Report A1 –Current Technology for Storing Domestic Rainwater (Part 1)

The work in this report forms the basis for the current DTU roofwater harvesting Web Site. The site can be found at:

http://www.eng.warwick.ac.uk/DTU/rainwaterharvesting/index.html

The work in this document is on-going and will be added to as the programme progresses. The aim is to collect examples of DRWH practice from around the world and to provide a useful resource for practitioners of DRWH. Many of the graphics shown in the Web Site are not shown in this document due to electronic storage requirement limitations. The report is in two parts so that the document remains manageable. This is Part 1.

Contents of report (Part 1)

Current Technology for Storing Domestic Rainwater

1. An Introduction to Domestic Roofwater Harvesting

A sufficient, clean drinking water supply is essential to life. Millions of people throughout the world still do not have access to this basic necessity. After decades of work by governments and organisations to bring potable water to the poorer people of the world, the situation is still dire. The reasons are many and varied. The poor of the world cannot afford the capital intensive and technically complex traditional water supply systems which are widely promoted by governments and agencies throughout the world.

Roof-water or rainwater harvesting (RWH) is an option which has been adopted in many areas of the world where conventional water supply systems have failed to meet the needs of the people. It is a technique which has been used since antiquity. Examples of RWH systems can be found in all the great civilisations throughout history. The technology can be as simple or as complex as required. In many African countries this is often as simple as placing a small container under the eaves of the roof to collect falling water during a storm. One 20 litre container of clean water captured from the roof can save a walk of many kilometres, in some cases, to the nearest clean water source. In the industrialised countries of the world, sophisticated RWH systems have been developed with the aim of reducing water bills or to meet the needs of remote communities or individual households in arid regions. Traditionally, in Uganda rainwater is also collected from trees, using banana leaves or stems as temporary gutters; up to 200 litres may be collected from a large tree in a single storm. Many individuals and groups have taken the initiative and developed a wide variety of different RWH systems throughout the world.

It is worth bearing in mind, however, that Domestic Rainwater Harvesting (DRWH) is not the definitive answer to household water problems. There is a complex set of inter-related circumstances which have to be considered when choosing the appropriate water source. Cost, climate, technology, hydrology, social and political elements all play a role in the eventual choice of water supply scheme which is adopted for a given situation. RWH is only one possible choice, but one which is often overlooked by planners, engineers and builders. The reason that RWH is rarely considered is often due to lack of information – both technical and otherwise. In many areas where RWH has been introduced as part of a wider drinking water supply programme, it was at first unpopular, simply because little was known about the technology by the eneficiaries. In most of these cases the technology has quickly gained popularity as the user realises the benefits of a clean, reliable water source at the home. In many cases RWH has been introduced as part of an integrated water supply system, where the town supply is unreliable or where local water sources dry up for a part of the year, but is also often used as the sole water source for a community or household. It is a technology which is flexible and adaptable to a very wide variety of conditions, being used in the richest and the poorest societies on our planet, and in the wettest and the driest regions of the world.

The aim of this web site is to enable readers to view a wide variety of these systems, with the aim of providing interested parties with a selection of possible technical solutions to their water problems. We try to provide guidelines for the sizing of RWH systems, a brief overview of the components of a RWHS, a critique for examining the systems with a mind to their possible application, and look at the cost of the system (or at least the material requirements). We also look at ways in which water quality can be improved and maintained before, during and after storage.

2. Styles of Roofwater Harvesting

User regimes

Rainwater harvesting is used in many different ways. In some parts of the world it is used merely to capture enough water during a storm to save a trip or two to the main water source. In this case only small storage capacity is required, maybe just a few small pots to store enough water for a day or half a day. At the other end of the spectrum we see, in arid areas of the world, systems which have sufficient collection surface area and storage capacity to provide enough water to meet the full needs of the user. Between these two extremes exists a wide variety of different user patterns or regimes. There are many variables that determine these patterns of usage for RWH. Some of these are listed below:

