous routines which assist in setting up and solving nonlinear and linear equations.

PDECOL is somewhat more complicated than the typical ODE integrator since: (a) PDE's are being solved, and (b) a finite element method requiring the evaluation of the piecewise polynomials (4.1) is being used. The interconnections and lines of communication in PDECOL are quite complicated and difficult to understand when viewed as a whole. However, when the driver program and the core integrator are isolated, the picture becomes more clear. Figures 1 and 2 illustrate all of the package and user routines and their interconnections. Some of the routines are duplicated in each figure. A brief summary of the basic functions of all of the package subroutines is contained in the Algorithm. We will now describe the principal routines in PDECOL.

Main Components. PDECOL. This routine is a driver for the entire package. It serves the following purposes. The locations and lengths of the storage arrays

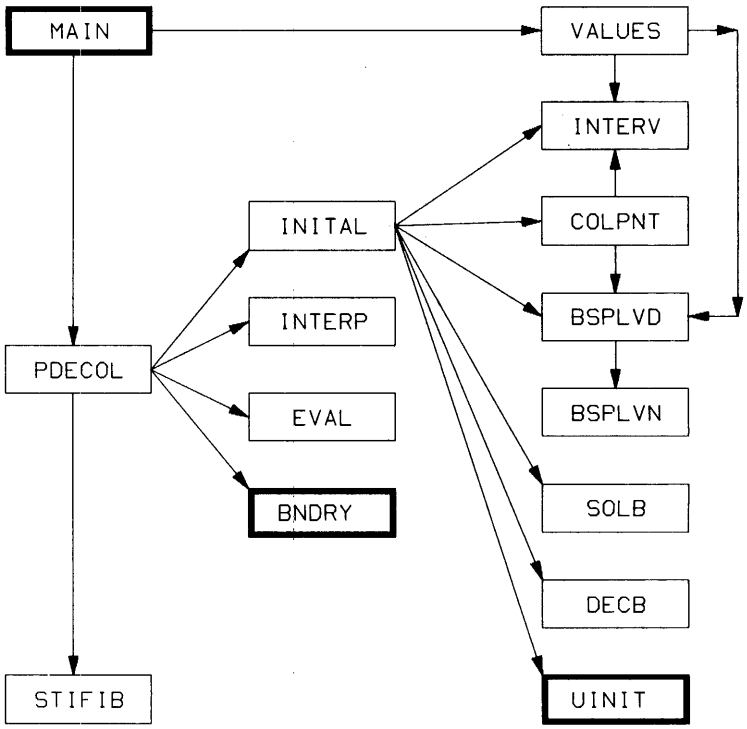

Fig. 1. Lines of communication between user routines and PDECOL package routines: Part 1, user routines are indicated by heavy borders

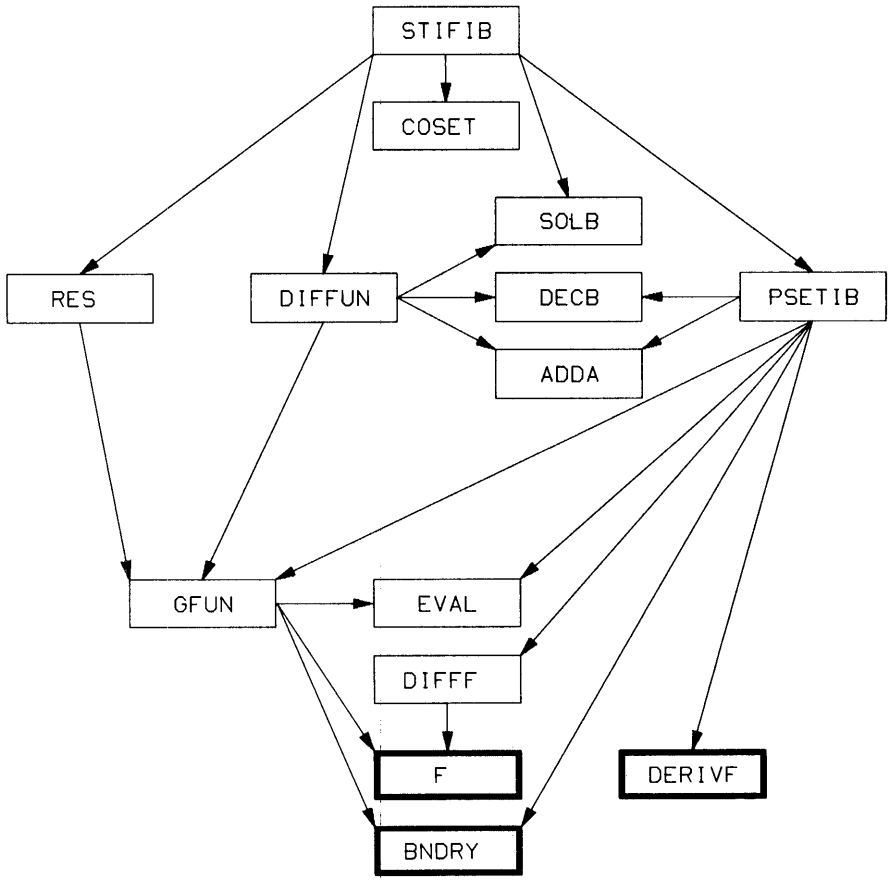

Fig. 2. Lines of communication between user routines and PDECOL package routines: Part 2, user routines are indicated by heavy borders

required by the package are allocated and defined in PDECOL. On the first call to the package, this routine checks the user's input for legality and performs initialization tasks such as setting problem parameters and calling the package routine INITAL. After the initialization is complete, PDECOL makes repeated calls to the core integrator routine STIFIB in order to advance the time variable a single step at a time until the user's desired output time is reached. At this time (since output times are not usually hit exactly) the package routine INTERP is called to interpolate the computed basis function coefficients to the desired output time. PDECOL also checks for possible error returns from STIFIB and either attempts to recover or provides the user with appropriate flags and/or messages.

VALUES. This is the routine the user must call in order to obtain the values of his computed approximate solution and its derivatives when his desired output time TOUT has been reached. VALUES performs the same basic function as EVAL (see below) except that it can evaluate the piecewise polynomial solution at *any* given spatial point or points—rather than just at collocation points. Since the computed solution is actually a continuous function, the user may desire solution values at arbitrary spatial points in the domain of interest. VALUES is structured much like EVAL. The basis function values are generated by BSPLVD as needed, and the user has the option of obtaining values at any number of points with a single call to VALUES.

INITAL. This routine performs functions which are very important to the entire package. Its main purpose is to determine the initial condition data for the package. This initial data consists of the basis function coefficients which are chosen so that the initial piecewise polynomial ((4.1) at $t = t_0$) interpolates the user's initial condition functions (2.4) at the collocation points. This requires that the collocation points and all of the basis function data be generated. INITAL generates (or causes to be generated) and stores the breakpoint sequence, the collocation points (see COLPNT), and the B-spline basis function and derivative values at the collocation points [3]. The basis function values and derivatives at the collocation points are calculated only once and saved so as to make the package efficient (see EVAL below).

COLPNT. The collocation points which are required by the collocation discretization procedure are calculated in this routine. In general we choose the collocation points to be the points in the domain $[x_L, x_R]$ at which the B-spline basis functions attain their unique maxima [1]. For the special piecewise polynomial spaces of order *KORD* with *NCC* = 2, a second more desirable choice is available (normal default choice). In this case the collocation points are chosen to be the unique *KORD* − *NCC* Gauss-Legendre quadrature points in each subinterval $[XBKPT(i), XBKPT(i + 1)]$, for $i = 1, 2, \ldots, NINT$, plus the two endpoints x_L and x_R. This choice of points for these piecewise polynomial spaces will produce more accurate approximate solutions for certain classes of problems [4].

BSPLVD, BSPLVN, and INTERV. These subprograms are the basic routines which are used to generate the B-spline basis function values and their derivative values at any desired points. They were developed and fully documented by deBoor [3] and are essentially unchanged from his original implementation. They provide for the reliable evaluation of arbitrary B-spline basis function values for polynomial orders up to 20.

STIFIB. This routine is the core integrator for the package. Its basic task is to advance the time value by taking a single time step. The routines STIFIB, COSET, DIFFUN, RES, ADDA, PSETIB, INTERP, DECB, and SOLB actually constitute a slightly modified version of an ODE package called GEARIB which has been developed by Hindmarsh [6]. The package GEARIB is designed to solve initial-value ODE problems of the form

$$A \frac{d\mathbf{y}}{dt} = \mathbf{g}(t, \mathbf{y}), \tag{6.1}$$

where $A(t, \mathbf{y})$ is a banded matrix, $\mathbf{y}$ is a vector, and $\mathbf{g}$ is a vector valued function. The semidiscrete equations (4.5) obtained by the collocation procedure above are particular examples of such equations. The time integration algorithms that are implemented in STIFIB are quite complex and we will discuss only the more important features. The methods used to advance the time are based on multipoint formulas of the form

$$\mathbf{y}_n = \sum_{j=1}^{k_1} \alpha_j \mathbf{y}_{n-j} + \Delta t \sum_{j=0}^{k_2} \beta_j \mathbf{y}'_{n-j}, \tag{6.2}$$

where $\mathbf{y}_k$ is an approximation to the exact value at $t = t_k$, $\mathbf{y}'$ denotes $d\mathbf{y}/dt$, $\Delta t = t_n - t_{n-1}$, and α_j and β_j are the method coefficients. Since $\beta_0 \neq 0$ for the methods used, the time integration methods (6.2) are *implicit* and so a nonlinear system of equations must in general be solved for every time step taken.

Proper choices of the coefficients in (6.2) can produce the standard Crank-Nicolson and backward difference methods so these techniques are generalizations of the classical, often used time integration methods.

There are two basic types of time integration formulas used in STIFIB. The first type of formula (Adams' methods) of order q, $1 \leq q \leq 12$, is obtained from (6.2) by setting $k_1 = 1$, $k_2 = q - 1$, and $\alpha_1 = 1$. The second type of formula (backward differentiation methods) of order q, $1 \leq q \leq 5$, is obtained by setting $k_1 = q$ and $k_2 = 0$. The remaining unspecified coefficients may be found in the book by Gear [5]. In general we recommend the use of the second type of formulas because of their better stability properties.

The time integration techniques in PDECOL feature automatic time step size and time integration formula order selection so as to efficiently solve the problem and yet achieve a user specified time integration error level.

For more specific details of the techniques and procedures implemented in STIFIB, we refer the reader to the comments in the program and the GEARIB report [6].

GFUN. The primary function of the routine GFUN is to properly evaluate the function $\mathbf{g}(t, \mathbf{y})$ of (6.1) when provided with input values of t and $\mathbf{y}$. In the package the vector function $\mathbf{g}(t, \mathbf{y})$ actually consists of values at the collocation points of the right-hand-side function $\mathbf{f}$, which defines the original PDE problem (2.1). Since the quantities actually being computed by the package (and the arguments input to GFUN) are basis function coefficients, GFUN must use these coefficients and the user defined subprograms F and BNDRY to generate the proper output values of $\mathbf{g}(t, \mathbf{y})$. The basis function coefficients are converted to piecewise polynomial values by EVAL (see below) and these values are then used to call the user's routines F and BNDRY. This conversion and evaluation process is performed at each collocation point in succession with BNDRY being called only for the boundary points. The first and last block rows of the A matrix (6.1) are also updated by GFUN to properly account for the boundary conditions (2.1).

GFUN is the routine which actually implements the collocation discretization process. It serves as the basic interface (via the method of lines) between the users' routines F and BNDRY and an ODE integrator (in this case a modified GEARIB). It serves the same interface role as the routine PDEONE [12] in a similar finite difference—method of lines implementation.

EVAL. The purpose of EVAL is to evaluate the piecewise polynomial (4.1) and its first two derivatives at a given collocation point, when the current basis function coefficients are provided as input. Since at any given point, at most *KORD* basis functions are nonzero, this computation involves computing three vector inner products where the vectors are of length *KORD*. This computation is the "innermost loop" in the package, since EVAL is called just prior to each call to the user's routine F (or BNDRY). Originally, the basis function values were not stored and were repeatedly computed (by BSPLVD) as needed. However, the expense of this repeated computation was so great that overall run times

were decreased by factors of from five to ten when it was decided to store all of the basis function (and derivative) values at the collocation points (see INITAL). This gain in speed is, of course, at the expense of additional storage.

PSETIB. This routine is required by STIFIB to compute and process the matrix $A - h\beta_0 (\partial \mathbf{g}/\partial \mathbf{y})$ where A is the banded matrix in (6.1) and $\partial \mathbf{g}/\partial \mathbf{y}$ is the banded Jacobian matrix of the function $\mathbf{g}(t, \mathbf{y})$ in (6.1). If the values of the partial derivatives of the user's function $\mathbf{f}$ in (2.1) with respect to $\mathbf{u}$, $\mathbf{u}_x$, and $\mathbf{u}_{xx}$ are known, then the Jacobian matrix $\partial \mathbf{g}/\partial \mathbf{y}$ can easily be computed using the chain rule. Once PSETIB has formed the desired matrix, it then LU decomposes the matrix for use in STIFIB by calling the package routine DECB. There are two options available in PSETIB for generating the needed partial derivatives and the user makes the selection. One option requires that the user construct a routine DERIVF to provide the partial derivative information (see the Algorithm). In the second option approximate partial derivatives are generated internally in the package routine DIFFF by finite difference quotients obtained by calling the user's routine F. The DERIVF option is only slightly more efficient (at most 10 percent faster). However, it does have the advantage that more accurate partial derivative values will be obtained. Inaccurate Jacobian matrix values do not directly affect the accuracy of the computed approximate solution, but can cause longer running times by forcing the package to take smaller time steps and to generate Jacobian matrices more frequently. For most problems we have found the second option totally adequate and recommend its use.

7. Example Problems

To illustrate the use of PDECOL, we present a main program and the user written subroutines required to solve the following problem on the interval [0, 1]:

$$\frac{\partial u}{\partial t} = v^2 \frac{\partial^2 u}{\partial x} + 2v \frac{\partial v}{\partial x} \frac{\partial u}{\partial x} - uv - u^2 + 10,$$

$$\frac{\partial v}{\partial t} = u^2 \frac{\partial^2 v}{\partial x^2} + 2u \frac{\partial u}{\partial x} \frac{\partial v}{\partial x} + \frac{\partial^2 u}{\partial x^2} + uv - v^2,$$

with boundary conditions

$$u = \tfrac{1}{2}, \qquad v = \pi \qquad \text{at } x = 0,$$

$$\frac{\partial u}{\partial x} + \sin(uv) = \tfrac{1}{2}, \qquad \frac{\partial v}{\partial x} - \cos(uv) = 1 \qquad \text{at } x = 1$$

and initial conditions

$$u = \tfrac{1}{2}(x + 1), \qquad v = \pi \qquad \text{at } t = 0.$$

Note that the initial conditions are consistent with the boundary conditions as required by PDECOL.

Figure 3 shows a main program and the user written subroutines F, BNDRY, UINIT, and DERIVF for this problem. Subroutine DERIVF is an optional routine which needs to be provided only if $MF = 11$ or 21 (see internal computer documentation for additional details). We present it here for completeness.

In Figure 4 we present some numerical results for this problem. These results were obtained using the piecewise polynomial space defined by $KORD = 4$, $NCC = 2$, and $NINT = 30$ with equally spaced breakpoints. The reader is referred to the internal program documentation in PDECOL for the definition of the quantities that appear in the figure. Since we do not know the exact solution to this problem, we are not able to determine the error in the calculated solution.

We next consider a relatively simple PDE problem where we know the exact solution. The purpose of this problem is to show the use of higher order methods

Fig. 3. (Continued)

and the execution times on a CDC-7600 computer. The problem is of a simple diffusion type and is described by

$$\frac{\partial u}{\partial t} = \frac{\partial^2 u}{\partial x^2} + \pi^2 \sin \pi x,$$

$$u(0, x) = 1, \qquad u(t, 0) = u(t, 1) = 1$$

for $0 < x < 1$ and $t > 0$. The exact solution for this problem is easily seen to be

$$u(t, x) = 1 + (\sin \pi x)(1 - e^{-\pi^2 t}).$$

Table I shows the results obtained for this problem at $t = 0.1$ with $NCC = 2$ for several values of *KORD* and *NINT*. Equally spaced breakpoints and $MF = 21$ were used in all cases. The values of *EPS*, the time integration error tolerance, were determined *by trial and error* to be as large as possible without affecting the spatial errors. The initial *DT* was chosen to be equal to *EPS*/2. *NSTEPS* is the number of time integration steps. The time, *TIME*, is the computer time in seconds (CDC-7600) required to produce the solution. The error, *ERROR*, is the maximum absolute difference between the exact solution and the numerical solution. The calculated order of convergence is shown in the last column. The numbers in parentheses are the theoretical values.

The preceding two examples illustrate the use of PDECOL and demonstrate the qualitative behavior of the higher order collocation methods that are implemented in the package. To consider all combinations of PDE methods that are built into PDECOL is virtually impossible since there are potentially over 3000 different methods in the package. We refer the reader to several other papers [9, 10] for additional results on the use, testing, and evaluation of PDECOL to solve partial differential equations and two-point boundary value problems. Some comparisons of PDECOL with low order finite difference methods are contained

Table I. Results at t = 0.1 for the Second Example Problem with *NCC* = 2 for Several Values of *KORD* and *NINT*

KORD	*NINT*	*EPS*	*NSTEPS*	*TIME* (sec)	*ERROR*	Order of convergence
3	10	3×10^{-5}	15	3.33×10^{-2}	1.14×10^{-3}	
3	20	1×10^{-5}	19	7.56×10^{-2}	2.94×10^{-4}	1.96 (2)
4	8	1×10^{-6}	25	9.53×10^{-2}	2.19×10^{-5}	
4	16	1×10^{-7}	33	2.32×10^{-1}	1.53×10^{-6}	3.90 (4)
5	4	1×10^{-6}	25	8.44×10^{-2}	1.38×10^{-5}	
5	8	1×10^{-8}	44	2.50×10^{-1}	4.33×10^{-7}	5.00 (5)
6	2	1×10^{-6}	25	6.61×10^{-2}	1.85×10^{-5}	
6	4	1×10^{-8}	41	1.84×10^{-1}	4.13×10^{-7}	5.50 (6)

in [9]. Our basic feelings are that for *smooth* problems and *high* accuracy demands, the higher order collocation techniques will be significantly more efficient, that is, produce more accuracy per unit of run time.

Our experience in using PDECOL has led us to firmly believe that PDECOL is a versatile software package that can solve a broad class of nonlinear partial differential equations. Its higher order methods can produce extremely accurate solutions quite efficiently when compared to lower order methods. The package is quite portable.

ALGORITHM 541
Efficient Fortran Subprograms for the Solution of Separable Elliptic Partial Differential Equations [D3]

Language: Fortran

DESCRIPTION

1. Introduction

Computer models of geophysical processes often require the numerical solution of elliptic partial differential equations. This is particularly true for models that make use of stream functions, velocity potentials, or vorticity equations and for models that compute the pressure of an incompressible fluid. The numerical solution of elliptic equations can be a formidable programming task. Moreover, the equations are often time dependent, requiring repeated solutions and, hence, considerable computing resources.

Recent advances in computing methods [1, 2] made it possible to solve a very large class of elliptic equations (the separable ones) rapidly and with minimal storage. And as a result of work on singular problems [6, 8], this class is free of special cases for which solutions cannot be obtained numerically. This paper describes a package of computer programs that make use of current methods for solving elliptic partial differential equations. The package is fully documented in [7].

We first became involved in implementing the Buneman algorithm [2] and its extensions via the capacitance matrix approach [1] for solving Poisson's equation in polar coordinates on a disk. This led directly to two important problems: the need to treat the coordinate singularity which occurs at the center of the disk [8] and the restriction that the number of unknowns in one coordinate must be a power of 2 [10]. It is desirable to relax that restriction for certain studies, since geophysicists often work on grids that result in a number of points which are not

Received 10 February 1977.

a power of 2; for example, the commonly used 5° grid results in 72 grid points in longitude.

This work demonstrated that a Poisson equation in any of the usual coordinate systems was readily solvable, except on the interior of the sphere. The equation for that problem is a special case of the general separable equation (see Section 2, subroutine S.7) and cannot be solved by the Buneman algorithm. This difficulty led to the development of a cyclic reduction algorithm for separable elliptic equations [5]. We then wrote two subroutines, POIS and BLKTRI, to implement the cyclic reduction and generalized cyclic reduction, respectively. But because users were significantly inconvenienced by having to set up the finite-difference approximations before using either of these subroutines, the routines were generally *not* well accepted. Hence the National Center for Atmospheric Research (NCAR) supported the development of the driver programs S.1 through S.5 (listed in Secton 2), which automated the process of generating the finite-difference equations for Poisson's equation in various coordinate systems. After these seven subroutines had been developed, we wrote a technical note [7] describing their use in detail. The combination of the ease of use of the subroutines and the complete documentation substantially increased the usage of the subroutines.

This experience made it quite apparent that even if a numerical method is excellent, the programs will not be widely used unless the software is easy to use and the documentation is quite clear. In addition to supporting user convenience, our philosophy has been to avoid terminology that might limit the class of users. For example, terms such as Dirichlet and Neumann boundary conditions, which tend to limit readership, have been replaced with either the solution or the derivative of the solution being specified.

The NCAR technical note [7] contains seven chapters, each describing one of the seven Fortran subroutines, and an Appendix dealing with least-squares solution of singular linear systems of equations. The first five subroutines solve a Helmholtz equation in Cartesian, polar, cylindrical, interior spherical, and surface spherical coordinates, respectively. The equations are solved on regular domains, namely, on a rectangle in the particular coordinate system that is chosen. For example, in polar coordinates the user can select the domain $a \leq r \leq b$ and $c \leq \theta \leq d$, where a can be zero. The user can also choose any of the standard boundary conditions. The solution or its derivative can be specified on the boundary, or periodic boundary conditions can be specified. Although these programs solve only two-dimensional problems, they can be adapted for use in three-dimensional problems by Fourier transforming in the third variable and using the parameter in the Helmholtz equation. This procedure is described in detail in the technical note [7]. Each chapter also contains a sample Fortran program which illustrates the use of the subroutine and provides a check during program installation.

In addition to the description of the Fortran subroutines, the first five chapters contain the finite-difference approximations used for the Helmholtz equation and the boundary conditions. Any special equations at singular points of the Helmholtz equation (e.g. at the origin, $r = 0$) are also presented. Approximations of second-order accuracy are used throughout. Each of these five chapters contains a section entitled "Singular Problems," which augments the Appendix in describing how solutions are obtained in the least-squares sense when a solution does not exist in the usual sense.

Each of these five subroutines calls one of the last two subroutines (POIS and BLKTRI), which can be used to solve a more general class of equation. Chapter VI describes subroutine POIS, which can be used to solve finite-difference approximations to an equation of the form

$$a(x)\frac{\partial^2 u}{\partial x^2} + b(x)\frac{\partial u}{\partial x} + c(x)u + \frac{\partial^2 u}{\partial y^2} = g(x, y).$$

Chapter VII describes subroutine BLKTRI, which can be used to solve finite-difference approximations to the general separable equation

$$a(x)\frac{\partial^2 u}{\partial x^2} + b(x)\frac{\partial u}{\partial x} + c(x)u + d(y)\frac{\partial^2 u}{\partial y^2} + e(y)\frac{\partial u}{\partial y} + f(y)u = g(x, y).$$

Although BLKTRI can solve problems that POIS solves, POIS is faster.

Subroutines POIS and BLKTRI use cyclic reduction and generalized cyclic reduction, respectively [2, 5, 10], to solve the large sparse linear systems. Although some discussion of these methods is included, program descriptions are presented separately for those who may wish to use the package only as a computational aid.

In Section 2 of this paper we briefly describe the capabilities of each of the seven subroutines; in Section 3 we summarize the various sections in the documentation; and in Section 4 we illustrate the documentation by presenting a small portion of the NCAR technical note [7]. And finally, in Section 5 we describe the modifications that have been made since the initial publication of the package and several developments that we are now planning or implementing.

2. Software Package

The package consists of seven subroutiness The first five, which are referred to as drivers, generate finite-difference approximations to a two-dimensional Helmholtz equation in a particular coordinate system. They are the following.

S.1 Subroutine PWSCRT solves the Helmholtz equation in Cartesian coordinates

$$\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} + \lambda u = f(x, y)$$

on the rectangle $a \le x \le b,\ c \le y \le d$.

S.2 Subroutine PWSPLR solves the Helmholtz equation in polar coordinates

$$\frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial u}{\partial r}\right) + \frac{1}{r^2}\frac{\partial^2 u}{\partial \theta^2} + \lambda u = f(r, \theta)$$

on the disk (or sector of the disk) $0 \le a \le r \le b,\ 0 \le c \le \theta \le d \le 2\pi$.

S.3 Subroutine PWSCYL solves the modified Helmholtz equation in cylindrical coordinates

$$\frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial u}{\partial r}\right) + \frac{\partial^2 u}{\partial z^2} + \frac{\lambda}{r^2}u = f(r, z)$$

on the slab of the cylinder $0 \le a \le r \le b,\ c \le z \le d$.

S.4 Subroutine PWSSSP solves the Helmholtz equation in spherical surface coordinates

$$\frac{1}{\sin\theta}\frac{\partial}{\partial \theta}\left(\sin\theta\frac{\partial u}{\partial \theta}\right) + \frac{1}{\sin^2\theta}\frac{\partial^2 u}{\partial \phi^2} + \lambda u = f(\theta, \phi)$$

on the sphere (or sector of the sphere) $0 \le a \le \theta \le b \le \pi,\ 0 \le c \le \phi \le d \le 2\pi$.

S.5 Subroutine PWSCSP solves the modified Helmholtz equation in interior spherical coordinates

$$\frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2\frac{\partial u}{\partial r}\right) + \frac{1}{r^2\sin\theta}\frac{\partial}{\partial \theta}\left(\sin\theta\frac{\partial u}{\partial \theta}\right) + \frac{\lambda}{r^2\sin^2\theta}u = f(\theta, r)$$

on all or a portion of a cross section of the sphere $0 \le a \le r \le b,\ 0 \le c \le \theta \le d \le \pi$.

On each of the boundaries, any of the following conditions can be specified.

B.1 The solution is specified (Dirichlet condition).

B.2 The derivative of the solution is specified (Neumann condition).

B.3 The solution is specified to be periodic.

B.4 The solution is unspecified (this condition applies when the domain of the equation includes a singularity of the coordinate system, e.g. when solving the Helmholtz equation in polar coordinates on the entire disk $0 \le r \le b$, $0 \le \theta \le 2\pi$).

Each of the five subroutines performs the following tasks.

T.1 defines the coefficients in the linear system of equations resulting from the finite-difference approximation.

T.2 incorporates the given boundary data into the right side of the equations.

T.3 perturbs the right side of the equation when the linear system is singular in order to guarantee that a solution exists.

Once the linear system has been defined, each of the routines calls one of the two following subroutines for solving linear systems.

S.6 Subroutine POIS solves systems resulting from finite-difference approximations to equations of the form

$$a(x)\frac{\partial^2 u}{\partial x^2} + b(x)\frac{\partial u}{\partial x} + c(x)u + \frac{\partial^2 u}{\partial y^2} = f(x, y).$$

S.7 Subroutine BLKTRI solves systems resulting from finite-difference approximations to general separable elliptic equations of the form

$$a(x)\frac{\partial^2 u}{\partial x^2} + b(x)\frac{\partial u}{\partial x} + c(x)u + d(y)\frac{\partial^2 u}{\partial y^2} + e(y)\frac{\partial u}{\partial y} + f(y)u = g(x, y).$$

3. Documentation of the Package

The documentation is completely contained in the NCAR technical note [7]. Each of the seven chapters is devoted to one subroutine and contains the following sections.

D.1 Calling Sequence and Parameter List Description. This section gives detailed descriptions of the parameters on input and output and information likely to be of value to a user deciding whether or not he can use the routine (e.g. memory space required, timing, and accuracy). This section will be of primary interest to those who wish to use the program strictly as a computational aid. This information is also contained on COMMENT cards at the beginning of each subroutine.

D.2 Difference Approximations. This section gives the detailed development of the difference approximations used for the equations, for the boundary conditions, and for the equations at coordinate singularities.

D.3 Singular Problems. This section gives the exact method used to perturb the right side of the equation when the user has specified a problem resulting in a singular linear system of equations.

D.4 Three-Dimensional Problems. This section demonstrates how to combine the use of the Fourier method with the routine in order to solve a Poisson equation in three space variables. (It is for this reason that the Helmholtz term involving λ sometimes has a function multiplying it.)

D.5 Sample Problem. This section gives a complete description of how to define input parameters for a selected differential equation. A Fortran implementation of the description is also given and certain output variables are given. These programs are included in the package as an aid to the user when the package is installed at his institution.

The documentation clearly states the locations of all machine-dependent constants used, e.g. π, and all required library routines, e.g. COS(X). The machine precision is required by BLKTRI, but it is computed (approximately) internally.

4. Sample Documentation

In this section we reproduce selected parts of the documentation for the routine PWSSSP to illustrate the use of the routine and the format of the documentation. We shall first state a continuous problem to be solved and then give a Fortran program that defines all the necessary input parameters. We then present the

formal parameter list description. Most of the following material is taken verbatim from Chapter V of the NCAR technical note [7], although in a different order.

Assume that we wish to approximate the solution of the Poisson equation

$$\frac{1}{\sin\theta}\frac{\partial}{\partial\theta}\left(\sin\theta\frac{\partial u}{\partial\theta}\right)+\frac{1}{\sin^2\theta}\frac{\partial^2 u}{\partial\phi^2}=2-6\sin^2\theta\sin^2\phi$$

on the northern hemisphere $0 \le \theta \le \pi/2$, $0 \le \phi \le 2\pi$, subject to equatorial symmetry, i.e. $(\partial u/\partial\theta)(\pi/2, \phi) = 0$, $0 \le \phi \le 2\pi$.

The exact solution to this problem is

$$u(\theta, \phi) = \sin^2\theta\sin^2\phi + c,$$

where c is any constant. Hence, this is a singular problem.

We choose a 5° grid for our approximation. The Fortran program that defines the necessary input parameters for subroutine PWSSSP is given in the first program of the listings which follow.

After the CALL to PWSSSP, the discretization error—the maximum absolute difference between the exact solution and the finite-difference approximation—is computed and printed along with the output parameter PERTRB. The printed output is

IERROR = 0

DISCRETIZATION ERR = 3.3811E − 03 PERTURBATION = 6.3220E − 04

The parameters in the call to PWSSSP are defined in the listing which appears at the end of this paper.

Accuracy and Timing. The execution time is proportional to MN $\log_2$ N and is given in Table I for the NCAR Control Data 7600 computer. To test the accuracy of the method, a uniform random number generator was used to create an array V(I, J), where $0 \leq V(I, J) \leq 1$. An array F(I, J) was then computed by differencing V(I, J) in double precision, using the difference equations that correspond to the sample problem. With F(I, J) as a right side, subroutine PWSSSP was used to compute a solution U(I, J). The maximum absolute difference between U(I, J) and V(I, J) is given in Table I. These errors can be compared with the accuracy of the NCAR 7600 (10^{-14}) to give a measure of the loss of significant digits due to roundoff. This error should not be confused with the discretization error given after the sample Fortran program.

5. Concluding Remarks

This package is not static, but is currently undergoing modifications to improve the solution techniques and extend the range of problems that can be solved. The following additions and modifications have already been made.

(1) Currently available is a subroutine, SEPELI, which discretizes the general separable elliptic equation. Thus the process of differencing the equations, incorporating the boundary conditions, and solving the resulting equations is automated as in the driver programs described in Section 2. Also included in this program is the option of obtaining fourth-order accurate solutions via the method of deferred corrections [3]. As in the other drivers, a weighted least-squares solution is obtained if that solution does not exist in the usual sense. More

Table I

M	N	Execution time (ms)	Maximum absolute difference
8	32	14	2.3×10^{-13}
16	64	60	1.3×10^{-12}
32	128	248	7.7×10^{-12}

Note: If NBDCND $\neq 0$, the execution times can be halved.

information may be obtained from John Adams, who has developed this program at NCAR.

(2) Replacements for the subroutines POIS and BLKTRI have been developed and tested and are in their final stage of documentation. The earlier versions of POIS and BLKTRI impose restrictions on the block order of the linear system of equations. The new algorithms eliminate this restriction. They also reduce to the efficient cyclic reduction algorithms when $N = 2^p$. The new algorithm for POIS is given in [9].

(3) With the use of this new algorithm, a subroutine, POISTG, has been developed [4] to solve finite-difference approximations to Helmholtz equations defined on staggered grids. This routine has been written in the format of POIS and BLKTRI. Drivers such as those described in Section 2 are now being written to solve finite-difference approximations to modified Helmholtz equations defined on a staggered grid.

In the early planning stage is a subroutine that will solve the general nonseparable linear elliptic equation in which the coefficients depend on both independent variables. However, it is anticipated that this program will use iterative rather than direct methods.

We feel that this package of high-quality, reliable, efficient programs for the solution of finite-difference approximations to elliptic equations is a significant step in the development of a complete package designed to solve an extremely wide class of elliptic partial differential equations.

NOTE ADDED IN PROOF. In the period since this paper was submitted for publication, all of the subroutines listed in modifications (1)–(3) above have been implemented in the latest version of the package. In addition, a driver for solving a three-dimensional Helmholtz equation in Cartesian coordinates, its associated solver, and two fast Fourier transform packages have been implemented. The interested reader should contact one of the authors at NCAR.

CERTIFICATION OF ALGORITHM 541

Efficient Fortran Subprograms for the Solution of Separable Elliptic Partial Differential Equations [D3]
[P.N. Swarztrauber and R.A. Sweet, *ACM Trans. Math. Software 5*, 3 (September 1979), 352-364.]

Michael Steuerwalt [Recd 10 Feb. 1977 and 31 Jan. 1979]
Los Alamos Scientific Laboratory, P.O. Box 1663, Los Alamos, NM 87545

INTRODUCTION

The problem of computing solutions to modified Helmholtz equations (or, more generally, separable linear elliptic equations) with simple boundary conditions on a rectangle in any of several coordinate frames arises frequently in applications and as an intermediate step in the solution of nonlinear and evolution problems. The cost of developing, documenting, and testing a package for this task is not negligible. Therefore several federal laboratories that can profitably use the National Center for Atmospheric Research (NCAR) package [2] chose to collaborate in its certification.

THE PACKAGE

Physically, the NCAR package consists of about 4700 lines of Fortran code (almost 40 percent are comments), 800 lines of example drivers, and 140 pages of documentation. The package cost about $300,000 to develop. In comparison, EISPACK has 11,500 lines of code (49 percent are comments), 10,000 lines of example drivers, 551 pages of documentation [1], and cost about $900,000.

The heart of the NCAR package is the two routines POIS and BLKTRI, which solve the linear systems arising from standard second-order finite-difference approximations of separable elliptic boundary value problems on rectangles. The package also includes five drivers that build the discrete system from the least possible information: the differential equation and boundary conditions, the geometric region, and the number of (evenly spaced) mesh points in each direction. Most users will communicate with the core routines only through these drivers.

THE CERTIFICATION EFFORT

Each of the five laboratories that had agreed to collaborate in the certification effort assumed responsibility for a particular driver:

PWSCRT: Air Force Weapons Laboratory, Kirtland Air Force Base, Albuquerque, N. Mex.
PWSPLR: Lawrence Livermore Laboratory, Livermore, Calif.
PWSCYL: Sandia Laboratories, Livermore, Calif.
PWSCSP: Sandia Laboratories, Albuquerque, N. Mex.
PWSSSP: Los Alamos Scientific Laboratory, Los Alamos, N. Mex.

Each laboratory agreed to

(a) Compile the entire package.
(b) Verify the results of the seven NCAR example programs.
(c) Verify the correct working of the input error detection code.
(d) For its particular driver, run a test problem using
  (1) several permissible regions,
  (2) several mesh sizes in each direction,
  (3) all possible boundary conditions,
  (4) zero and nonzero values of λ.
(e) Evaluate the documentation.

It is important to note what we did *not* try to do:

(a) Explicitly test the core routines POIS and BLKTRI. Access to these routines was through the drivers alone.

(b) Make efficiency tests. The methods of the core routines are among the best direct methods available, but neither the authors nor the certifiers claim that there are no methods more efficient. In particular, we expect that higher-order discretization schemes would be more efficient for a given (small enough) accuracy.

(c) Make severe tests of the package's robustness.

The schedule outlined above entails a considerable effort. Among the five laboratories there are perhaps 10 different Fortran compilers, so the simple compilation of the package is a good test of its portability. The testing implied by (d) is substantial. For example, the driver PWSSSP admits 9 different possible boundary conditions in the θ direction and 5 in the ϕ direction; not all combinations are compatible, and some are valid only for certain geometries. To complete part (d) for the PWSSSP routine, 8 different regions were used with all possible valid boundary conditions, and with 5 different mesh sizes in the θ direction and 4 in the ϕ direction, for a total of 2360 runs per value of λ. Testing of the other drivers was similar. See the Appendix for details of the test problems.

RESULTS OF THE CERTIFICATION EFFORT

After initial tests, the certification team suggested several changes in the package and the documentation. All our recommendations were adopted. The most significant of these changes are the following.

(1) Version numbers for the package. The version we are certifying here is Version 2.

(2) Correction of initialization errors. The core routines POIS and BLKTRI perform some preliminary computations that need not be repeated if certain problem parameters remain unchanged. Our first tests had revealed program errors that could be avoided only by reinitializing every problem.

(3) Additional code to check for illegal combinations of problem parameters. The documentation clearly indicates that certain choices of boundary conditions are incompatible with particular geometries. For instance, in PWSSSP, three possible choices of the boundary condition at the final value TF of θ require that $TF = \pi$. A sample problem was run with these choices of boundary condition but with $TF < \pi$. The package did not check for such illegal combinations, but simply computed, producing wrong answers. In Version 2, the drivers will also set an error flag if, say, $|TF - \pi|$ is "too large." We feel that the package's robustness

is well enhanced by including this check, which has been done in a portable way and at little computing expense. On the other hand, we should remark that Swarztrauber and Sweet have indicated to us some uneasiness regarding the introduction of the imprecise and machine-dependent notion of "too large," and that no package, whatever its robustness or quality of documentation may be, can protect a user bent on self-immolation.

(4) An extensive list of errata and changes to the documentation. The documentation is neither so exhaustive as the EISPACK guide nor so rich in examples of the routines' use. This is no handicap: use of the NCAR routines is straightforward, whereas EISPACK often provides several options for doing a computation.

All the program tests were repeated for Version 2 to verify the corrections. The tests show that the methods are indeed of second-order accuracy. We deem the package to be valuable software of good quality. We especially commend its design, which permits users to communicate with it in familiar terms so that they do not have to grasp the mechanics of the discretization procedure. We believe the documentation will help that user who only wants answers to his problems to get those answers while remaining in blissful ignorance of details peripheral to his interests.

APPENDIX. DETAILS OF THE TEST PROBLEMS

Each driver may distinguish types of regions according to the geometry of the problem. Some combinations of boundary conditions and regions are not admissible. In this Appendix we tabulate the valid combinations for each driver; the entry "—" indicates no legal combination. We also list the intervals whose Cartesian products form the regions used in the certification tests, and give the true solution u of the various boundary value problems. The appropriate boundary values and the function f can be determined for a given problem from u, λ, and the region. For all problems the values of λ, M, and N used were

λ :	0.0	−1.0			
M :	9	18	36	72	144
N :	15	30	45	60	

PWSCRT

All 25 possible combinations of MBDCND and NBDCND are valid. The two regions used were

$$[A, B] = [-1/2, 1/2]$$

$$[C, D] = [-1/2, 1/2] \qquad [0, 2].$$

The true solution was

$$u = \sin 2\pi(x + 1/8) \cos 2\pi(y + 1/8).$$

PWSPLR

This driver distinguishes two types of regions:

$0 < A$	P
$0 = A$	Z

The compatibility table has 34 entries:

MBDCND	NBDCND 0	1	2	3	4
1	PZ	PZ	PZ	PZ	PZ
2	PZ	PZ	PZ	PZ	PZ
3	P	P	P	P	P
4	P	P	P	P	P
5	Z	—	—	Z	—
6	Z	—	—	Z	—

The four regions used were

$$[A, B] = [1/4, 1] \qquad [0, 1]$$
$$[C, D] = [0, 2\pi/3] \qquad [2\pi, 8\pi/3].$$

The true solution was

$$u = r^3 \cos(4\pi\theta/[D - C] + \pi/4).$$

PWSCYL

This driver distinguishes two types of regions:

$0 < A$	P
$0 = A$	Z

The compatibility table has 40 entries:

	NBDCND				
MBDCND	0	1	2	3	4
1	PZ	PZ	PZ	PZ	PZ
2	PZ	PZ	PZ	PZ	PZ
3	P	P	P	P	P
4	P	P	P	P	P
5	Z	Z	Z	Z	Z
6	Z	Z	Z	Z	Z

The two regions used were:

$$[A, B] = [1, 2] \qquad [0, 1]$$
$$[C, D] = [0, 2\pi].$$

The true solution was

$$u = r^2\cos(z + \pi/4).$$

PWSCSP

This driver recognizes eight types of regions:

	$0 < RS$	$0 = RS$
$0 < TS, TF < \pi$	A	E
$0 = TS, TF < \pi$	B	F
$0 < TS, TF = \pi$	C	G
$0 = TS, TF = \pi$	D	H

The compatibility table has 72 entries:

	NBDCND					
MBDCND	1	2	3	4	5	6
1	ABCD	ABCD	ABCD	ABCD	—	—
2	AB	AB	AB	AB	—	—
3	A	A	A	A	E	E
4	AC	AC	AC	AC	—	—
5	BD	BD	BD	BD	—	—
6	B	B	B	B	F	F
7	CD	CD	CD	CD	—	—
8	C	C	C	C	G	G
9	D	D	D	D	H	H

The eight regions used were

$$[TS,TF] = [\pi/4, \pi/2] \qquad [0, \pi/2] \qquad [\pi/2, \pi] \qquad [0, \pi]$$
$$[RS, RF] = [1, 2] \qquad [0, 1].$$

The true solution was

$$u = r^4\cos^4\theta.$$

PWSSSP

This driver distinguishes four types of regions:

$0 < TS, TF < \pi$	A
$0 = TS, TF < \pi$	B
$0 < TS, TF = \pi$	C
$0 = TS, TF = \pi$	D

There are 59 entries in the compatibility table:

MBDCND	NBDCND 0	1	2	3	4
1	ABCD	ABCD	ABCD	ABCD	ABCD
2	AB	AB	AB	AB	AB
3	A	A	A	A	A
4	AC	AC	AC	AC	AC
5	BD	—	—	BD	—
6	B	—	—	B	—
7	CD	—	—	CD	—
8	C	—	—	C	—
9	D	—	—	D	—

The tests used eight regions:

$[TS, TF] = [\pi/4, \pi/2]$ $[0, \pi/2]$ $[\pi/2, \pi]$ $[0, \pi]$
$[PS, PF] = [\pi/2, 3\pi/2]$ $[0, 2\pi]$.

The true solution was

$$u = \sin^2 \theta \cos 2\phi.$$

72	60	2	1	138	0.0	0.414E−02

We close with some remarks about the accuracy and speed of the package. Tables I and II summarize some of the test results obtained on a 7600 at Los Alamos, using a local compiler similar to the FTN compiler (optimization level 2). The CPU times, given in milliseconds, reflect the influences of boundary condition and mesh size and are in very good agreement with times reported in [2]. Error is measured in the sup norm over the interior of the mesh of (M + 1) × (N + 1) points; the entries indicate that the finite-difference scheme of the package has second-order accuracy. To see this, note that if the scheme is of second order, then the error on the ith mesh is approximately

$$\text{error}_i = \alpha M_i^{-2} + \beta N_i^{-2},$$

where $M_i = 9*2^i$, $N_i = 15*(i + 1)$, $0 \leqq i \leqq 3$. The Cartesian problem of Table I is symmetric about the line $x = y$, and so $\alpha = \beta$. We therefore expect the ratios $\text{error}_{i-1}/\text{error}_i$ to have the values of 4.00, 3.32, 2.69, respectively. For the spherical surface problem of Table II, α is nearly zero and the expected ratios are 4.00, 2.25, 1.78.

These observations—second-order accuracy and good agreement with the timings of [2]—hold true across the entire test set.

ALGORITHM 542
Incomplete Gamma Functions [S14]

WALTER GAUTSCHI
Purdue University

Key Words and Phrases: computation of incomplete gamma functions, Taylor's series, continued fractions
CR Categories: 5.12
Language: Fortran

DESCRIPTION

This algorithm implements the procedure developed in [1].

ALGORITHM 543
FFT9, Fast Solution of Helmholtz-Type Partial Differential Equations [D3]

E. N. HOUSTIS
Purdue University
and
T. S. PAPATHEODOROU
Clarkson College of Technology

Key Words and Phrases: fast Fourier transform, fast Helmholtz solver, fast Poisson solver
CR Categories: 5.17
Language: Fortran

DESCRIPTION

The algorithm given here is a complement to [1] where the description, test results, and references are given.

ALGORITHM 544
L2A and L2B, Weighted Least Squares Solutions by Modified Gram-Schmidt with Iterative Refinement [F4]

ROY H. WAMPLER
National Bureau of Standards

Key Words and Phrases: covariance matrix, curve fitting, iterative refinement, least squares solution, linear constraints, overdetermined system of equations, regression, underdetermined system of equations
CR Categories: 5.14, 5.5
Language: PFORT, a portable subset of ANSI Fortran

DESCRIPTION

The two algorithms given here are a complement to [1] where the types of problems which can be solved by L2A and L2B, together with the method of solution and details of the calling sequences, are described.

C UNKNOWNS, AND MATRIX W IS A GIVEN DIAGONAL MATRIX OF WEIGHTS WITH ALL L2B  12Ø
C DIAGONAL ELEMENTS NONNEGATIVE.  LET H = (SQRT(W))*A.                  L2B  13Ø
C IN THE EVENT THAT N1 (THE COMPUTED RANK OF MATRIX H) IS LESS THAN N   L2B  14Ø
C (THE NUMBER OF UNKNOWN COEFFICIENTS), A UNIQUE SOLUTION VECTOR HAVING L2B  15Ø
C N ELEMENTS CAN BE OBTAINED BY IMPOSING THE CONDITION THAT THE         L2B  16Ø
C SOLUTION BE OF MINIMAL EUCLIDEAN NORM.  SUCH A SOLUTION IS SOUGHT IN  L2B  17Ø
C THE CASE OF UNDERDETERMINED OR RANK-DEFICIENT PROBLEMS.               L2B  18Ø
C                                                                       L2B  19Ø
C ** INPUT VARIABLES **                                                 L2B  2ØØ
C M       TOTAL NUMBER OF EQUATIONS.                                    L2B  21Ø
C N       NUMBER OF UNKNOWN COEFFICIENTS.                               L2B  22Ø
C M1      NUMBER OF LINEAR CONSTRAINTS (Ø.LE.M1.LE.M AND M1.LE.N).      L2B  23Ø
C L       NUMBER OF RIGHT-HAND SIDES (VECTORS OF OBSERVATIONS).         L2B  24Ø
C A       TWO-DIMENSIONAL ARRAY OF SIZE (MM,N).  ON ENTRY, THE ARRAY A  L2B  25Ø
C         CONTAINS THE GIVEN MATRIX OF A SYSTEM OF M LINEAR EQUATIONS   L2B  26Ø
C         IN N UNKNOWNS, WHERE THE FIRST M1 EQUATIONS ARE TO BE         L2B  27Ø
C         SATISFIED EXACTLY.  A IS LEFT INTACT ON EXIT.                 L2B  28Ø
C B       TWO-DIMENSIONAL ARRAY OF SIZE (MM,L).  ON ENTRY, B CONTAINS   L2B  29Ø
C         THE L GIVEN RIGHT-HAND SIDES (VECTORS OF OBSERVATIONS).  B IS L2B  3ØØ
C         LEFT INTACT ON EXIT.                                          L2B  31Ø
C W       VECTOR OF SIZE M.  ON ENTRY, W CONTAINS THE DIAGONAL ELEMENTS L2B  32Ø
C         OF A GIVEN DIAGONAL MATRIX OF WEIGHTS, ALL NONNEGATIVE.       L2B  33Ø
C         (THE FIRST M1 ELEMENTS OF W ARE SET EQUAL TO 1.Ø BY THE       L2B  34Ø
C         PROGRAM WHEN M1 IS GREATER THAN ZERO.)  ON EXIT, THE ORIGINAL L2B  35Ø
C         ELEMENTS OF W HAVE BEEN REPLACED BY THEIR SQUARE ROOTS.       L2B  36Ø
C TOL     PARAMETER USED IN DETERMINING THE RANK OF MATRIX H.           L2B  37Ø
C         NOTE --                                                       L2B  38Ø
C         (1) IF TOL EQUALS ZERO, THE TOLERANCE USED IN SUBROUTINE      L2B  39Ø
C             DECOM2 WILL BE BASED ON MACHINE PRECISION.                L2B  4ØØ
C         (2) IF TOL IS GREATER THAN ZERO, THIS VALUE OF TOL WILL BE    L2B  41Ø
C             USED IN SETTING AN ABSOLUTE TOLERANCE FOR COMPARISON WITH L2B  42Ø
C             DIAGONAL ELEMENTS OF THE TRIANGULAR MATRIX OBTAINED IN    L2B  43Ø
C             SUBROUTINE DECOM2.  THE VALUE OF TOL CAN BE BASED ON      L2B  44Ø
C             KNOWLEDGE CONCERNING THE ACCURACY OF THE DATA.            L2B  45Ø
C MM      DIMENSIONING PARAMETER SPECIFYING MAXIMUM NUMBER OF ROWS IN   L2B  46Ø
C         THE ARRAYS A, B AND RES.  MM MUST SATISFY MM.GE.M.            L2B  47Ø
C NN      DIMENSIONING PARAMETER SPECIFYING MAXIMUM NUMBER OF ROWS IN   L2B  48Ø
C         THE ARRAY X.  NN MUST SATISFY NN.GE.N.                        L2B  49Ø
C MMPNN   DIMENSIONING PARAMETER SPECIFYING MAXIMUM NUMBER OF ROWS IN   L2B  5ØØ
C         THE ARRAY QR.  MMPNN MUST SATISFY MMPNN.GE.M+N.               L2B  51Ø
C                                                                       L2B  52Ø
C ** OUTPUT VARIABLES AND INTERNAL VARIABLES **                         L2B  53Ø
C N1      COMPUTED RANK OF MATRIX H, WHERE H = (SQRT(W))*A.             L2B  54Ø
C IPIVOT VECTOR OF SIZE N.  ON EXIT, THIS ARRAY RECORDS THE ORDER       L2B  55Ø
C         IN WHICH THE COLUMNS OF H WERE SELECTED BY THE PIVOTING       L2B  56Ø
C         SCHEME IN THE COURSE OF THE ORTHOGONAL DECOMPOSITION.         L2B  57Ø
C         WHENEVER N1.LT.N, THE FIRST N1 ELEMENTS OF IPIVOT INDICATE    L2B  58Ø
C         WHICH COLUMNS OF H WERE FOUND TO BE LINEARLY INDEPENDENT.     L2B  59Ø
C X       TWO-DIMENSIONAL ARRAY OF SIZE (NN,L).  ON EXIT, X CONTAINS    L2B  6ØØ
C         THE SOLUTION VECTORS.                                         L2B  61Ø
C RES     TWO-DIMENSIONAL ARRAY OF SIZE (MM,L).  ON EXIT, RES CONTAINS  L2B  62Ø
C         THE RESIDUAL VECTORS.                                         L2B  63Ø
C QR      TWO-DIMENSIONAL ARRAY OF SIZE (MMPNN,N).  ON EXIT, QR         L2B  64Ø
C         CONTAINS THE LOWER TRIANGULAR PORTION OF THE SYMMETRIC        L2B  65Ø
C         UNSCALED COVARIANCE MATRIX.  (THIS ARRAY IS USED INTERNALLY   L2B  66Ø
C         TO STORE RESULTS FROM SUBROUTINE DECOM2 WHICH ARE             L2B  67Ø
C         DESTROYED IN COMPUTING THE COVARIANCE MATRIX.)                L2B  68Ø
C C       VECTOR HAVING AT LEAST 6*(M+N)+2*L ELEMENTS USED (1) FOR      L2B  69Ø
C         INTERNAL WORK SPACE AND (2) FOR RETURNING INFORMATION ON THE  L2B  7ØØ
C         BEHAVIOR OF THE ITERATIVE REFINEMENT PROCEDURE.               L2B  71Ø
C         (A) NUMIT IS THE NUMBER OF ITERATIONS CARRIED OUT DURING THE  L2B  72Ø
C             ITERATIVE REFINEMENT IN ATTEMPTING TO OBTAIN A SOLUTION   L2B  73Ø
C             FOR THE K-TH RIGHT-HAND SIDE.                             L2B  74Ø
C             ON EXIT, C(K) = +NUMIT IF THE SOLUTION CONVERGED, AND     L2B  75Ø
C                      C(K) = -NUMIT IF THE SOLUTION FAILED TO CONVERGE. L2B  76Ø
```

```
C         (B) DIGITX GIVES AN ESTIMATE OF THE NUMBER OF CORRECT DIGITS   L2B  77Ø
C             IN THE INITIAL SOLUTION OF THE COEFFICIENTS FOR THE K-TH   L2B  78Ø
C             RIGHT-HAND SIDE.  ON EXIT, C(K+L) = DIGITX.                L2B  79Ø
C IFAULT FAULT INDICATOR WHICH IS ZERO IF NO ERRORS WERE ENCOUNTERED     L2B  8ØØ
C        AND POSITIVE IF ERRORS WERE DETECTED OR IF EVIDENCE OF SEVERE   L2B  81Ø
C        ILL-CONDITIONING WAS FOUND.  DIAGNOSTIC MESSAGES ARE PRINTED    L2B  82Ø
C        FROM SUBROUTINE ERROR.  IF IFAULT IS SET EQUAL TO 1, 2, 3, 4,   L2B  83Ø
C        5, 6 OR 7, EXECUTION IS TERMINATED.  EXECUTION CONTINUES WHEN   L2B  84Ø
C        IFAULT IS SET EQUAL TO 8, 9 OR 1Ø PROVIDED THAT A SOLUTION      L2B  85Ø
C        WAS OBTAINED FOR AT LEAST ONE RIGHT-HAND SIDE.  THE VALUE OF    L2B  86Ø
C        IFAULT IS USED TO INDICATE THE FOLLOWING --                     L2B  87Ø
C        Ø = NO ERRORS ENCOUNTERED.                                      L2B  88Ø
C        1 = BAD INPUT PARAMETER (M, N OR L).                            L2B  89Ø
C        2 = BAD INPUT PARAMETER (M1).                                   L2B  9ØØ
C        3 = BAD DIMENSION.  EITHER M.GT.MM, N.GT.NN OR M+N.GT.MMPNN.    L2B  91Ø
C        4 = AT LEAST ONE WEIGHT IS NEGATIVE.                            L2B  92Ø
C        5 = EITHER MATRIX H OR MATRIX OF CONSTRAINTS EQUALS ZERO.       L2B  93Ø
C        6 = CONSTRAINTS ARE LINEARLY DEPENDENT.                         L2B  94Ø
C        7 = ALL SOLUTIONS FAILED TO CONVERGE.                           L2B  95Ø

ALGORITHM 545
An Optimized Mass Storage FFT [C6]

DONALD FRASER

CSIRO, Australia

Key Words and Phrases: multidimensional FFT, fast Fourier transform, FFT, mass storage FFT, mass store sorting, optimal sorting
CR Categories: 4.9, 5.19, 5.31
Language: Fortran

DESCRIPTION

The program is an implementation of the optimal sorting algorithm of the author [8] which allows a base-2 version of the Cooley–Tukey FFT algorithm [2–4] efficient access to a mass store array. Optimal sorting for the mass storage FFT has been determined independently by DeLotto and Dotti [5, 6], but in the author's version the emphasis is on "in-place" array modification. This results in slightly higher mass store I/O than the minimum, but requires no additional mass store working space. The method is a logical extension of the work of Singleton [9] and Brenner [1].

The program computes in place the discrete Fourier transform of a one-dimensional or a multidimensional array. In the one-dimensional case the transform is defined by

$$A(J) = SCAL \sum_{j=0}^{N1-1} a(j) \exp(\pm i\, 2\pi jJ/N1) \quad \text{for} \quad J = 0, 1, \ldots, N1 - 1 \quad (1)$$

where SCAL is an arbitrary scaling factor, exp is the exponential function, and $i = \sqrt{-1}$, the sign of the exponent being either plus or minus, depending on the desired transform.

The definition (1) is easily generalized to cover more than one dimension; for example, the two-dimensional case is given by

$$A(K, J) = SCAL \sum_{k=0}^{N2-1} \sum_{j=0}^{N1-1} a(j, k) \exp(\pm i\, 2\pi(jJ/N1 + kK/N2))$$

$$\text{for} \quad K = 0, 1, \ldots, N2 - 1 \quad \text{and} \quad J = 0, 1, \ldots, N1 - 1. \quad (2)$$

The elements a(j) or a(j, k) in (1) or (2) are the initial complex data in a mass store array. These are replaced by the elements A(J) or A(K, J) as the final complex data. Index reversal in the two-dimensional case is used to indicate dimension transposition by the program (dimension order reversal in general). This may be suppressed in certain cases.

The program consists of a set of subroutines written in ANSI Fortran, only two

Received 24 October 1975 and 27 June 1979.

Author's address: Division of Computing Research, CSIRO, P.O. Box 1800, Canberra City, ACT 2601, Australia.

of which are called by a user program. If the data are always complex, the user program calls subroutine CMFFT. If the input data or the result are real, the user program may call the faster subroutine RMFFT. Either subroutine replaces a one-dimensional or a multidimensional array in mass store by its discrete Fourier transform, as defined by eq. (1) or (2).

(If the elements of the mass store array are considered to be singly indexed by i = 0, 1, 2, . . . , then the indices of the definitions map into i = j in the one-dimensional case or i = j + k·N1 in the two-dimensional case, resultant transposition giving i = K + J·N2. In general, i = j1 + j2·N1 + j3·N2·N1 + ... Remember also that indices are increased by 1 for Fortran.)

The mass store file is assumed to exist and to have been previously defined to the Fortran system and opened for random access by the user. The file is accessed through two system-dependent subroutines MFREAD and MFWRIT (see Appendix F). All other subroutines are system independent.

The user has freedom to specify total array size, mass store block or record size, core store working space size, and the dimensioning of the array, except that all sizes are to base 2 and are given by their binary exponents.

Complex data are transformed by an in-place, base-2 algorithm using postcomputation bit reversal to sort the array [2]. The computation is handled by a modified, in-core FFT routine which does a sequence of partial transforms of the mass store array (the method is discussed further in the following section). The sorting algorithm [8] calculates the most efficient way to access the mass store array for these computations. Finally, the sorting algorithm is used to carry out an overall bit-reversed permutation of the array, again with as few accesses as possible (I/O efficiency is discussed in the conclusion section).

Computation and sorting occur in place, through a combination of "virtual" permutations, where mass store blocks are accessed according to an indexing algorithm but are left physically unpermuted, and symmetric permutations, which interchange blocks according to a generalized index bit reversal. In [8] it is shown that any unsymmetric permutation can be formed from two suitable symmetric permutations, each of which can be done in place.

Multidimensional transforms are achieved automatically by making use of the indexing structure of the FFT algorithm itself. No change to the order of access of elements is necessary, so that the full advantage of the sorting algorithm and program simplicity is maintained.

For transforms in which the initial or final data are real, the usual time-saving algorithm [4] is available to unscramble a half-length complex transform of packed real data (or vice versa). This requires an extra accessing and computing pass through the mass store array but still results in a saving of nearly half the computation and I/O time. In this method it is easy to allow a choice in the degree of redundancy in the final, complex result. The array may be expanded to full redundancy (twice the physical length of the original packed real array), or to partial redundancy, or maintain the same physical length by elimination of all redundancy.

Finally, we must define a number of terms used in the discussion. "Core store" is used to describe a region where the elements of an array are equally accessible at random. "Mass store" implies a region where elements are grouped into "blocks" or "records" which must be accessed as units, but which units are accessible efficiently at random. A "pass" is an array operation which leaves the array elements in place ready for another array operation. Thus an "I/O pass" reads and writes back once all the blocks of an array (this is a logical definition—sometimes in practice not all blocks need be physically accessed, or some may be accessed more than once).

Algorithm Details

General. The structure of the mass storage FFT program is shown in Figure 1. When using real data, routine RMFFT calls CMFFT with a half-length complex

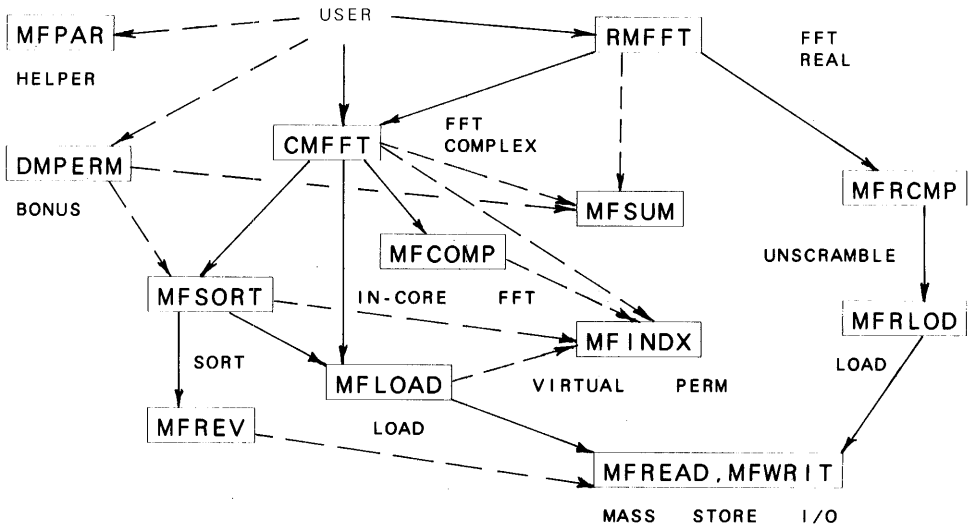

Fig. 1. Internal subroutine calling network. (Solid and dashed lines distinguished roughly between "main path" and "reference" calls.)

array before unscrambling by MFRCMP. If necessary, routines CMFFT and below may be overlaid with routines MFRCMP and MFRLOD. CMFFT controls the sequence of mass store accessing for in-core computation and sorting of the complex FFT. Routines MFCOMP and MFRCMP carry out the FFT computation and unscrambling of data in core store. MFREV, controlled by routine MFSORT, carries out a bit-reversed permutation on elements in core store or on whole blocks in mass store. MFLOAD and MFRLOD load and unload core store for the in-core routines, calling on MFREAD and MFWRIT (Appendix F). MFINDX defines a virtual permutation of the mass store array during the complex FFT operation. MFSUM sums elements in the dimensioning list MEXA( ), sorting them if necessary. Routine MFPAR is discussed in Appendix B and routine DMPERM in Appendix D.

The main problem in writing a mass store FFT program is to devise an efficient means of accessing widely spaced data elements for use in the FFT computation kernel and for sorting from bit-reversed order [2]. Singleton [9] describes an algorithm for accessing a mass store array two blocks at a time to carry out each computing pass of an FFT. He organizes mass store accesses in such a way that each I/O and computing pass results in a one-place cyclic shift of array element index bits. This allows the FFT kernel program to access the same elements in core store on each pass, which not only simplifies the program but also brings "widely separated" elements in the original array "within reach" of the in-core computation. Bit-reversed sorting is done in a similar manner. For an array of 2**M elements, the basic method requires (2M − 1) I/O passes.

With efficient, random access mass store it is possible to use an indexing algorithm to read widely scattered blocks, equivalent to a virtual permutation of the array. After an in-core operation the blocks are written back in place, the blocks remaining physically unpermuted by the operation. In [8] an algorithm is described which uses this method to compute the FFT. The indexing subroutine MFINDX computes the required sequence of block indices using an algorithm which is a generalization of the Block Indexing Algorithm of [8, p. 303]. This is equivalent to a cyclic shift (a number of places) of a set of the block index bits.

Complex Data. Unlike Singleton's algorithm, an attempt is made to load as many blocks together as possible in core store. In this way it is possible to include a number of FFT computing passes while the blocks are in core store, reducing the number of I/O passes by a factor ICEX − IBEX (see the conclusion section). Routine CMFFT uses a slightly modified version of the algorithm of [8, p. 307] for this purpose, doing M − C instead of M − B initial computing passes with

virtual permutations, followed by final C pass computations with direct access, instead of final B pass computations. I/O efficiency is unchanged, but the algorithm is neater (sizes being 2**B elements per block, 2**C in core store, 2**M total, all complex).

Routine MFCOMP computes the FFT in core store. But, unlike other FFT routines, the number of computing passes NPAS, and the effective initial pass number IPAS, are not fixed but are passed by the calling routine CMFFT. Weighting factors are computed using SIN, COS functions on mass store block boundaries but recursively within block boundaries, while array element accessing is ordered to minimize these computations. Multidimensional transforms are achieved by restarting the weighting factor sequence over passes corresponding to the exponent of each dimension, requiring no change to the order of access of elements.

Finally, routine MFSORT is called to sort the array from bit-reversed order. The algorithm is a slightly modified version of the sorting algorithm of [8, pp. 305–307], to allow the reversal of a more general set of index bits. Its structure is very similar to CMFFT, having a first stage using the virtual cyclic shift permutation for block access, with pairs of in-core bit-reversed permutations (MFREV) instead of FFT computations. (The pairs allow unsymmetric cyclic bit shift permutations to be done in place, in core). Only one in-core permutation is required on the first I/O pass. These are followed by a final bit-reversed permutation of whole blocks, if necessary.

In the special case when IDIR = 0, MFSORT is called a number of times to individually reverse bits corresponding to each dimension exponent. This allows the complex FFT to be done without dimension reversal (but note that dimension reversal is required by RMFFT). The dimension shifting subroutine DMPERM, of Appendix D, also uses this feature. In both these cases, I/O is not fully optimized and specially written programs could reduce the number of I/O passes by combining some of the separate, in-core permutations.

Bit-reversed index pairs are generated by a very efficient recursion algorithm (routine MFREV). The algorithm maintains a hierarchy of "reversed" integers of increasing number of bits, up to 2 less than the number being reversed. Incrementing a reversed integer then requires the alternate simple addition of a constant or replacement by the next lower incremented reversed integer in the hierarchy, recursively. For example, with a 3-bit reversal, the reversed set is (0, 4, 2, 6, 1, 5, 3, 7) where the next value is obtained either by adding 4 to the last or by replacing it by one of the values (0, 2, 1, 3) of a 2-bit reversed set.

This method of reversed series generation is in itself fast, as recursion depths are small on the average. But, in addition, only quarter-length series are generated (−2 bits) and the full-length series is derived by scaling by 2 and adding offsets. This is equivalent to reversing an integer a(integer − 2 bits)b to b(reversed integer − 2 bits)a where a and b are the outer bits. There are four possible combinations for ab, but only those reversals greater numerically than before reversal are required (to prevent nullifying double swaps), leaving in general the three offsets $1\cdots0$, $0\cdots0$, and $1\cdots1$. In particular, only the first offset is required if the internal (reversed integer − 2 bits) is smaller than or the same as before reversal. Thus, only valid swap index pairs are generated, saving the unnecessary reversed integer generation of some other methods.

Real Data. For transforms in which the initial or final data is real, a half-length complex transform of packed real data must be unscrambled (or vice versa) by routine MFRCMP. The method relies on complex-conjugate symmetry in the transform of real data [4]. Calculation of indices of multidimensional symmetry is more difficult than in the one-dimensional case. To do this a recursion algorithm is used, which is most easily described by the following Fortran program (for two dimensions, N1-by-N2 elements):

```
L2 = N2/2 + 1
DO 1 J2 = 1, L2
```

```
      K2 = N2 + 2 - J2
      IF(J2.EQ.1)K2 = 1
      L1 = N1
      IF(J2.EQ.K2)L1 = N1/2 + 1
      DO 1 J1 = 1, L1
      K1 = N1 + 2 - J1
      IF(J1.EQ.1)K1 = 1
C     Now have A(K1, K2) and A(J1, J2) as a pair with conjugate symmetry
    1 CONTINUE
```

Note is taken of the special cases which exist when the J index is 1 (Fortran) and when the J and K indices are equal. The general case follows by repetition of the code between the two DO statements, replacing J2 by Jj, etc. In routine MFRCMP arrays JAYA(4), etc., are used for this purpose. To increase the number of dimensions allowed in RMFFT (Appendix A), increase the array sizes. To help visualize the result, the index relationships (Fortran index −1) for an 8-by-4 array are as follows (r for real IF(index(K1, K2).EQ.index(J1, J2)), where index(J1, J2) = J1 + (J2 −1)*N1, for example, c for complex conjugate):

r00	01	02	03	r04	c03	c02	c01
10	11	12	13	14	15	16	17
r20	21	22	23	r24	c23	c22	c21
c10	c17	c16	c15	c14	c13	c12	c11

The array above represents the transformation and transposition of a 4-by-8 real array (imaginary part zero). However, we may also consider it to represent the scrambled transform of an array of initially packed real data, occupying alternately real and imaginary elements, that is, initially 8-by-8 real values. In this case the result is only half-length, element pairs such as 15 and c15 above containing information which can be unscrambled to give a new element 15 and an element 33 in place of c15. In addition, new elements c15 and c33 are derived. Thus the array is expanded to an 8-by-8 full transform of the real data:

r00	01	02	03	r04	c03	c02	c01
10	11	12	13	14	15	16	17
20	21	22	23	24	25	26	27
30	31	32	33	34	35	36	37
r40	41	42	43	r44	c43	c42	c41
c30	c37	c36	c35	c34	c33	c32	c31
c20	c27	c26	c25	c24	c23	c22	c21
c10	c17	c16	c15	c14	c13	c12	c11

Note that the same indexing algorithm applies in both examples (with different N2) but during unscrambling and expansion only the half-length symmetry is used (N2 = 4); corresponding expanded rows in the new array are obtained by a direct offset (4 in this case). Thus, by half-length symmetry, initial rows 1 and 3 are accessed together for unscrambling; these are replaced by unscrambled rows 1 and 3 of the full array while new rows 5 and 7 are also computed and added to the array. It is this ability to add data beyond the existing data which makes dimension reversal essential for in-place computation in the real mass store FFT routine RMFFT.

The complete array is "fully redundant," nearly half the elements being complex conjugates of the other half. If the last three rows of the example are left out, the result is "partially redundant," since row 0 and row 4 still have some internal redundancy. To eliminate all redundancy, rows 0 and 4 can be merged (c43, c42, c41 replacing c03, c02, c01), and pairs of real elements combined as single complex elements (r40 as the imaginary part with r00 real, r44 with r04).

The exact algorithm by which an array with IPAK = 0 or −1 (see Appendix A) can be restored to full redundancy is given by the half-length symmetry program above, putting

```
A(J1, J2 + N2) = CONJG(A(K1, K2))
A(K1, K2 + N2) = CONJG(A(J1, J2)),   IF(J2.NE.1)
```

with special provision IF(J2.EQ.1) when IPAK = −1:

```
A(K1, K2 + N2) = A(K1, K2)
A(J1, J2 + N2) = CONJG(A(K1,K2))
A(K1, K2) = CONJG(A(J1, J2))
```

and IF(index(K1, K2).EQ.index(J1, J2)) when IPAK = −1, values are real:

```
A(J1, J2 + N2) = CMPLX(AIMAG(A(J1, J2)), 0.)
A(J1, J2) = CMPLX(REAL(A(J1, J2)), 0.)
```

the general case follows with Jj and Nj instead of J2 and N2 and as before with repetition of the code between DO statements.

Conclusion

The number of I/O passes through the mass store array depends on the array size (2**M), the core store working space size (2**ICEX), and the I/O block or record size (2**IBEX). In general, the larger the working space and the smaller the block size the better, but block size should not be made too small because of other overheads. The FFT computation requires

$$\mathcal{I}((M - IBEX + 1)/(ICEX - IBEX))$$

passes involving I/O (where $\mathcal{I}(x)$ is the smallest integer greater than or equal to x). Postcomputation sorting requires a similar number of passes (without sorting overlap), although DeLotto and Dotti [5] mention

$$\mathcal{I}((M - ICEX + 1)/(ICEX - IBEX))$$

passes. The reason this is not achieved is that in-place sorting requires M − IBEX + 1 virtual permutations to leave a physically unpermuted array. A change in the algorithm to a smaller number M − ICEX + 1 virtual permutations requires an extra block-sorting pass of mass store, nullifying the advantage.

Figure 2 gives the maximum range of block size exponent IBEX necessary to keep the number of I/O passes N of the mass store array low, given ICEX and M. Solid lines bound the optimum N = 4. Dashed lines are the boundaries for the next best N = 6 passes, and it should not be difficult to operate with N = 4 or 6 in most cases. When calling the half-length transform by subroutine RMFFT, increase diagram M and N by 1 to obtain the working M and N.

The hatched line cutting across the figure gives a bound below which all mass store passes access all blocks. In the area above the line,

$$\mathcal{I}((IBEX - 1)/(ICEX - IBEX))$$

sorting passes are required with an additional pass of mass store involving a block reshuffle, in which only some of the blocks are accessed. That is, the optimum can approach N = 3 passes. Given an I/O system which allows alteration of the index key of a block, the block shuffle can be replaced by an index shuffle, giving N − 1 passes in the upper area. Note also that the diagram is only approximate, as integral rounding effects may increase or decrease the number of passes by one at some points.

Run time depends on two main factors, the computation time of the in-core FFT and the I/O time. A total elapsed time can be written approximately

$$T = TC*M*2**M + TM*N*2**M$$

where TC and TM are unit computation and unit mass store average access and transfer times corresponding to each complex element. As an example, consider two very different computer systems, a PDP 11/40 system and a CYBER 76 installation. Then we may expect TC = 0.5 ms (PDP 11) or 2 μs (CYBER), and TM = 1 ms (PDP 11, IBEX = 7) or 0.5 ms (CYBER, IBEX = 9) for routine CMFFT. Calling subroutine RMFFT with packed real data roughly halves the time, so that a 256-by-256 real array can be transformed in about 5 min (PDP 11) or 1 s (CYBER) CPU time and 8 min (PDP 11) or 1 min (CYBER) elapsed time.

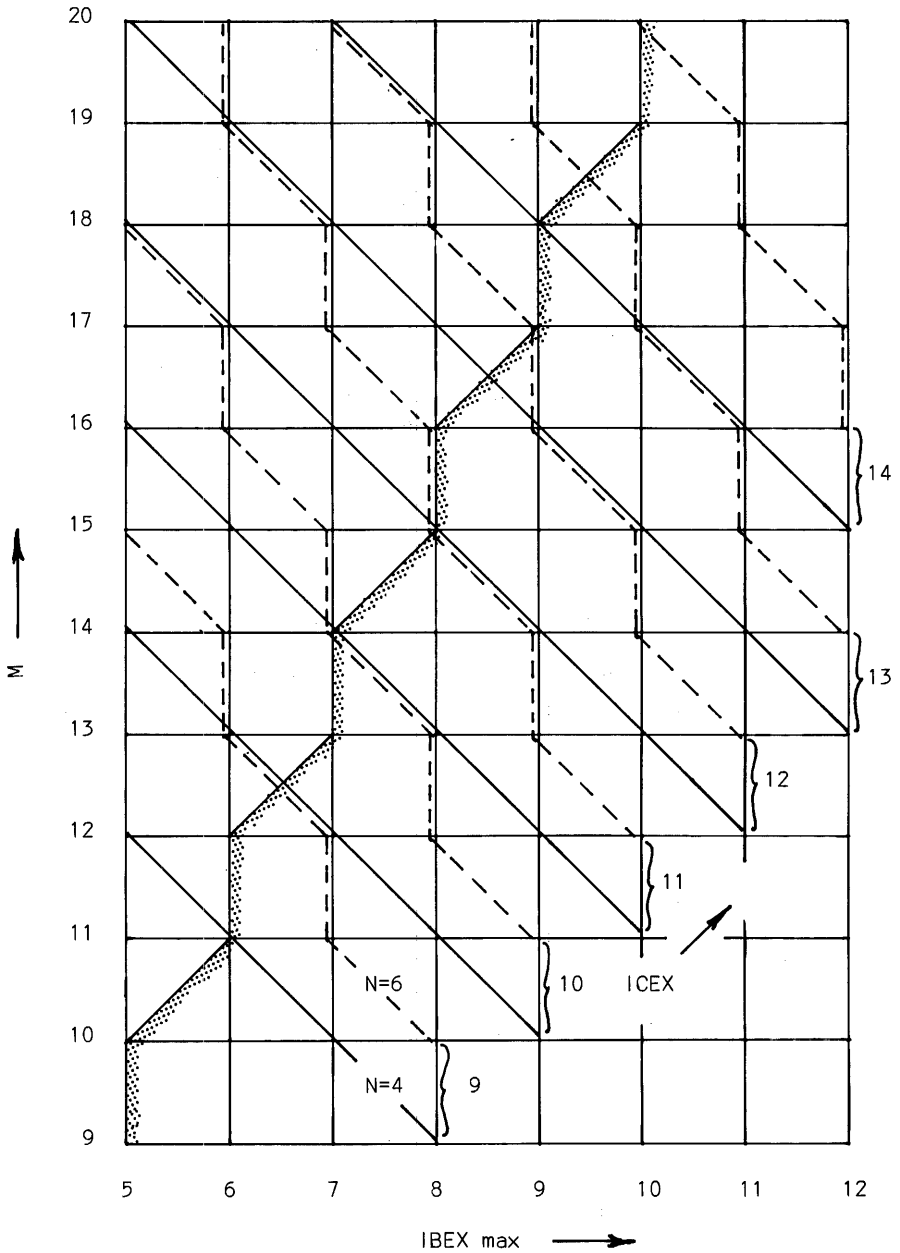

Fig. 2. Mass store I/O passes N related to binary exponents IBEX, ICEX, and M for routine CMFFT. Increase diagram values of M and N by 1 to obtain working M and N for routine RMFFT.

But in machines such as the CYBER, where computing speed is very great compared to I/O latency, the routines are used to great advantage for transforming arrays in LCM (extended memory) in place of mass store, using high-speed, block-copy operations between this and main memory (see Appendixes E and F). Whether an array is multidimensional or not makes little difference to efficiency.

Both TC and TM are block size dependent, there being fixed overheads per block. Both therefore can be written

$$TC = TCO + TCA/2^{**}(IBEX - 1), \qquad TM = TMO + TMA/2^{**}(IBEX - 1)$$

where TCA is the FFT computation overhead per block and TMA is the average mass store access time per block. TCO and TMO are the limits for large block size. TCA and TMA set a useful lower limit for block size. In the examples above TM is mainly the result of TMA, or system block access time. Increasing block size reduces TM but with a probable increase in N (depending on M and ICEX).

TC is mainly due to TCO, TCA becoming important typically when IBEX < 5. To determine the most efficient parameter combination, begin by choosing ICEX as large as possible; use Figure 2 as a guide in choosing IBEX but follow this up by timing comparisons over a range of IBEX.

The program was written to test the sorting algorithm [8] in practice. At the same time a useful and efficient Fourier program has been obtained, operating with a very general set of parameters. Some parameter combinations can lead to short cuts, not detected or implemented here (see the section, Algorithm Details). Efficiency in a particular case can no doubt be improved by some recoding at the expense of a loss in generality or increase in code complexity.

Hopefully this program will stimulate designers not only of fast transforms but also of general purpose systems. Sorting by index bit manipulation should be considered an important concept for new machine architecture. Index bit reversal is simple to achieve in hardware and, in its generalized form [8], is a symmetric permutation (allowing in-place operation) which forms the basis of a number of useful permutations, not exclusively associated with the FFT.

Appendix A. Program Usage

The complex FFT routine is called by

```
CALL CMFFT (MEXA, NDIM, ISGN, IDIR, SCAL, BUFA, IBEX, ICEX)
```

while the faster, real-to-complex (or vice versa) FFT routine is called by

```
CALL RMFFT (MEXA, NDIM, ISGN, IDIR, SCAL, BUFA, IBEX, ICEX, IPAK)
```

where the subroutine arguments have the following meanings:

MEXA Integer array of size NDIM (defined below). MEXA consists of a list of dimension size binary exponents, defining the dimensioning of the mass store array. For example, a one-dimensional array has a size of 2**MEXA(1) elements. A two-dimensional array has 2**MEXA(2) sets of 2**MEXA(1) adjacent elements each (N1 and N2 of definition equations (1) or (2) are 2**MEXA(1) and 2**MEXA(2) in initial order).

Notes: (1) The FFT routines actively modify the MEXA list, if necessary, leaving it in the order corresponding to the final array dimensioning. In general, its order is reversed by the FFT, except in the special case with routine CMFFT discussed under parameter IDIR below. The MEXA list should therefore be linked to a unique mass store array so that it always indicates the current dimensioning of that array.

(2) The MEXA list of exponents always refers to the dimensioning of a full array, as required by routine CMFFT or by routine RMFFT with IPAK = +1 (defined below). The complex result of routine RMFFT operating on real data is truncated when IPAK = 0 or −1, so that the MEXA list elements in these cases may refer to a virtual array length.

(3) The first element of the list always gives the size 2**MEXA(1) of the set or sets of adjacent elements in the first dimension of the mass store array. If data are of type complex, this is the number of complex elements in each set while if data are of type real (e.g., before calling routine RMFFT in direction real to complex), this is the number of real elements.

(4) Mass store array dimensioning is independent of I/O block transfer size and core working space size.

NDIM Number of dimensions in mass store array (size of MEXA list). Range $1 \leq NDIM \leq 4$ (RMFFT), to increase (see the section, Algorithm Details), or $1 \leq NDIM \leq M$ (CMFFT).

(M) Not a call parameter, but defined here for convenience. M = sum to NDIM of MEXA list, giving total mass store array size = 2**M elements

(number of complex elements for routine CMFFT, real or complex elements for routine RMFFT; but see under IPAK packing parameter below).

ISGN The sign of ISGN is the sign of the complex exponent of the transform definition (e.g., eq. (1) or (2)). A positive or negative sign results in the inverse transform of the other; but see also below.

IDIR Transform direction (RMFFT), reversal (CMFFT) parameter. Routine RMFFT converts packed real data to complex data (or vice versa) during transformation, so that IDIR is needed to determine the direction, independently of ISGN; thus

IDIR = −1, real to complex (RMFFT), dimension reversal;
IDIR = +1, complex-to-real (RMFFT), dimension reversal.

(Note that it is usually most convenient to use the same variable for both ISGN and IDIR so that a single negation results in transform inversion.)

Routine CMFFT does not need a direction parameter, other than ISGN, and IDIR is used in this case to set dimension reversal (transposition in two dimensions) or not, as required, thus

IDIR not zero, dimension reversal (more efficient I/O);
IDIR = 0, do not use (RMFFT), suppress reversal (CMFFT).

SCAL Arbitrary type real scale factor of eq. (1) or (2). If SCAL = 1.0 computation is fastest as no scaling occurs.

BUFA Array in core to be used as workspace by FFT routines. Note that internal FFT subroutines assume the following: (1) BUFA is either type real or complex, to suit local needs. (2) BUFA is given the trivial dimension BUFA(1) internally, since its actual size is known only as the exponent ICEX (defined below). (3) Type complex data are assumed to be stored in the sequence real/imaginary/real/imaginary/... in core store and mass store. Some of these points may upset some Fortran compilers.

IBEX Mass store I/O block transfer size binary exponent.
Block or record size = 2**IBEX real elements.

Limits are $2 \le IBEX \le ICEX - 2$ (RMFFT),
or $1 \le IBEX \le ICEX - 1$ (CMFFT).

ICEX Core store working space size binary exponent.
Dimension of BUFA = 2**ICEX real elements.

Limits are $IBEX + 2 \le ICEX \le M$ (RMFFT),
or $IBEX + 1 \le ICEX \le M + 1$ (CMFFT).

IPAK Packing parameter (routine RMFFT only). Determines the degree of redundancy (discussed further in the section, Algorithm Details) desired in the complex result after a real-to-complex transform; thus:

IPAK = +1 gives a fully redundant complex result. The final mass store array is exactly twice the physical length of the initial real array, having the same number, 2**M, of complex elements as initial real elements. This is the same result that is obtained when calling CMFFT with the initial data occupying the real part of a complex array, zero imaginary.

IPAK = 0 gives a partly redundant complex result, slightly longer than the initial real array. In this case there are 2**(M − 1) + 2**(M − MEXA(NDIM)) complex elements in the final array, the MEXA list in the order after the transform (increased to an integral number of mass store blocks, if necessary). This is probably the most useful packing.

IPAK = −1 gives a result containing no redundancy and having exactly the same physical length as the initial 2**M real elements, or 2**(M − 1) complex elements. This is achieved by squeezing together those parts of the array cussed in the section, Algorithm Details. No information is lost and, for one or two dimensions, only a little sorting is needed to access unsqueezed information. For example, in one dimension, the real value at the Nyquist frequency becomes the imaginary part of the zero frequency element, which also must be real.

Notes: (1) For IPAK = +1 or 0 the mass store array file must be extendable. IPAK = −1 has the advantage that the mass store array file remains a fixed length, but has the disadvantage that some user effort is needed to access complex data correctly.

(2) In the complex-to-real direction, IPAK = +1 or 0 are equivalent, since only part of a fully redundant complex array is accessed by RMFFT in this direction. But IPAK = −1 must be used in both directions to correctly handle the squeezed complex array.

Appendix B. Helper Routine

To help the user set up the arguments of Appendix A and to determine the mass store file and block sizes, a helper routine MFPAR is included. Use of the routine is not essential, but is recommended. The routine is called by

```
IERR = MFPAR (IRMF, ICOMP)
```

with IRMF = −1 if mass store data are currently packed real or +1 if data are currently complex when using routine RMFFT. When using routine CMFFT, IRMF = 0. If ICOMP = 0 the argument exponents MEXA( ), IBEX, and ICEX are defined by the user while if ICOMP is not zero the exponents are to be computed by MFPAR.

Three COMMON blocks are used to transmit other data; thus

```
COMMON/MFARG/MEXA(4), NDIM, ISGN, IDIR, SCAL, IBEX, ICEX, IPAK
COMMON/MFVAL/DIMA (4), TDM1, RDM1, FBLK, TBLK, RBLK, RCOR, SIZE
COMMON/MFINT/ NDMA(4), NTD 1, NRD1, NFBK, NTBK, NRBK, NRCR, NSZE
```

MFARG holds a four-element MEXA( ) list (for up to four dimensions) followed by the other mass store FFT call arguments (except BUFA). NDIM, IBEX, ICEX, and IPAK must be preset (unless ICOMP not zero), while ISGN, IDIR, and SCAL are ignored here.

COMMON blocks MFVAL and MFINT return data computed by routine MFPAR. These include the four-element arrays DIMA( ) and NDMA( ) corresponding element by element to MEXA( ) but containing the actual dimension sizes 2**MEXA( ). Similarly, RBLK, NRBK, RCOR, and NRCR hold the sizes 2**IBEX and 2**ICEX. Note that MFINT variables are one-to-one integer conversions of MFVAL variables, which are of type real. A local variable FIXMAX determines whether a conversion is allowed (set to 32767. by a data statement in MFPAR, but which may be altered to suit). Any values not converted are set to −1 in MFINT and the function returns MFPAR = −1 to indicate this. IBEX and ICEX are forced to be within the limits defined in Appendix A, and MFPAR = +1 if IBEX is forced too small. Otherwise the function returns MFPAR = 0 normally.

If the helper subroutine argument ICOMP is not zero, the computation is reversed and MEXA( ) exponents are computed from given DIMA( ) real sizes, IBEX and ICEX computed from RBLK and RCOR real sizes. Sizes are adjusted to be integral powers of 2, adjusted up or down to the closest power on a log scale. NDIM and IPAK must still be given in MFARG.

The most useful values computed by MFPAR are NTD1, NRD1, NFBK, NTBK, and NRBK (in MFINT). NRBK is 2**IBEX and is the number of reals in the "record" used for mass store access by the FFT. NTBK is the current total number of records of size NRBK or the current file length. NFBK, on the other hand, is the maximum number of records of size NRBK to be expected, including any mass store array expansion by routine RMFFT (see IPAK = 0 or 1 in Appendix A). NFBK is thus useful for defining the maximum file length to the operating system.

NRD1 is the number of reals in an equivalent record of the current first dimension length ("first" defined by current MEXA(1)). NTD1 is the current number of such equivalent records and these two values are useful for logically accessing a multidimensional mass store array by the user (though not so useful if NDIM = 1). Note that to do this the I/O routines MFREAD and MFWRIT must be able to handle correctly records different in length from NRBK; otherwise NTBK and NRBK should be used. This will be system dependent (see Appendix F).

NSZE, SIZE is the effective total size of the mass store array (2**M) and is useful, for example, in computing the scale factor SCAL.

Note that MFPAR should be called just prior to user file access, and with the correct value for IRMF, to ensure the computed variables reflect the current state of the mass store array.

Appendix C. Example

Suppose we wish to transform a two-dimensional real array having 512 rows (2**9) of 256 adjacent real elements each (2**8), or a total of 128K real elements (2**17), where K = 1024. Suppose we decide to allow a core store working space of 8K real elements (2**13) and to access the mass store array in blocks of 128 real elements (2**7) each, these being quite independent of array dimensioning. Then, using the helper routine MFPAR (Appendix B) to compute file parameters, the mass store file is defined and opened for random access, loaded with data, and subroutine RMFFT is called with

```
      COMMON/MFARG/MEXA(4), NDIM, ISGN, IDIR, SCAL, IBEX, ICEX, IPAK
      COMMON/MFVAL/DIMA(4), TDM1, RDM1, FBLK, TBLK, RBLK, RCOR, SIZE
      COMMON/MFINT/NDMA(4), NTD1, NRD1, NFBK, NTBK, NRBK, NRCR, NSZE

C
      REAL BUFA(8192)
      COMPLEX CBUFA(4096)
      EQUIVALENCE (BUFA(1), CBUFA(1))
C     WORKING ARRAY IN CORE (EQUIVALENCED FOR USER ACCESS)
C
      MEXA(1) = 8
      MEXA(2) = 9
      NDIM = 2
      ISGN = -1
      IDIR = -1
      SCAL = 1.0
      IBEX = 7
      ICEX = 13
      IPAK = 1
C     MASS STORE FFT ARGUMENTS INITIALIZED
C
      IRMF = - 1
      ICOMP = 0
      IERR = MFPAR (IRMF, ICOMP)
C     HELPER ROUTINE, DATA REAL, RMFFT, EXPONENTS DEFINED,
C     IF(IERR.EQ.0) OK
C     COMPUTES FILE PARAMETERS IN COMMON AREAS (NOT ESSENTIAL)
```

(open mass store file here)

```
C     HERE CAN OPEN MASS STORE FILE, NFBK MAX 'RECDS' OF NRBK REALS
C
```

```
      DO 2 JB = 1, NTD1                    (or NTBK)
      DO 1 I = 1, NRD1                     (or NRBK)
1     BUFA(I) = (Enter a real variable here)
2     CALL MFWRIT (BUFA, NRD1, JB)         (or (BUFA, NRBK, JB))
C   LOAD MASS STORE FILE WITH PACKED REAL DATA
C   (IF MFREAD/MFWRIT REQUIRE FIXED RECD LENGTH, USE NTBK, NRBK)
C
```

CALL RMFFT (MEXA, NDIM, ISGN, IDIR, SCAL, BUFA, IBEX, ICEX, IPAK)

resulting in the transform of eq. (2), with SCAL = 1.0, N1 = 256, N2 = 512, and a negative complex exponent. Because the initial data are packed real and because the parameter IPAK = 1 is chosen, the mass store array will be extended to 128K complex elements, or twice its initial physical size. This array is a fully redundant transform of the original, having 256 rows (2**8) of 512 adjacent complex elements (2**9), the dimensions being reversed or transposed. To indicate transposition to the MEXA list will be reversed (MEXA(1) = 9, MEXA(2) = 8 after the transform).

To save unnecessary array extension, the last parameter IPAK can be made 0 or −1. If IPAK = 0 the result is a partially redundant transform, being the first 129 rows (2**MEXA(2)/2 + 1) of the transform, of 512 adjacent complex elements each. The first and last rows each have an internal conjugate symmetry, but other redundancy is deleted.

If IPAK = −1 the first and last rows above are "squeezed" together, the second half of the last row becoming the second half of the first row. In addition, the first and middle real elements of the last row become the imaginary parts of the first and middle elements of the first row, resulting in an array of 128 rows of 512 complex elements, exactly the same physical length as the initial array, so that no file extension is necessary (see the section, Algorithm Details).

The complex result is accessed, then an inverse transform is called by

```
      IRMF = 1
      IERR = MFPAR (IRMF, ICOMP)
C   HELPER ROUTINE AGAIN, DATA COMPLEX, ROUTINE RMFFT,
C   IF(IERR.EQ.0) OK
C
      NCNT = NRD1/2                        (or NRBK/2)
C   NCNT IS THE NUMBER OF COMPLEX ELEMENTS IN RECORD
      DO 4 JB = 1, NTD1                    (or NTBK)
      CALL MFREAD (BUFA, NRD1, JB)         (or (BUFA, NRBK, JB))
      DO 3 I = 1, NCNT

3     (access each complex element CBUF(I) here)

4   CALL MFWRIT (BUFA, NRD1, JB)           (or (BUFA, NRBK, JB))

C   COMPLEX RESULT READ BY USER (WRITING NEW VALUES IF DESIRED)
C   (IF MFREAD/MFWRIT REQUIRE FIXED RECD LENGTH, USE NTBK, NRBK)
C
      ISGN = −ISGN
      IDIR = −IDIR
      SCAL = 1.0/SIZE
      CALL RMFFT (MEXA, NDIM, ISGN, IDIR, SCAL, BUFA, IBEX, ICEX, IPAK)
```

The scale factor SCAL, using SIZE = 2.**M computed by MFPAR, is chosen here to normalize the result to the same scale as the original data. The result is a real array having 512 rows of 256 adjacent real elements each, the MEXA list being restored to its initial order.

Appendix D. Bonus Routine

The sorting algorithm used in the mass storage FFT may also be used for changing the order of dimensioning of a multidimensional mass store array. This is similar to, but more general than, Eklundh's method [7]. As an example, and in addition to the FFT routines, a dimension-shifting routine DMPERM is included for completeness, called by

```
CALL DMPERM (MEXA, NDIM, NSHFT, IREX, BUFA, IBEX, ICEX)
```

where the arguments MEXA, NDIM, BUFA, IBEX, ICEX have the same meaning as in the FFT calls.

The other parameters are

NSHFT	Dimension shift count.	
	NSHFT = 0	No shift or change occurs.
	NSHFT = 1, 2 etc.	First-to-next dimension, circular NSHFT place shift, modulo (NDIM).
	NSHFT = −1	Dimension order reversed.
IREX	"Element size" binary exponent (size = 2**IREX reals); thus IREX = 0 for real array, IREX = 1 for complex array.	

Most of the comments concerning the FFT routine parameters apply also to this routine. The mass store array is either real or complex (or "elements" of multiple reals), with an MEXA list defining the current dimensioning (binary exponents). The MEXA list is actively modified by the routine if necessary. (Note that to sort arrays of elements smaller in size than type real, such as the type byte elements of some systems, it is necessary to alter type statements for BUFA and TEMP variables in all subroutines called.)

The routine is quite trivial in design, consisting of only 20 statements. It operates by calling the generalized mass store bit-reversed sorting routine MFSORT, used internally by the FFT routines, and therefore has a similar I/O efficiency to the FFT routines (see the conclusion section).

Appendix E. Test Programs

A universal test program is provided which sets up, for a given M, exhaustive permutations and combinations of the different parameters IBEX, ICEX, and NDIM from one to three dimensions. Mass store is simulated, through dummy routines MFREAD and MFWRIT, by a core store array so that the program is independent of system I/O.

The program stores a pseudorandom number sequence in the simulated mass store, transforms this by the mass store FFT routines, and compares the result with a discrete Fourier transform computed naively by routine NAIVE. An inverse mass store FFT is called and the result compared with the initial data. Maximum differences are noted and various levels of data and difference printout are available through parameter IPRINT. The test is considered successful if maximum differences are explainable in terms of machine roundoff errors.

Because the tests are exhaustive and because of the naive DFT computation the program is quite slow when the overall array size exponent M is other than very small. For example, in a CYBER 76 computer with M = 5 the program takes 0.3 s while with M = 10 the program takes about 800 s. Less exhaustive testing can be done by replacing program DO-loop variables by fixed variables (see program comments).

Example test programs are also included for accessing mass store in two specific computer systems. These are a CYBER 76 (true mass store and LCM "static" mass store) and a PDP 11. Mass store I/O routines for other systems should be easily devised based on these examples and the comments of Appendix F.

Appendix F. System-Dependent I/O Routines

The system-dependent random access transfers between mass store and core store are handled by two subroutines called internally by the FFT routines; thus

```
CALL MFREAD (BUFA, NB, JB)      read block into core store
CALL MFWRIT (BUFA, NB, JB)      write block from core store
```

where BUFA is the core store address for the start of the transfer, NB is the number of real elements to be transferred, and JB is the desired block or record number. The range of JB is as follows:

for CMFFT or RMFFT if IPAK = +1,

$1 \le JB \le 2**(M - IBEX + 1),$

for RMFFT if IPAK = 0,

$1 \le JB \le 2**(M - IBEX) + 2**(M - MEXA(NDIM) - IBEX + 1),$ for $MEXA(NDIM) + IBEX < M + 1,$

or

$1 \le JB \le 2**(M - IBEX) + 1,$ for $MEXA(NDIM) + IBEX \ge M + 1,$

(the MEXA list in the order after the transform)

for RMFFT if IPAK = −1,

$1 \le JB \le 2**(M - IBEX).$

In addition, the I/O subroutines must know what file to access and any starting block offset, which may be given through COMMON variables, for example. The routines expect the mass store file to be defined and opened. The user program may, of course, call MFREAD and MFWRIT itself to load mass store with data or read the transform result.

For example, in PDP 11 Fortran a random access occurs with

```
      SUBROUTINE MFREAD (BUFA, NB, JB)
C   READ BLOCK, INDEX JB, FROM MASS STORE TO BUFA, NB REAL VALUES
      REAL BUFA(NB)
      COMMON/FFTCOM/LUN
      READ (LUN'JB)(BUFA(I), I = 1, NB)   or   READ (LUN'JB) BUFA
      RETURN
      END
```

and similarly for subroutine MFWRIT.

As discussed in Appendixes B and C it may be useful to call MFREAD/MFWRIT with a record length NB different from 2**IBEX. This can give a user more logical access to a multidimensional array, in records of first dimension length, for example. Some systems allow a redefinition of the file structure, in which case the problem is solved. Others allow a "word-addressable" file structure in which an I/O transfer may start at any word in the file. In this case, MFREAD/MFWRIT can include the following:

$INDEX = (JB - 1)*NB + 1$

(transfer between file real element indices (INDEX) and (INDEX + NB − 1). The dummy I/O routines of the universal test program of Appendix E and the CYBER Extended Core/LCM and PDP 11 Macro routines include this feature.

Subroutines MFREAD and MFWRIT allow the user considerable scope for modifying the operation of the FFT routines. In the universal test driver program (Appendix E) the subroutines simply copy data from one core store array to another. In some systems external core store can be accessed efficiently in blocks, which allows this to be used as a fast, static mass store. Using different files on the first I/O pass for MFREAD and MFWRIT allows data to be copied automatically from a source file to a working and result file. In this case care must be taken to allow only a single read of each block of the source file, any subsequent read, even on the "first" I/O pass, being from the working file (important during complex-to-real transformation by routine RMFFT).

ALGORITHM 546
SOLVEBLOK [F4]

CARL DE BOOR
Mathematics Research Center, The University of Wisconsin–Madison
and
RICHARD WEISS
Technische Universität Wien, Austria

Key Words and Phrases: almost block diagonal systems, Gaussian elimination, spline approximation, ordinary differential equations
CR Categories: 5.13, 5.14, 5.17
Language: Fortran

DESCRIPTION

This Fortran package is a complement to [1] where its design is explained and it is compared with related algorithms.

ALGORITHM

```
      SUBROUTINE SLVBLK ( BLOKS, INTEGS, NBLOKS, B, IPIVOT, X, IFLAG )  BLKØØ1ØØ
C     THIS PROGRAM SOLVES  THE  LINEAR SYSTEM  A*X = B  WHERE A IS AN    BLKØØ2ØØ
C  ALMOST BLOCK DIAGONAL MATRIX.  SUCH ALMOST BLOCK DIAGONAL MATRICES    BLKØØ3ØØ
C  ARISE NATURALLY IN PIECEWISE POLYNOMIAL INTERPOLATION OR APPROX-      BLKØØ4ØØ
C  IMATION AND IN FINITE ELEMENT METHODS FOR TWO-POINT BOUNDARY VALUE    BLKØØ5ØØ
C  PROBLEMS.  THE PLU FACTORIZATION METHOD IS IMPLEMENTED HERE TO TAKE   BLKØØ6ØØ
C  ADVANTAGE OF THE SPECIAL STRUCTURE OF SUCH SYSTEMS FOR SAVINGS IN     BLKØØ7ØØ
C  COMPUTING TIME AND STORAGE REQUIREMENTS.                              BLKØØ8ØØ
C                                                                        BLKØØ9ØØ
C                  PARAMETERS                                            BLKØ1ØØØ
C  BLOKS   A ONE-DIMENSIONAL ARRAY, OF LENGTH                           BLKØ11ØØ
C                   SUM( INTEGS(1,I)*INTEGS(2,I) , I = 1,NBLOKS )       BLKØ12ØØ
C          ON INPUT, CONTAINS THE BLOCKS OF THE ALMOST BLOCK DIAGONAL    BLKØ13ØØ
C          MATRIX  A  .  THE ARRAY INTEGS (SEE BELOW AND THE EXAMPLE)    BLKØ14ØØ
C          DESCRIBES THE BLOCK STRUCTURE.                                BLKØ15ØØ
C          ON OUTPUT, CONTAINS CORRESPONDINGLY THE PLU FACTORIZATION     BLKØ16ØØ
C          OF  A  (IF IFLAG .NE. Ø).  CERTAIN OF THE ENTRIES INTO BLOKS  BLKØ17ØØ
C          ARE ARBITRARY (WHERE THE BLOCKS OVERLAP).                     BLKØ18ØØ
C  INTEGS  INTEGER ARRAY DESCRIPTION OF THE BLOCK STRUCTURE OF  A .      BLKØ19ØØ
C            INTEGS(1,I) = NO. OF ROWS OF BLOCK I        =  NROW        BLKØ2ØØØ
C            INTEGS(2,I)= NO. OF COLUMNS OF BLOCK I      =  NCOL        BLKØ21ØØ
C            INTEGS(3,I) = NO. OF ELIM. STEPS IN BLOCK I =  LAST        BLKØ22ØØ
```

ALGORITHM 547
Fortran Routines for Discrete Cubic Spline Interpolation and Smoothing [E1], [E3]

CHARLES S. DURIS
Drexel University

Key Words and Phrases: discrete splines, discrete cubic splines, discrete natural splines, interpolation, smoothing
CR Categories: 5.12, 5.13
Language: Fortran

DESCRIPTION

1. Introduction

Two Fortran subroutines, DCSINT and DCSSMO, are presented here for discrete cubic spline interpolation and smoothing. The theory for discrete cubic spline interpolation is given by Lyche in [5, 6]. The theory for discrete natural cubic spline smoothing is given by the author in [2]. For most applications continuous splines (see [3, 4, 7]) are probably more appropriate than discrete splines. Discrete spline interpolation and smoothing are worth considering for problems involving functions defined on discrete equally spaced points, or when difference quotients are available as data rather than derivatives. Possible areas of application are discrete time series analysis, computer routines for plotting data, and actuarial- and demographic-type data analysis.

For both discrete cubic spline interpolation and smoothing we direct our attention to the problem of approximating a function $g(t)$ defined on an interval $[\tau_1, \tau_n]$. The values $g(\tau_i) = g_i$ are specified for $i = 1, 2, \ldots, n$, where $\tau_i < \tau_{i+1}$. For many applications and for deriving the equations in Sections 2 and 3, it is convenient to assume that $g(t)$ is defined on a discrete point set $T_M = \{t_0, t_1, \ldots, t_M\}$ where $t_j = \tau_1 + jh$ for some fixed step size $h > 0$, and also that the τ_i's belong to T_M. Neither the theory nor the routines DCSINT and DCSSMO require that the τ_i's belong to T_M. The only mandatory restriction on the τ_i's is $\tau_i < \tau_{i+1}$.

Discrete cubic splines defined on $[\tau_1, \tau_n]$ with nodes (or knots) $\Lambda_n = \{\tau_1, \tau_2, \ldots, \tau_n\}$ are functions $S(t)$ having the form $S(t) = S_i(t)$ where

$$S_i(t) = g_i + b_i(t - \tau_i) + c_i(t - \tau_i)^2 + d_i(t - \tau_i)^3 \qquad (1)$$

for $t \in [\tau_i, \tau_{i+1}]$ (i.e., $S(t)$ is piecewise cubic). The $S_i(t)$'s satisfy the joining

Received 22 November 1976 and 8 January 1979.

Author's address: Because Dr. Charles Duris has recently passed away, all correspondence regarding this paper should be directed to Dr. Robert Busby, Department of Mathematical Sciences, Drexel University, Philadelphia, PA 19104.

conditions

$$S_i(\tau_{i+1}) = S_{i+1}(\tau_{i+1}), \tag{2}$$

$$\tfrac{1}{2}(\nabla + \Delta)S_i(\tau_{i+1}) = \tfrac{1}{2}(\nabla + \Delta)S_{i+1}(\tau_{i+1}), \tag{3}$$

$$\nabla\Delta S_i(\tau_{i+1}) = \nabla\Delta S_{i+1}(\tau_{i+1}), \tag{4}$$

where $\Delta f(x) = f(x + h) - f(x)$ and $\nabla f(x) = f(x) - f(x - h)$. Conditions (3) and (4) should be recognized as requiring the matching up of the first central and the second central differences at τ_{i+1} for adjacent cubics.

Subroutine DCSINT constructs the discrete cubic spline function on the interval $[\tau_1, \tau_n]$ which interpolates the data (τ_j, g_j) for $j = 1, 2, \ldots, n$ and satisfies one of the three following end conditions:

I. The first central divided difference end conditions

$$\frac{1}{2}\frac{(\nabla + \Delta)S(\tau_1)}{h} = S_1^{(1)} \qquad \text{and} \qquad \frac{1}{2}\frac{(\nabla + \Delta)S(\tau_n)}{h} = S_n^{(1)}$$

for specified values of $S_1^{(1)}$ and $S_n^{(1)}$.

II. The second central divided difference end conditions

$$\frac{\nabla\Delta S(\tau_1)}{h^2} = S_1^{(2)} \qquad \text{and} \qquad \frac{\nabla\Delta S(\tau_n)}{h^2} = S_n^{(2)}$$

for specified values of $S_1^{(2)}$ and $S_n^{(2)}$.

III. The periodic end conditions

$$\tfrac{1}{2}(\nabla + \Delta)S(\tau_1) = \tfrac{1}{2}(\nabla + \Delta)S(\tau_n) \qquad \text{and} \qquad \nabla\Delta S(\tau_1) = \nabla\Delta S(\tau_n)$$

where we assume the data are periodic ($g_1 = g_n$).

In formulating discrete natural cubic spline smoothing, we assume $g(t)$ is defined on a discrete point set T_M. Subroutine DCSSMO constructs the function $S(t)$ which smooths through the data (τ_i, g_i) for $i = 1, 2, \ldots, n$ in the sense that (see [3, 7, 8, 9])

$$\sigma(f(t)) = \rho \sum_{i=1}^{n} W_i[f(\tau_i) - g_i]^2 + \sum_{j=1}^{M-1} [\nabla\Delta f(t_j)]^2 \tag{5}$$

is minimized for $f(t) = S(t)$. This $S(t)$ turns out to be a discrete natural cubic spline ($\nabla\Delta S(\tau_1) = \nabla\Delta S(\tau_n) = 0$). In (5) the W_i's are positive weights specifying the relative importance of the data, and $\rho > 0$ specifies the amount of smoothing in comparison to data fitting. If ρ is small, the smoothness of the approximation is emphasized at the expense of closely fitting the data. If ρ is large, the discrete natural cubic spline more closely fits the data at the expense of smoothness. In particular, as ρ approaches infinity, the smoothing discrete natural spline approaches the interpolating discrete natural spline.

Sections 2 and 3 describe the equations for constructing the discrete cubic splines for interpolating and smoothing, respectively. Those readers mainly interested in seeing how to use subroutines DCSINT and DCSSMO may turn directly to Sections 4 and 5. Section 6 describes how to construct test examples, and Section 7 presents estimates for execution times.

2. Discrete Cubic Spline Interpolation

The discrete cubic spline $S(t) = S_i(t)$ for $t \in [\tau_i, \tau_{i+1}]$ for $i = 1, 2, \ldots, n - 1$ where $S_i(t)$ is given in (1). A better form for deriving equations is to represent $S_i(t)$ using factorial polynomials as follows:

$$\begin{aligned} S_i(t) = {} & g_i + \bar{b}_i(t - \tau_i) + c_i(t - \tau_i)(t - \tau_i - h) \\ & + d_i(t - \tau_i + h)(t - \tau_i)(t - \tau_i - h). \end{aligned} \tag{6}$$

The g_i, c_i, and d_i in (6) are the same as those found in (1), but

$$b_i = \bar{b}_i - c_i h - d_i h^2. \tag{7}$$

The joining conditions (2), (3), and (4) together with $S(\tau_n) = g_n$ give the equations

$$\gamma_i c_i + (\eta_i + \eta_{i+1})c_{i+1} + \gamma_{i+1}c_{i+2} = 3[g_{i+1}^{(1)} - g_i^{(1)}] \tag{8}$$

for $i = 1, 2, \ldots, n-3$, where $H_i = \tau_{i+1} - \tau_i$,

$$\gamma_i = H_i - \frac{h^2}{H_i}, \tag{9}$$

$$\eta_i = 2H_i + \frac{h^2}{H_i}, \tag{10}$$

$$g_i^{(1)} = g[\tau_{i+1}, \tau_i] = \frac{(g_{i+1} - g_i)}{H_i}. \tag{11}$$

The remaining linear equations for the c_i's come from the end conditions. The complete system of linear equations denoted by

$$Ac = g \tag{12}$$

is now described for the three types of end conditions, I, II, and III. These systems are modified forms of the systems found in Lyche [6].

I. The first central divided difference end conditions have

$$\mathrm{A} = \begin{bmatrix} \eta_1 & \gamma_1 & 0 & \cdots & 0 \\ \gamma_1 & (\eta_1 + \eta_2) & \gamma_2 & & \\ 0 & \gamma_2 & (\eta_2 + \eta_3) & \ddots & \\ \vdots & & \ddots & (\eta_{n-2} + \eta_{n-1}) & 0 \\ & & \gamma_{n-2} & & \gamma_{n-1} \\ 0 & \cdots & 0 & \gamma_{n-1} & \eta_{n-1} \end{bmatrix} \tag{13a}$$

$$c = (c_1, c_2, \ldots, c_n)^{\mathrm{T}}, \tag{13b}$$

$$g = 3(g_1^{(1)} - S_1^{(1)}, g_2^{(1)} - g_1^{(1)}, \ldots, g_{n-1}^{(1)} - g_{n-2}^{(1)}, S_n^{(1)} - g_{n-1}^{(1)})^{\mathrm{T}}. \tag{13c}$$

The c_n in (13b) is $\nabla\Delta S(\tau_n)/2h^2$ and is introduced to preserve symmetry.

II. The second central divided difference end conditions have

$$A = \begin{bmatrix} (\eta_1 + \eta_2) & \gamma_2 & 0 & \cdots & 0 \\ \gamma_2 & (\eta_2 + \eta_3) & \gamma_3 & & \vdots \\ 0 & \gamma_3 & & \ddots & \vdots \\ \vdots & & \ddots & & 0 \\ & & & & \gamma_{n-2} \\ 0 & \cdots & 0 & \gamma_{n-2} & (\eta_{n-2} + \eta_{n-1}) \end{bmatrix} \tag{14a}$$

$$\mathrm{c} = (\mathrm{c}_2, \mathrm{c}_3, \ldots, \mathrm{c}_{n-1})^{\mathrm{T}}, \tag{14b}$$

$$g = (g_2^{(1)} - g_1^{(1)} - \tfrac{1}{6}\gamma_1 S_1^{(2)}, g_3^{(1)} - g_2^{(1)}, \ldots, g^{(1)} - g^{(1)} - \tfrac{1}{6}\gamma_{n-1}S^{(2)}). \tag{14c}$$

In [2] it is shown that the natural end conditions $S_1^{(2)} = S_n^{(2)} = 0$ produce the function which interpolates the given data and minimize $\sum_{i=1}^{N-1} [\nabla\Delta w(t_i)]^2$.

III. The periodic end conditions have

$$A = \begin{bmatrix} (\eta_{n-1} + \eta_1) & \gamma_1 & 0 & \cdots & 0 & \gamma_{n-1} \\ \gamma_1 & (\eta_1 + \eta_2) & \gamma_2 & & & 0 \\ 0 & \gamma_2 & & & & \vdots \\ \vdots & & & \ddots & & 0 \\ & & \ddots & & & \gamma_{n-2} \\ \gamma_{n-1} & 0 & \cdots & 0 & \gamma_{n-2} & (\eta_{n-2} + \eta_{n-1}) \end{bmatrix} \tag{15a}$$

$$c = (c_1, c_2, \ldots, c_{n-1})^T, \tag{15b}$$

$$g = 3(g_1^{(1)} - g_{n-1}^{(1)}, g_2^{(1)} - g_1^{(1)}, \ldots, g_{n-1}^{(1)} - g_{n-2}^{(1)}). \tag{15c}$$

The matrix of the system is tridiagonal except for the γ_{n-1} in the remote corners. This type of linear system is solved in DCSINT using a method described by Björck and Golub in [1], which uses a rank one modification to make (15a) tridiagonal. The number of multiplications and divisions needed to solve system (15) is about $9n$.

The linear systems arising for end conditions I, II, and III are all positive definite and symmetric with nonnegative coefficient matrices A. In all three cases the matrix is strictly diagonally dominant. The infinity condition number for the matrix A in (14a) and (15a) is bounded by (see [2])

$$\text{cond}_\infty(A) \le \|A\|_\infty \|A^{-1}\| \le 3\frac{\max_i(H_{i+1} + H_i)}{\min_i(H_{i+1} + H_i)}. \tag{16a}$$

For (13a) the bound is

$$\text{cond}_\infty(\text{A}) \le 3\frac{\max_i(H_{i+1} + H_i)}{\min_i(H_i)}. \tag{16b}$$

Hence the A matrices are normally very well conditioned.

Once the c_i's are known, the b_i and d_i in (1) are given by

$$d_i = \frac{1}{3H_i}[c_{i+1} - c_i], \tag{17}$$

$$b_i = g_i^{(1)} - \frac{H_i}{3}(2c_i + c_{i+1}) \tag{18}$$

for $i = 1, 2, \ldots, n-1$ (for the periodic case $c_n = c_1$).

In [5] Lyche gives error bounds for discrete cubic spline interpolation using (I) the first central divided difference end conditions. These bounds involve differences for $g(t)$. He also gives an $O(h^2)$ bound for the distance between the discrete cubic spline and the continuous cubic spline interpolating the same data.

3. Discrete Cubic Spline Smoothing

In [2] the author develops the theory for discrete natural spline smoothing. This type of smoothing was originally studied by Whittaker [8] in a slightly different form (see also [9, pp. 303–316]). The equations for the cubic case can be derived without too much difficulty by developing the cubic discrete analog of Theorem 14.1 given by Greville in [3]. This discrete analog is now stated.

THEOREM 3.1. *Let ρ, h, and W_i, $i = 1, 2, \ldots, n$, be positive real numbers. Then there exists a unique function $S(t)$ defined on $T_M = \{t_0, t_1, \ldots, t_M\}$ which minimizes*

$$\sigma(f(t)) = \rho \sum_{j=1}^{n} W_j(f(\tau_j) - g_j)^2 + \sum_{i=1}^{M-1} [\nabla\Delta f(t_i)]^2. \tag{19}$$

This $S(t)$ is the unique discrete natural cubic spline (see (1) or (6)) *satisfying*

$$S(\tau_i) = g_i - \frac{6h^3}{\rho W_i}[d_i - d_{i-1}] \tag{20}$$

where $d_i = (c_{i+1} - c_i)/(3H_i)$ and $d_0 = d_n = 0$.

The resulting system of linear equations for the c_i's in (1) or (6) is obtained from (14a-c) and (17) by putting $S_1^{(2)} = S_n^{(2)} = 0$ and replacing the g_i's used in computing the $g_i^{(1)}$'s by $\tilde{g}_i = S(\tau_i)$, where $S(\tau_i)$ is given by (21).

This linear system is five banded, positive definite, and symmetric (see [2]). The following equations describe this system. For $i = 2, 3, \ldots, n-1$ with the

understanding that $c_0 = c_1 = c_n = c_{n+1} = 0$,

$$\beta_{i-1}c_{i-2} + [\gamma_{i-1} - (\beta_{i-1} + \beta_i + \epsilon_{i-1})]c_{i-1} + [(\eta_{i-1} + \eta_i) + (2\beta_i + \epsilon_{i-1} + \epsilon_i)]c_i$$
$$+ [\gamma_i - (\beta_i + \beta_{i+1} + \epsilon_i)]c_{i+1} + \beta_{i+1}c_{i+2} = 3(g_i^{(1)} - g_{i-1}^{(1)}). \tag{21}$$

The γ_i, η_i, and $g_i(1)$ are given by (9)-(11),

$$\beta_i = \frac{6h^3}{\rho W_i H_{i-1} H_i} \tag{22}$$

for $i = 1, 2, \ldots, n$ with $H_0 = H_n = 1$ ($H_i = \tau_{i+1} - \tau_i$), and

$$\epsilon_i = \frac{(\beta_i H_{i-1} + \beta_{i+1} H_{i+1})}{H_i} \tag{23}$$

for $i = 1, 2, \ldots, n-1$.

The discrete cubic spline smoothing the data (τ_i, g_i) for $i = 1, 2, \ldots, n$ has the form $S(t) = S_i(t)$ for $t \in [\tau_i, \tau_{i+1}]$ with

$$S_i(t) = \tilde{g}_i + b_i(t - \tau_i) + c_i(t - \tau_i)^2 + d_i(t - \tau_i)^3 \tag{24}$$

where the c_i's solve (22), (17) gives d_i, (18) gives b_i, and $\tilde{g}_i = S(\tau_i)$ is given in (21).

The five-banded, positive definite, symmetric matrix arising from (22) need not be strictly diagonal dominant, as was the case for interpolation. The condition number of this matrix becomes large as ρ approaches 0. This is to be expected, since the solution to the smoothing problem is not unique when $\rho = 0$. From (23) and (24) we can see that as ρ becomes large, (22) takes the form of the equations for interpolation. Hence (22) is still reasonably conditioned for many useful values of ρ.

4. Examples for DCSINT

We now show how DCSINT is used to find the discrete cubic spline interpolating the data ($h = 0.1$, $n = 6$)

i	τ_i	g_i
1	0.5	1.0
2	0.7	0.5
3	1.0	2.0
4	1.5	2.5
5	2.1	2.0
6	2.5	1.0

for the three end conditions:

I. First central divided difference

$$\frac{1}{2}\frac{(\nabla + \Delta)S(\tau_1)}{h} = -1.0, \qquad \frac{1}{2}\frac{(\nabla + \Delta)S(\tau_n)}{h} = 0.0.$$

II. Second central divided difference

$$\frac{\nabla\Delta S(\tau_1)}{h^2} = 0.0, \qquad \frac{\nabla\Delta S(\tau_n)}{h^2} = 0.0.$$

(These are the natural end conditions.)

III. Periodic

$$S(\tau_1 - h) = S(\tau_n - h), \qquad S(\tau_1) = S(\tau_n), \qquad S(\tau_1 + h) = S(\tau_n + h).$$

A possible dimension statement for the calling program is

```
DIMENSION TNODE (10), G(10), B(10), C(10), D(10)
```

The nodes τ_i are stored in array TNODE. Note that TNODE (I) must be less than TNODE (I + 1). The data values g_i are stored in array G, and N = 6 and H = 0.1.

I. First Central Divided Difference End Conditions

Put IENT = 1, ENDI = −1.0, and ENDN = 0.0 and call the subroutine as follows:

CALL DCSINT (IENT, H, N, TNODE, G, ENDI, ENDN, B, C, D)

The solution is found in arrays G, B, C, and D.

Solution for I:

I	Interval	G(I)	B(I)	C(I)	D(I)
1	[0.5, 0.7]	1.0	−1.751037	−18.76556	75.10376
2	[0.7, 1.0]	0.5	0.9306393	2.629669	−42.44052
3	[1.0, 1.5]	2.0	4.736782	−11.89979	8.852451
4	[1.5, 2.1]	2.5	−0.4001307	1.378888	−3.501484
5	[2.1, 2.5]	2.0	−2.697525	−4.923788	13.54401

In particular, the discrete cubic spline $S(\tau)$ for $\tau = 1.2$ is given by

$$S(1.2) = 2.0 + 4.736782 \times T - 11.89979 \times T^2 + 8.852451 \times T^3 \qquad (25)$$

where $T = (1.2 - 1.0)$

II. Second Central Divided Difference End Conditions

Put IENT = 2, ENDI = 0.0, and ENDN = 0.0, and call DCSINT as before.

Solution for II:

I	G(I)	B(I)	C(I)	D(I)
1	1.0	−4.069061	0.0	39.22655
2	0.5	1.416796	23.53593	−38.63974
3	2.0	4.640036	−11.23984	7.9195391
4	2.5	−0.5627829	0.6394691	−1.817308
5	2.0	−1.798219	−2.631689	2.193076

III. Periodic End Conditions

Put IENT = 3. ENDI and ENDN may contain anything. Call DCSINT as before. (The subroutine assumes G(1) = G(N), so the content of G(N) is never used.)

Solution for III:

I	G(I)	B(I)	C(I)	D(I)
1	1.0	−3.801780	−2.156043	43.32474
2	0.5	1.357985	23.83881	−38.99586
3	2.0	4.663832	−11.25748	7.8596271
4	2.5	−0.6051248	0.5319628	−1.520514
5	2.0	−1.624539	−2.204966	0.04076882

5. An Example for DCSSMO

We now show how DCSSMO is used to find the discrete cubic natural spline which smoothes through the data used in Section 4. No end conditions are needed. A possible dimension statement for the calling program is

DIMENSION TNODE(10), G(10), GS(10), B(10), C(10), D(10), WGS(10)

The subroutine was run for ρ = RHO = 0.01 and for ρ = RHO = 1.0. The weights W_i, stored in array WGS, were taken to be $W_1 = W_5 = W_6 = 2.0$, $W_2 = 2.5$, $W_3 = 1.0$, and $W_4 = 1.5$. The subsolution is called as follows:

CALL DCSSMO (H, N, TNODE, G, WGS, RHO, GS, B, C, D)

The two solutions are as follows.

$\rho = 0.01$:

I	GS(I)	B(I)	C(I)	D(I)
1	0.7307289	1.536621	0.0	0.8975704
2	1.045234	1.667059	0.5385422	−1.374241
3	1.556716	1.611752	−0.6982756	−0.6354344
4	2.108594	0.4271141	−1.651427	0.3430809
5	1.844454	−1.189260	−1.033881	0.8615685

$\rho = 1.0$:

I	GS(I)	B(I)	C(I)	D(I)
1	0.9166568	−2.545056	0.0	27.78108
2	0.6298941	1.329906	16.66866	−26.34149
3	1.817824	3.915267	−7.038706	4.021049
4	2.518413	−0.06161821	−1.007132	−0.5822141
5	1.993115	−1.921916	−2.055118	1.712599

Theoretically, the discrete cubic spline smoothing the given data will approach, in the limit as ρ goes to infinity, the discrete natural cubic spline interpolating these data. From the graphs given in Figure 1 we can see that the discrete smoothing spline for $\rho = 1.0$ more closely follows the discrete natural interpolating spline than does the discrete smoothing spline for $\rho = 0.01$.

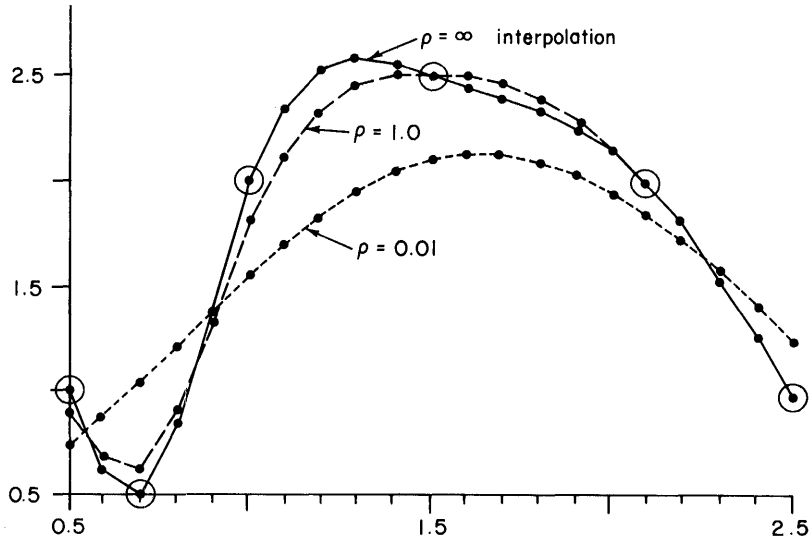

Fig. 1

6. Test Data

Any values may be used for test data g_i, $i = 1, 2, \ldots, n$, when interpolating. The correctness of the interpolating solution provided by DCSINT can be checked by verifying that the end conditions are satisfied and that

$$S_i(t) = S_{i+1}(t) \tag{26}$$

for $t = \tau_{i+1} - h$, τ_{i+1}, and $\tau_{i+1} + h$.

Test data for smoothing (DCSSMO) can be constructed from the discrete natural cubic spline represented in the form

$$S(t) = \alpha_0 + \alpha_1(t - \tau_1) + \sum_{i=1}^{n} \beta_i(t - \tau_i - h)(t - \tau_i)(t - \tau_i + h)\phi_i(t) \tag{27}$$

where

$$\phi_i(t) = \begin{cases} 0 & \text{for } t < \tau_i \\ 1 & \text{for } t \geq \tau_i \end{cases}$$

and the β_i's satisfy

$$\sum_{i=1}^{n} \beta_i = 0, \qquad \sum_{i=1}^{n} \beta_i \tau_i = 0. \tag{28}$$

The data values g_i which produce the $S(t)$ in (28) as the solution to the smoothing problem are given by

$$g_i = S(\tau_i) + 3! \frac{\beta_i}{(\rho W_i)} \tag{29}$$

for $i = 1, 2, \ldots, n$. This follows from Theorem 3.1, eq. (20).

7. Timing Estimates

DCSINT and DCSSMO have been run on the IBM 370/168 computer at the UNI-COLL Corporation in Philadelphia. The subroutines have been compiled and run using the WATFIV compiler and the Fortran G and H compilers. Timing estimates were made for the codes compiled by the G and H compilers. These are now listed.

DCSINT

For IENT = 1 (first central divided difference end conditions),

$$T_1 \approx 5.3N \times 10^{-5} \quad \text{seconds.}$$

For IENT = 2 (second central divided difference end conditions),

$$T_2 \approx 5.7N \times 10^{-5} \quad \text{seconds.}$$

For IENT = 3 (periodic end conditions),

$$T_3 \approx 7.3N \times 10^{-5} \quad \text{seconds.}$$

The above timing estimates are about right for the G compiler but are approximately 20 or 25 percent too large for the H compiler using the two-mode optimization parameter.

DCSSMO

$$T_S \approx 11N \times 10^{-5} \quad \text{seconds.}$$

Again this estimate is right for the G compiler but about 20 or 25 percent too large for the H compiler.

ACKNOWLEDGMENT

The author is indebted to two referees and to Prof. M.J.D. Powell for excellent comments and criticisms of an earlier version of this algorithm.

ALGORITHM 548
Solution of the Assignment Problem [H]

GIORGIO CARPANETO and PAOLO TOTH
University of Bologna, Italy

Key Words and Phrases: assignment problem, Hungarian algorithm
CR Categories: 5.39, 8.3
Language: Fortran

DESCRIPTION

Problem

The algorithm presented in this paper solves the assignment problem of the following form: given an $n \times n$ cost matrix $(a_{i,j})$, find a permutation (C_i) of integers $1, \ldots, n$ that minimizes

$$T = \sum_{i=1}^{n} a_{i,Ci}.$$

It is supposed, without loss of generality, that the elements of the cost matrix are nonnegative integers.

Algorithm

To give the reader a better understanding of the algorithm proposed below, we define:

C_j	as the row assigned to column j ($j = 1, \ldots, n$);
LC_j	as the label of column j; if $LC_j = 0$, column j is unlabeled ($j = 1, \ldots, n$);
LR_i	as the label of row i; if $LR_i = 0$, row i is unlabeled ($i = 1, \ldots, n$);
T	as the assignment cost;
P_i	as the set containing the columns corresponding to the unassigned zero elements of row i of the cost matrix ($i = 1, \ldots, n$);
RH	as the set containing the current not-completely-explored rows;
U	as the set containing the unassigned rows;
first (s)	as the first element of set s;
next (s)	as the element following the last considered element of set s;
last (s)	as the last element of set s.

Step 1. [Initialization]
Set $C_j = 0$, for $j = 1, \ldots, n$;
set $U = \emptyset$, $N = \{i \mid 1 \leq i \leq n\}$.
Step 2. [Reduction of the initial cost matrix]
Set $S_j = \min_{i \in N} [a_{i,j}]$, for all $j \in N$;

Received 5 August 1976 and 23 October 1978.

Author's address: Istituto di Automatica, Facoltà di Ingegneria, Universita Di Bologna, Viale Risorgimento 2, 40136 Bologna, Italy.

set $Q_i = \min_{j \in N} [a_{i,j} - S_j]$, for all $i \in N$;
set $a'_{i,j} = a_{i,j} - S_j - Q_i$, for all $i \in N, j \in N$;
set $P_i = \{j \in N \mid a'_{i,j} = 0\}$, for all $i \in N$; set $T = \sum_{k \in N} (S_k + Q_k)$.

Step 3. [Choice of the initial solution]
Set $i = 1$.
a. Set $j = first\,\{k \in P_i \mid C_k = 0\}$; if j exists, go to Step 3d. Otherwise, set $j = first\,\{P_i\}$.
b. Set $m = first\,\{k \in P_{C_j} \mid C_k = 0\}$; if m exists, go to Step 3c. Otherwise, set $j = next\,\{P_i\}$; if j exists, repeat Step 3b; if not, set $U = U \cup \{i\}$, go to Step 3e.
c. Set $C_m = C_j$, $P_{C_j} = P_{C_j} \cup \{j\} - \{m\}$.
d. Set $C_j = i$, $P_i = P_i - \{j\}$.
e. If $i < n$, set $i = i + 1$, go to Step 3a.

Step 4. [Search for a new assignment]
If set U is empty, stop (the optimal assignment is given by vector (C_j), the minimum cost is given by T). Otherwise, set $RH = \varnothing$; set $LR_k = LC_k = 0$, for $k = 1, 2, \ldots, n$; set $r = first\,\{U\}$, $LR_r = -1$.
a. If set P_r is empty, go to Step 4c. Otherwise, if set P_r has at least two elements, set $RH = RH \cup \{r\}$; in any case, set $l = first\,\{P_r\}$.
b. If $LC_l = 0$, set $LC_l = r$, if $C_l = 0$, go to Step 6; if not, set $r = C_l$, $LR_r = l$, go to Step 4a. Otherwise ($LC_l \neq 0$), if $r \in RH$, go to Step 4d.
c. If set RH is empty, go to Step 5. Otherwise, set $r = first\,\{RH\}$.
d. Set $l = next\,\{P_r\}$, if $l = last\,\{P_r\}$, set $RH = RH - \{r\}$; in any case, go to Step 4b.

Step 5. [Reduction of the current cost matrix]
Set $SLR = \{i \in N \mid LR_i \neq 0\}$, $SUC = \{j \in N \mid LC_j = 0\}$.
Set $H = \min_{i \in SLR, j \in SUC} [a'_{i,j}]$.
For all $i \in SLR, j \in SUC$: set $a'_{i,j} = a'_{i,j} - H$, if $a'_{i,j} = 0$, set $P_i = P_i \cup \{j\}$, $RH = RH \cup \{i\}$;
For all $i \in N - SLR, j \in N - SUC$: if $j \in P_i$, set $P_i = P_i - \{j\}$; in any case set $a'_{i,j} = a'_{i,j} + H$.
Set $T = T + H$, $r = first\,\{RH\}$, go to Step 4d.

Step 6. [Assignment of a new row]
Set $C_l = r$, $P_r = P_r - \{l\}$; if $LR_r < 0$, set $U = U - \{r\}$, go to Step 4.
Otherwise, set $l = LR_r$, $P_r = P_r \cup \{l\}$, $r = LC_l$, repeat Step 6.

The efficiency of the algorithm is mainly due to the pointer technique utilized to locate the unexplored rows and the zero elements of the current cost matrix. It is worthwhile to note that, as far as storage requirement is concerned, for each set P_i ($i = 1, \ldots, n$) only the pointer to the first element needs to be stored; in fact, if column j is contained in set P_i, the corresponding element of the current cost matrix (i.e., $a'_{i,j}$) is zero and it is thus possible to replace this element by the pointer to the column following j in set P_i.

We obtained a further improvement on the original Hungarian algorithm by modifying the choice of the initial solution, as described in Step 3 of the proposed algorithm.

Program

Fortran IV subroutine ASSCT, based on the algorithm previously presented, is completely self-contained and communication to it is made solely through the parameter list. The subroutine is called by means of the statement:

CALL ASSCT (N, A, C, T).

All the parameters are integer and their meanings are the following:

Input: N = number of rows and columns of the cost matrix;
A = cost matrix.
Output: C = assignment vector;
T = minimum assignment cost.

After execution of subroutine ASSCT, the values of the elements of the cost matrix are changed. Vector C must be dimensioned at least at N; matrix A at least at (N, N + 1). As presently dimensioned, the size limitation for ASSCT is $N \leq 200$.

Table I. Cost Range 1–100

	A		B		C	
n	Average	Maximum	Average	Maximum	Average	Maximum
50	0.16	0.20	0.21	0.31	0.23	0.33
100	0.54	0.66	0.93	1.15	1.10	1.27
150	0.96	1.10	2.10	2.81	2.79	3.42
200	1.40	1.68	4.37	5.27	5.38	7.24

Table II. Cost Range 1–1000

	A		B		C	
n	Average	Maximum	Average	Maximum	Average	Maximum
50	0.41	0.51	0.56	0.78	0.60	0.89
100	2.15	2.61	2.97	3.92	3.34	4.24
150	4.55	6.28	6.60	8.37	7.24	8.42
200	6.70	8.01	10.36	12.26	11.83	13.15

Table III. Cost Range 1–10,000

	A		B		C

100	3.71	4.60	5.78	7.49	6.80	9.55
150	11.74	15.57	18.72	21.96	21.35	23.94
200	19.85	25.40	32.69	43.52	42.63	48.16

Table IV. Sparse Matrices, Cost Range 1–100, $n = 200$

Number of coefficients	1500	2250	3000	3750	4500
AP-AB	0.97	1.12	1.48	1.61	1.68
PD-AAL	1.63	1.14	1.89	1.29	1.80
SUPERT-2	1.26	1.57	1.98	2.17	2.53
ASSCT	15.29	5.80	6.49	2.62	2.17

Computational Results

Subroutine ASSCT was tested in a CDC 6600 with over 1500 random problems of varying sizes. No breakdown in the method occurred.

To evaluate the efficiency of the proposed algorithm, the computing times of subroutine ASSCT were compared with those of the most efficient algorithms for solution of the assignment problem for dense matrices [1, 3].

Tables I, II, and III show the computing times corresponding to the algorithms:

A: Subroutine ASSCT.
B: Hungarian algorithm as presented in [5] and coded in Fortran IV by the authors.
C: Algorithm presented in [3] (the Fortran IV program, coded by Bourgeois and Lassalle, is taken from the CDC library of CERN (Geneva, Switzerland).

In Tables I, II, and III the values of the cost matrix were generated as uniformly random integers in the ranges, respectively, 1–100, 1–1000, and 1–10,000. All codes were run on a CDC 6600. For each cost range, each algorithm, and each value of n, 20 different problems were solved, and the average and maximum computing times, expressed in seconds, are given.

The tables show that subroutine ASSCT is always superior to the other codes, mainly for large values of n and for small ranges of costs. In addition, for all codes the computing times get worse with the increase in size of coefficients; in fact, when the size increases, the number of zero elements of the current cost matrix decreases.

In order to evaluate the effect of sparseness on the performance of the proposed algorithm, the same test problems considered by Barr, Glover, and Klingman in [2] were solved on the same machine (a CDC-6600). Subroutine ASSCT was compared with the most efficient codes for the solution of sparse assignment problems, viz., codes AP-AB, PD-AAL, and SUPERT-2 presented, respectively, in [2], [6], and [1]; the corresponding computing times, expressed in seconds, are given in Table IV.[1]

Table IV shows that the codes designed to solve sparse assignment problems are superior to subroutine ASSCT for very sparse matrices because this subroutine does not include any mechanism for taking advantage of sparsity. However, the trends of the computing times indicate that for fairly dense matrices the performance of the proposed algorithm greatly increases with respect to those of the other codes.

Further details of the algorithm and extensive computational results are given in [4].

Weierstrass' Elliptic Functions [S21]

ULRICH ECKHARDT
University of Hamburg, Germany

Key Words and Phrases: Weierstrass' elliptic functions
CR Categories: 5.12
Language: Fortran

DESCRIPTION

Weierstrass' $\mathcal{P}$-function and its derivative can be approximated in the complex plane by a rational expression as described in [3, 4]. The following programs evaluate these approximations for the case of a unit period parallelogram. They are written according to the rules given in [2].

Programs PEQ and PEQ1 evaluate Weierstrass' $\mathcal{P}$-function in the equianharmonic case for a unit period parallelogram defined by the complex numbers

$$2\omega = \frac{1}{2} - \frac{1}{2}\sqrt{3}\,i, \qquad 2\omega' = \frac{1}{2} + \frac{1}{2}\sqrt{3}\,i$$

(see [1, Sec. 18.13] for notation). Because of the periodicity of Weierstrass' functions it is sufficient to calculate them only in the fundamental rectangle of all $z = x + iy$ with

$$-\frac{1}{2} \le x \le \frac{1}{2}, \qquad -\frac{\sqrt{3}}{4} \le y \le \frac{\sqrt{3}}{4}$$

which implies $|z| \le \sqrt{7}/4$. The theoretical absolute error of the approximation in this rectangle can be estimated as in [3] by the following bounds:

PEQ: 9.31×10^{-19}
PEQ1: 4.594×10^{-18}.

Numerical experiments were performed on different computers in order to obtain the actual errors of the programs. For large values of $|\mathcal{P}|$ the actual error is mainly due to the limited word length of the computer, whereas for small $|\mathcal{P}|$ the actual error approaches the theoretical error. Therefore a "mixed" error was calculated; it is the absolute error for $|\mathcal{P}| \le 1$ and the relative error elsewhere. The bounds for the mixed errors were obtained by comparing the programs with ϑ-series evaluations for randomly and systematically chosen arguments. Each program was tested on the computers given in Table I for more than 20,000 argument values.

Received 1 July 1977 and 19 March 1979.

Author's address: Institut für Angewandte Mathematik, Universität Hamburg, Bundesstrasse 55, 2 Hamburg 13, Germany.

Table I. Bounds for the Mixed Error for PEQ and PEQ1 on Different Computers

Computer	Mantissa length		PEQ	PEQ1
	Bits	Decimal		
IBM 370/168 (double precision)	56	16	2×10^{-15}	2×10^{-14}
CDC Cyber 172	48	14	7×10^{-13}	7×10^{-13}
TR 440	38	11	2×10^{-9}	3×10^{-9}

Table II. Bounds for the Mixed Error for PLEM and PLEM1

Computer	PLEM	PLEM1
IBM 370/168 (double precision)	4×10^{-15}	8×10^{-15}
CDC Cyber 172	6×10^{-13}	6×10^{-13}
TR 440	4×10^{-9}	5×10^{-9}
Theoretical absolute error	4.482×10^{-17}	8.033×10^{-17}

The difference between the numerical accuracy obtainable by using full word length of the computer and the values given in Table I is due to

(1) a loss of nearly one significant figure in computing powers of the variable z;
(2) a loss of one significant figure in evaluating the first line of the last assignment statement in each program.

Programs PLEM and PLEM1 evaluate Weierstrass' $\mathcal{P}$-function and its derivative in the lemniscatic case where

$$2\omega = 1, \qquad 2\omega' = i.$$

The fundamental rectangle is defined by

$$-\frac{1}{2} \le x \le \frac{1}{2}, \qquad -\frac{1}{2} \le y \le \frac{1}{2}$$

so that $|z| \le 1/\sqrt{2}$. The theoretical absolute error as given in [4] and the actual mixed error which was found by numerical experiments are given in Table II.

In using the programs it should be observed that the functions have poles at the lattice points $2\omega M + 2\omega' N$. If z happens to coincide with one of these poles, an overflow occurs. This can be avoided by checking after the reduction of z (see comments in the program listings) whether the reduced value of z is close to zero.

Full machine accuracy can be obtained in all programs by specifying the argument z and all its powers in greater precision and by performing all operations of the first line of the last assignment statement in double precision.

Note. The programs are written in single precision. On IBM computers they should be declared as

$$\text{COMPLEX FUNCTION} \left\{ \begin{array}{l} \text{PEQ} \\ \text{PEQ1} \\ \text{PLEM} \\ \text{PLEM1} \end{array} \right\} * 16(Z).$$

The first declaration should be COMPLEX * 16 and the second REAL * 8. All constants and functions should be given in double precision.

ACKNOWLEDGMENTS

The programs were written and tested on the IBM 370/168 of the Central Institute for Applied Mathematics of the Nuclear Research Center Jülich. They were also tested on the CDC Cyber 172 and the Telefunken TR 440 of the

Regionales Rechenzentrum Erlangen. The author is very much indebted to W. Alt of the University of Bayreuth for kind assistance.

I.T.T. Federal Electric Corporation

Key Words and Phrases: polyhedron, graphics, numerical integration
CR Categories: 3.2, 5.16, 8.2
Language: Fortran

DESCRIPTION

Surface area, centroid, volume, weight, moments, and products of inertia are computed by numerical integration over the bounding surfaces of solid polyhedra. This routine operates directly on geometric definitions consisting of vertex coordinates and face lists, in a format similar to the format employed in graphics and in plotting computer programs [1, 3, 5]. Integration is performed through a quadrature rule that is exact for the equations involved.

METHOD

The several equations, eqs. (1) through (10), to be integrated over the surface of the polyhedra were derived from volume integral forms through application of the Gauss divergence theorem.

$$\text{mass} = \frac{\rho}{3}\int\int [xn_x + yn_y + zn_z]\, dS = M \tag{1}$$

$$\text{CG}_x = \frac{\rho}{2M}\int\int [x^2 n_x]\, dS \tag{2}$$

$$\text{CG}_y = \frac{\rho}{2M}\int\int [y^2 n_y]\, dS \tag{3}$$

$$\text{CG}_z = \frac{\rho}{2M}\int\int [z^2 n_z]\, dS \tag{4}$$

$$I_{xx} = \frac{\rho}{3}\int\int [y^3 n_y + z^3 n_z]\, dS \tag{5}$$

Received 27 January 1976 and 6 November 1977.

Authors' addresses: A.M. Messner, General Dynamics Pomona Division, Pomona, CA; G.Q. Taylor, I.T.T. Federal Electric Corporation, RPL Project, Edwards Airforce Base, CA.

$$I_{yy} = \frac{\rho}{3} \iint [z^3 n_z + x^3 n_x]\, dS \tag{6}$$

$$I_{zz} = \frac{\rho}{3} \iint [x^3 n_x + y^3 n_y]\, dS \tag{7}$$

$$P_{xy} = \frac{-\rho}{2} \iint [y x^2 n_x]\, dS \tag{8}$$

$$P_{yz} = \frac{-\rho}{2} \iint [z y^2 n_y]\, dS \tag{9}$$

$$P_{zx} = \frac{-\rho}{2} \iint [x z^2 n_z]\, dS \tag{10}$$

where $\iint dS$ implies integration over the entire bounding surface; x, y, and z are right-hand Cartesian coordinates; n_x, n_y, and n_z are components of the outward directed normal vector of unit length; ρ is density per cubic unit; CG_x, CG_y, and CG_z are coordinates of the centroid; I_{xx}, I_{yy}, and I_{zz} are moments of inertia about the x, y, and z axes; P_{xy}, P_{yz}, and P_{zx} are products of inertia with respect to the subscripted axes with sign convention as shown.

Consider, for example, the moment of inertia about the x axis (as given in [2]):

$$I_{xx} = \iiint \rho(y^2 + z^2)\, dV.$$

We define a specific vector function $\mathbf{F}$ as follows:

$$\mathbf{F} = \frac{\rho}{3} \{y^3 \mathbf{j} + z^3 \mathbf{k}\}$$

where $\mathbf{j}$ and $\mathbf{k}$ are unit vectors in the coordinate directions y and z, respectively. The divergence of $\mathbf{F}$ is

$$\text{div } \mathbf{F} = \frac{\rho}{3} \left\{ \frac{\partial(y^3)}{\partial y} + \frac{\partial(z^3)}{\partial z} \right\} = \rho(y^2 + z^2).$$

Gauss's divergence theorem states

$$\iiint \text{div } \mathbf{F}\, dV = \iint \mathbf{F} \cdot \mathbf{n}\, dS$$

yielding

$$\iiint \rho(y^2 + z^2)\, dV = \iint \frac{\rho}{3} (y^3\, \mathbf{ny} + z^3\, \mathbf{nz})\, dS$$

which verifies that the surface integral form, eq. (5), is the equivalent of the volume representation.

Computation of the surface integrals is done through a quadrature rule applied to the triangular elements of the surface polygons. We employ a four-point rule, eq. (11), that is exact for polynomials up to degree three. This rule, a minimum-point exact rule for our purpose [6] converts the continuous integral into a sum of four discrete values evaluated at specific points in each triangle. Point locations and associated weights are as follows:

$$\iint f\, dA = \text{area}[f(p_1)w_1 + f(p_2)w_2 + f(p_3)w_3 + f(p_4)w_4] \tag{11}$$

where p_1 is the centroid of the triangle, $w_1 = -27/48$, $w_2 = w_3 = w_4 = 25/48$. p_2, p_3, and p_4 are located along lines from the centroid to the triangle vertices such that the distance to these points is equal to 40 percent of the distance from the centroid to the respective vertex.

Each surface polygon is treated as a group of triangles that are constructed as follows: Vertices 1, 2, and 3 form the first triangle, vertices 1, 3, and 4, form the second triangle, etc., with 1, $n - 1$, and n being the last triangle in a perimeter of n vertices. Normal vectors are computed for each triangle to ensure that concave polygons yield negative contributions when the perimeter reverses direction relative to the initial vertex. Contributions to mass, CG, products of inertia, and moments of inertia are accumulated in sequence to cascade the calculations and thereby reduce arithmetic operations. Global factors such as density are applied after all faces have been processed. Properties are finally shifted to parallel axes through the computed centroid. In this form, standard methods can be employed to yield values about arbitrary axes or to solve for principal values.

DESCRIPTION OF THE ALGORITHM

The algorithm is presented as two subroutines: PROPS and SRFINT, which are structured to operate on polyhedrons defined as a series of vertices and associated connectivity (faces) lists. Specific details of an appropriate data structure are illustrated by the example shown in Figure 1 and a driver program based on this format is included. Vertices are numbered, and defined in terms of their components in a right-hand rectangular Cartesian coordinate system. Faces are also numbered, and listed as a series of vertices in the order encountered while traversing the perimeters. Perimeters are traversed in a direction that is consistent with an inward surface vector definition. This ordering convention can be envisioned as follows: If one were to stand on the face with the left foot on the edge of the face and the right foot on the interior of the face and then traverse forward around the perimeter, vertices would be encountered in the required order. Perimeter lists are closed (the first vertex number is repeated at the end of the list) and each face consists of one or more perimeters. These aspects are illustrated by the example shown in Figure 1. Large faces are accommodated for in the driver program by continuing perimeter lists on subsequent cards using all data fields (including the first field normally used for the face number). A repeat of the initial vertex designates the end of the list.

Errors in the input data can occur, and are often difficult to detect unless systematic tests of data integrity are adopted. Geometric tests can be made to insure that the polyhedron is connected and has planar faces. These tests will vary with the application; nonplanar faces, for example, may be permitted in a mechanically deformed solid, relying on the triangulation process within the algorithm to enforce planarity. In our experience the most useful test has been a connectivity evaluation that sorts all edges and proceeds to match each edge against its reciprocal (same edge lists in the opposite order on another face). This test is easily accomplished while generating plots [3]. If each edge has one and only one reciprocal in the face lists there is reasonable assurance that the connectivity is valid. Another data error encountered in extensive polygon definitions is the omission of coordinates of one or more vertices. This error will usually result in coordinate values of zero, which can be tested, and appropriate cautionary messages printed out to aid the correction process. Large data sets may require graphic-generation techniques such as the use of digitizers or interactive entry devices. In most instances computer plots should be obtained as a further data check. Our experience is primarily with computations relating to designed components which are defined by engineering drawings. These drawings are reduced to appropriate card formats through digitizer equipment interfaced to a keypunch machine. Perspective plots (Figures 2 and 3) generated through a derivative of the Loutrel Algorithm [3] have been valuable guides to data integrity.

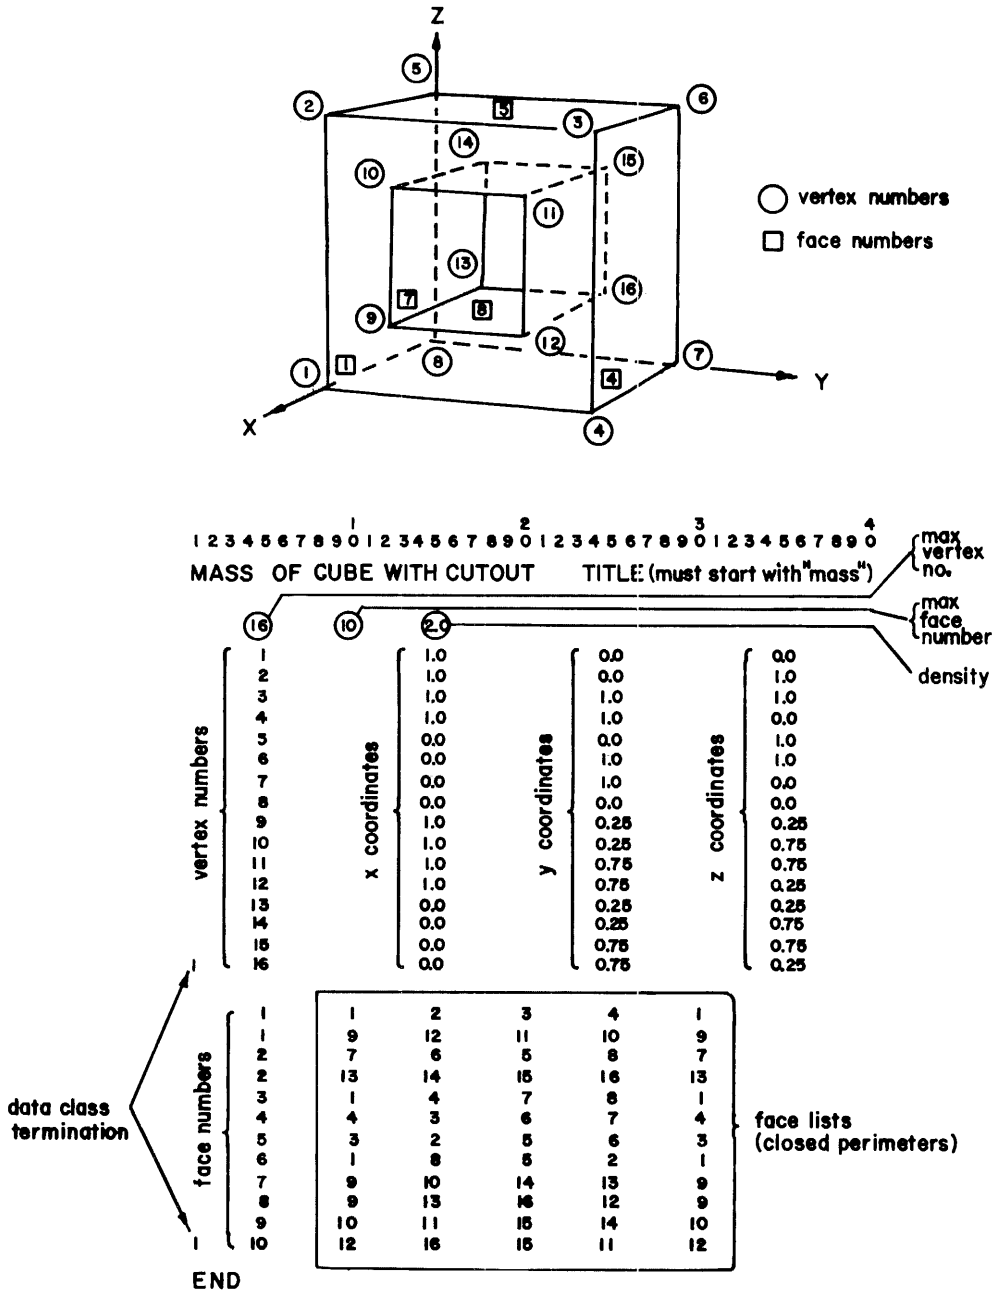

Fig. 1. Input definitions.

TESTS

This algorithm has been in use for several years and checked for simple geometries such as cubes and prisms as well as for complex configurations. Comparisons have also been made with fabricated components where computed values were compared with measured quantities of finished parts. Accuracies in all instances were within manufacturing tolerances. Computational errors arise from roundoff operations within the computer and can be minimized by multiple-precision arithmetic or through specific protection algorithms [4].

Several specific test problems are presented to illustrate the accuracies obtainable in single and double precision with the IBM 370 equipment. The first

problem consists of a 100.0-inch cube, with cutout as in Figure 1. Cutout dimensions are such that the remaining wall thickness is 0.01 inch. Computations involve powers of coordinates which differ by the wall thickness; therefore, as the wall gets sufficiently thin, accuracy deteriorates. The complete single- and double-precision solution to this problem is presented in Table I. It can be seen that inaccuracies are evident in the single-precision solution, although even this problem, which is somewhat extreme for practical purposes, did not produce catastrophic errors. A second test has been constructed to indicate the accuracies related to geometries containing numerous faces with diverse orientations. This second test relates to the symmetry of results obtained for a generated configuration depicted in Figure 2. It was constructed by displacing an 8-inch square cross section normal to its plane in such a manner that its center traversed a 10-inch-radius circle while rotating 180 degrees in its plane during one traverse of the circle. The circle has its center at the origin and lies in the x–y plane. Single- and double-precision solutions are presented in Table II. Moments about x and y should be equal and the centroid and products of inertia components should be zero. It is of interest to note that the volume is some 2 percent smaller than would be obtained with a continuous solid generated in this manner. This discrepancy arises from the inscribing character of the polyhedron construction and would decrease as the number of faces increase. A final test is presented in Figure 3.

This third test problem is similar in configuration to the second except that the cross section is now a 1- by 4-inch rectangle (finite thickness Möbius strip). A plane through the generating circle of this configuration bisects it identically. Solutions in single precision are presented to the complete and the sectioned solid in Table III where it can be seen that the volume, weight, moments about the axes, and the y-z product moment are halved as required. The x coordinate of the centroid is not zero due to the discretization errors associated with the geometry construction.

ALGORITHM 551
A Fortran Subroutine for the L_1 Solution of Overdetermined Systems of Linear Equations [F4]

NABIH N. ABDELMALEK
National Research Council, Ottawa, Canada

Key Words and Phrases: overdetermined system of linear equations, discrete linear L_1 approximation, linear programming, dual simplex algorithm, triangular decomposition
CR Categories: 5.13, 5.41
Language: Fortran

DESCRIPTION

This algorithm is a Fortran implementation for the procedure developed in [1] and [2]. It solves an overdetermined system of linear equations of the form

$$Ca = f,$$

in the L_1 norm. C is a given real n-by-m matrix of rank $k \leq m \leq n$ and f is a given real n-vector.

The L_1 solution to this system is the m-vector a^* which minimizes the L_1 norm

$$z = \sum_{i=1}^{n} |r_i|,$$

where r_i is the ith residual and is given by

$$r_i = \sum_{j=1}^{m} c_{ij}a_j - f_i.$$

This subroutine uses a dual simplex method and a suitable triangular decomposition method to the basis matrix. In [2] the testing of this subroutine, as well as numerical results and comments, are given.

ALGORITHM

```
C     THIS PROGRAM IS A DRIVER FOR THE SUBROUTINE  L1
C WHICH SOLVES AN OVERDETERMINED SYSTEM OF LINEAR EQUATIONS
C IN THE L1 NORM, USING A DUAL SIMPLEX METHOD.
C     THE OVERDETERMINED SYSTEM HAS THE FORM  CA=F
C   C IS A GIVEN REAL N BY M MATRIX OF RANK K, K.LE.M.LE.N
C   F IS A GIVEN REAL N-VECTOR.
```

Received 12 March 1974; revised 17 March 1977 and 19 June 1979; accepted 10 July 1979.

Author's address: Division of Electrical Engineering, National Research Council of Canada, Ottawa, Ont., Canada, KIA OR8.

C PREC   THE ROUND-OFF LEVEL OF THE COMPUTER. FOR THE IBM          L1  Ø32Ø
C        36Ø/67 COMPUTER, PREC IS ABOUT 1.E-6 AND 1.E-16 FOR       L1  Ø33Ø
C        SINGLE AND DOUBLE PRECISION RESPECTIVELY.                 L1  Ø34Ø
C EPS    A SPECIFIED TOLERANCE SUCH THAT A CALCULATED NUMBER       L1  Ø35Ø
C        X IS CONSIDERED ZERO IF  ABS(X) <EPS. FOR THE IBM 36Ø/67  L1  Ø36Ø
C        COMPUTER, EPS IS USUALLY TAKEN 1.E-4 AND 1.E-11           L1  Ø37Ø
C        RESPECTIVELY.                                             L1  Ø38Ø
C     THE RESULTS OF THE PROBLEM.                                  L1  Ø39Ø
C IRANK  THE CALCULATED RANK OF MATRIX C.                         L1  Ø4ØØ
C ITER   THE NUMBER OF ITERATIONS WHICH THE SOLUTION NEEDED.      L1  Ø41Ø
C A      AN MM-VECTOR. ITS FIRST M ELEMENTS ARE THE SOLUTION      L1  Ø42Ø
C        VECTOR A*.                                                L1  Ø43Ø
C R      AN NN-VECTOR. ITS FIRST N ELEMENTS CONTAIN THE           L1  Ø44Ø
C        THE RESIDUAL VECTOR R=C*A-F.                              L1  Ø45Ø
C Z      THE MINIMUM L1 NORM OF THE RESIDUAL VECTOR R.            L1  Ø46Ø
C IND    A RETURN INDICATOR. IND=Ø INDICATES THAT THE             L1  Ø47Ø
C        SOLUTION VECTOR A* IS UNIQUE. IND=1, INDICATES THAT       L1  Ø48Ø
C        A* IS MOST PROBABLY NOT UNIQUE. IND=-1 INDICATES          L1  Ø49Ø
C        PREMATURE TERMINATION OF THE CALCULATION DUE TO           L1  Ø5ØØ
C        VERY ILL-CONDITIONING OF MATRIX C.                        L1  Ø51Ø
C     THE MEANING OF THE OTHER PARAMETERS.                         L1  Ø52Ø
C GINV   AN MM-SQUARE MATRIX. ITS FIRST IRANK COLUMNS AND         L1  Ø53Ø
C        FIRST IRANK ROWS CONTAIN THE INVERSE OF THE INITIAL       L1  Ø54Ø
C        BASIS MATRIX AND ITS UPDATE.                              L1  Ø55Ø
C VB     AN MM-VECTOR. ITS FIRST IRANK ELEMENTS CONTAIN THE        L1  Ø56Ø
C        INITIAL BASIC SOLUTION AND ITS UPDATE.                    L1  Ø57Ø
C T      AN NN-VECTOR. ITS FIRST N ELEMENTS CONTAIN THE            L1  Ø58Ø
C        ELEMENTS OF THE ROW IN THE SIMPLEX TABLEAU, THAT          L1  Ø59Ø
C        CORRESPONDS TO THE COLUMN WHICH LEAVES THE BASIS.         L1  Ø6ØØ
C ALFA   AN NN-VECTOR. ITS FIRST N ELEMENTS CONTAIN THE           L1  Ø61Ø
C        RATIOS:  ALFA(J) = R(J)/T(J).                             L1  Ø62Ø
C IC     AN NN-VECTOR. ITS FIRST N ELEMENTS CONTAIN THE           L1  Ø63Ø
C        COLUMN INDICES OF MATRIX CT.                              L1  Ø64Ø
C IR     AN MM VECTOR. ITS FIRST IRANK ELEMENTS CONTAIN THE       L1  Ø65Ø
C        ROW INDICES OF THE LINEARLY INDEPENDENT ROWS OF CT.       L1  Ø66Ø
C IB     A SIGN NN-VECTOR. ITS FIRST N ELEMENTS HAVE THE          L1  Ø67Ø
C        VALUES +1 OR -1. IB(J)=+1 INDICATES THAT COLUMN J         L1  Ø68Ø
C        IN THE TABLEAU IS AT ITS LOWER BOUND Ø. IB(J)=-1          L1  Ø69Ø
C        INDICATES THAT COLUMN J IS AT ITS UPPER BOUND 2.          L1  Ø7ØØ
C P      AN MMM-VECTOR. ITS FIRST ((IRANK*(IRANK+3))/2)-1         L1  Ø71Ø
C        ELEMENTS CONTAIN THE (IRANK*(IRANK+1))/2 ELEMENTS OF      L1  Ø72Ø
C        THE UPPER TRIANGULAR MATRIX + EXTRA (IRANK-1) WORKING     L1  Ø73Ø
C        LOCATIONS. SEE THE COMMENTS IN SUBROUTINE PSLV.           L1  Ø74Ø
C BP     AN MM-VECTOR. ITS FIRST IRANK ELEMENTS ARE THE           L1  Ø75Ø
C        R.H.S. OF THE TRIANGULAR EQUATIONS AS P*XP=BP.            L1  Ø76Ø
C XP     AN MM-VECTOR . ITS FIRST IRANK ELEMENTS ARE THE          L1  Ø77Ø
C        SOLUTION OF THE TRIANGULAR EQUATIONS AS P*XP=BP.          L1  Ø78Ø

ALGORITHM 552
Solution of the Constrained l_1 Linear Approximation Problem [F4]

I. BARRODALE and F. D. K. ROBERTS
University of Victoria, Canada

Key Words and Phrases: constrained l_1 approximation, linear programming, simplex method
CR Categories: 5.13, 5.41
Language: Fortran

DESCRIPTION

1. Introduction

Given a $k \times n$ system of linear equations

$$Ax = b, \tag{1}$$

the algorithm calculates an l_1 solution of (1) subject to l linear equality constraints

$$Cx = d \tag{2}$$

and m linear inequality constraints

$$Ex \leq f; \tag{3}$$

i.e., the subroutine determines a column vector x^* which minimizes

$$\| b - Ax \|_1 = \sum_{i=1}^{k} | b_i - A_i x | \tag{4}$$

subject to the given constraints (2) and (3). (In expression (4), b_i denotes the ith component of b and A_i denotes the ith row of A.)

The method is completely general in the sense that no restrictions are imposed on the ranks of the matrices A, C, and E, or on the signs of the elements of f. Furthermore, if no vector x satisfying (2) and (3) exists, the subroutine detects this and informs the user that the problem is infeasible.

The algorithm can be used to solve the constrained l_1 approximation problem. Suppose that data consisting of k points (t_i, y_i) are to be approximated by a linear approximating function $x_1\phi_1(t) + x_2\phi_2(t) + \cdots + x_n\phi_n(t)$, where certain linear constraints are imposed on the parameters $x_1, x_2, \ldots, x_n$. This is equivalent to finding an l_1 solution to the system of equations

$$\sum_{j=1}^{n} \phi_j(t_i)x_j = y_i, \qquad i = 1, 2, \ldots, k,$$

subject to the given linear constraints. If the data values y_i contain some large

Authors' address: Department of Mathematics, University of Victoria, P.O. Box 1700, Victoria, B. C., Canada V8W 2Y2.

errors, then an l_1 approximation may be preferable to an l_2 (least-squares) solution. This aspect of robust regression is discussed, for example, in [5, 7].

The algorithm is a modification of the simplex method applied to the primal formulation of the constrained l_1 problem as a linear program. The modification allows many intermediate simplex vertices to be bypassed, thus reducing the total number of simplex iterations required. A complete description of the method is given in [3]. In the absence of constraints, the algorithm reduces to our earlier unconstrained l_1 algorithm [1], which has proved to be most effective in practice. Indeed, in this case the program which follows produces identical results to the code given in [2].

Following [3], the constrained l_1 problem is posed as the following linear programming problem:

$$\begin{aligned} \text{minimize} \quad & e(u+v) + Me'(u'+v') + Me''v'' \\ \text{subject to} \quad & A(x'-x'') + u - v = b \\ & C(x'-x'') + u' - v' = d \\ & E(x'-x'') + u'' - v'' = f \\ & x', x'' \geq 0, \qquad u, v \geq 0, \qquad u', v' \geq 0, \qquad u'', v'' \geq 0. \end{aligned} \tag{5}$$

In (5), e, e', and e'' are vectors of 1's of appropriate dimensions and u', v', and v'' are artificial vectors with a large positive cost M in the objective function. Our modified simplex method is applied to a condensed tableau of size $(k + l + m + 2) \times (n + 2)$, using the usual two-phase approach in which the artificial part of the objective function is minimized first.

Our algorithm can be used to calculate a weighted constrained l_1 solution, merely by multiplying A_i and b_i by a chosen positive weight before entering the subroutine. Also, as is explained in the comment section of our listing, simple nonnegativity constraints on the variables need not be included explicitly in the contraints (3), since these can be handled most efficiently by assigning the appropriate variables x_j'' in (5) a cost M in the objective function, thus making them artificial variables. Similarly, a nonnegativity constraint on the ith row $b_i - A_i x$ can be handled by making the variable v_i in (5) artificial.

2. Numerical Results

The algorithm has been tested on a variety of problems, several of which are presented in [3]. We include here the following three additional test problems, which have been run on an IBM 370/158 using single-precision arithmetic (approximately 7 decimal digits).

Example 1. Bartels et al. [4] present an example of a spline approximation due to Maurice Cox which is constrained to be convex. This corresponds to an l_1 solution of a 9×7 system of equations whose unknowns are subject to 5 inequality constraints. Our algorithm requires 10 simplex iterations to reproduce (to single-precision accuracy) the results given in [4], where 17 iterations of their penalty function technique are required.

Example 2. This example was devised to demonstrate the ability of our algorithm to handle rank deficient problems. The matrices and vectors are defined as follows:

$$A = \begin{bmatrix} 2 & 0 & 1 & 3 & 1 \\ 7 & 4 & 4 & 15 & 7 \\ 9 & 4 & 7 & 20 & 6 \\ 2 & 2 & 1 & 5 & 3 \\ 9 & 3 & 2 & 14 & 10 \\ 4 & 5 & 0 & 9 & 9 \\ 4 & 4 & 9 & 17 & -1 \\ 1 & 6 & 2 & 9 & 5 \end{bmatrix}, \qquad b = \begin{bmatrix} 7 \\ 4 \\ 7 \\ 4 \\ 0 \\ 4 \\ 9 \\ 6 \end{bmatrix},$$

$$C = \begin{bmatrix} 0 & 4 & 5 & 9 & -1 \\ 3 & 2 & 7 & 12 & -2 \\ 3 & 6 & 12 & 21 & -3 \end{bmatrix}, \quad d = \begin{bmatrix} 5 \\ 1 \\ 6 \end{bmatrix},$$

$$E = \begin{bmatrix} 0 & 3 & 6 & 9 & -3 \\ 6 & 2 & 4 & 12 & 4 \end{bmatrix}, \quad f = \begin{bmatrix} 5 \\ 6 \end{bmatrix}.$$

The 8×5 matrix A is of rank 3. The 3×5 matrix C is of rank 2, which causes one artificial vector to remain in the basis at the end of phase I. Our algorithm includes an adaptation of a standard device (e.g., see Hadley [6, p. 153]) to handle such situations. The solution is obtained with no difficulty in 3 iterations with ERROR = 26.148.

Example 3. Compute a best l_1 approximation by $p_5(t) = \sum_{j=1}^{6} x_j t^{j-1}$ to the function $y(t) = \min(e^t, e^{1/2})$ on the 101 points defined by $t = 0(0.01)1$, subject to the interpolation condition that $p_5(t) = y(t)$ for $t = 0$, 0.5, and 1. This gives rise to a 98×6 overdetermined system with 3 equality constraints. The algorithm requires 8 iterations to solve the problem (with ERROR = 2.8513), and it requires 13 iterations to solve the 101×6 overdetermined system *without* the 3 constraints (with ERROR = 1.1473).

ALGORITHM 553

M3RK, An Explicit Time Integrator for Semidiscrete Parabolic Equations [D3]

J. G. VERWER

Mathematical Center, Amsterdam, The Netherlands

Key Words and Phrases: parabolic partial differential equations, semidiscretization, explicit time integrator
CR Categories: 5.17
Language: Fortran

DESCRIPTION

This algorithm is a complement to [2] where it is explained and described.