- Rainfall quantity (mm/year) – the total amount of water available to the consumer is a product of the total available rainfall and the collection surface area. There is usually a loss coefficient included to allow for evaporation and other losses. Mean annual rainfall data will tell us how much rain falls in an average year.
- Rainfall pattern - climatic conditions vary widely throughout the world. The type of rainfall pattern, as well as the total rainfall, which prevails will often determine the feasibility of a RWHS. A climate where rain falls regularly throughout the year will mean that the storage requirement is low and hence the system cost will be correspondingly low and vice versa. More detailed rainfall data is required to ascertain the rainfall pattern. The more detailed the data available, the more accurately the system parameters can be defined.
- Collection surface area (m2) - this, where rooftop catchment systems are used, is restricted by the size of the roof of the dwelling. Sometimes other surfaces are used to supplement the rooftop catchment area.
- Storage capacity (m3) - the storage tank is usually the most expensive component of the RWHS and so a careful analysis of storage requirement against cost has to be carried out.
- Daily consumption rate (litres/capita /day or lpcd) - this varies enormously – from 10 – 15 lpcd a day in some parts of Africa to several hundred lpcd in some industrialised countries. This will have obvious impacts on system specification.
- Number of users - again this will greatly influence the requirements.
- Cost – a major factor in any scheme.
- Alternative water sources – where alternative water sources are available, this can make a significant difference to the usage pattern. If there is a groundwater source within walking distance of the dwelling (say within a kilometre or so), then a RWHS that can provide a reliable supply of water at the homestead for the majority of the year, will have a significant impact to lifestyle of the user. Agreed, the user will still have to cart water for the remainder of the year, but for the months when water is available at the dwelling there is a great saving in time and energy. Another possible scenario is where rainwater is stored and used only for drinking and cooking, the higher quality water demands, and a poorer quality water source, which may be near the dwelling, is used for other activities.
- Water management strategy – whatever the conditions, a careful water management strategy is always a prudent measure. In situations where there is a strong reliance on stored rainwater, there is a need to control or manage the amount of water being used so that it does not dry up before expected.

Ideally, we would like to be able to classify the various common user regimes that are adopted. This can help us to develop a nomenclature for dealing with the systems we will look at later. We can simply classify most systems by the amount of 'water security' or 'reliability' afforded by the system. There are four types of user regimes listed below:

Occasional (or opportunist) - water is collected occasionally with a small storage capacity, which allows the user to store enough water for a maximum of, say, one or two days. During the wet season this means that the user will benefit considerably from having such a system and most, if not all, of the user needs will be met during this time. After a day or two of dry weather the user will have to return to using an alternative water source. This type of system is ideally suited to a climate where there is a uniform, or bimodal, rainfall pattern with very few dry days during the year and where an alternative water sources is close at hand.

Intermittent – this type of pattern is one where the requirements of the user are met for a part of the year. A typical scenario is where there is a single long rainy season and, during this time, most or all of the user needs are met. During the dry season an alternative water source has to be used or, as we see in the Sri Lankan case, water is carted/ bowsered in from a nearby river and stored in the RWH tank. Usually, a small or medium size storage vessel is required to bridge the days when there is no rain.

Partial – this type of pattern provides for partial coverage of the water requirements of the user, during the whole of the year. An example of this type of system would be where a family gather rainwater to meet only the high-quality needs, such as drinking or cooking, while other needs, such as bathing and clothes washing, are met by a water source with a lower quality. This could be achieved either in an area with a uniform rainfall pattern and with a small to medium storage capacity or in an area with a single (or two short) wet season(s) and a larger storage capacity to cover the needs during the dry season.

Full – with this type of system the total water demand of the user is met for the whole of the year by rainwater only. This is sometimes the only option available in areas where other sources are unavailable. Sufficient a/ rainfall, b/ collection area, c/ storage capacity is required to meet the needs of the user and a careful feasibility study must be carried out before hand to ensure that conditions are suitable. In areas where there is a bimodal rainfall pattern (i.e. two rainy seasons) this type of system is far more attractive, as the tank will be recharged during both wet seasons. Where there is a single (unimodal) wet season the storage capacity will normally be very large – and therefore expensive. A strict water management strategy is required when such a system is used to ensure that the water is used carefully and will last until the following wet season.

3. Components of a DRWH system

Introduction

Technically, DRWH systems vary in complexity. Some of the traditional Sri Lankan systems are no more that a pot situated under a piece of cloth or plastic sheet tied at its corners to four poles. The cloth captures the water and diverts it through a hole in its centre into the pot. On the other hand, some sophisticated systems used in the industrialised nations, incorporate clever computer management systems, submersible pumps, and links into the grey water and mains domestic plumbing systems.
Somewhere between these two extremes we find the typical DRWH system that is used in a typical developing country scenario. Such a system will usually comprise a collection surface, a roof, a storage tank, and guttering to transport the water from the roof to the storage tank. Other peripheral equipment is sometimes incorporated: first flush systems to divert the dirty water which contains roof debris after prolonged dry periods; filtration equipment and settling chambers to remove debris and contaminants before water enters the storage tank or cistern.

In this section we will look at the various components commonly found in typical DRWH systems. In the Case Studies section we will look at actual systems. In the Case Studies section, where possible, we have tried to look at full systems, showing how the various components interact. In some cases, however, we have been able to show only certain components of the system – usually the tank or cistern as this is the most costly and critical component of the DRWH system, and the area that has attracts most design attention.

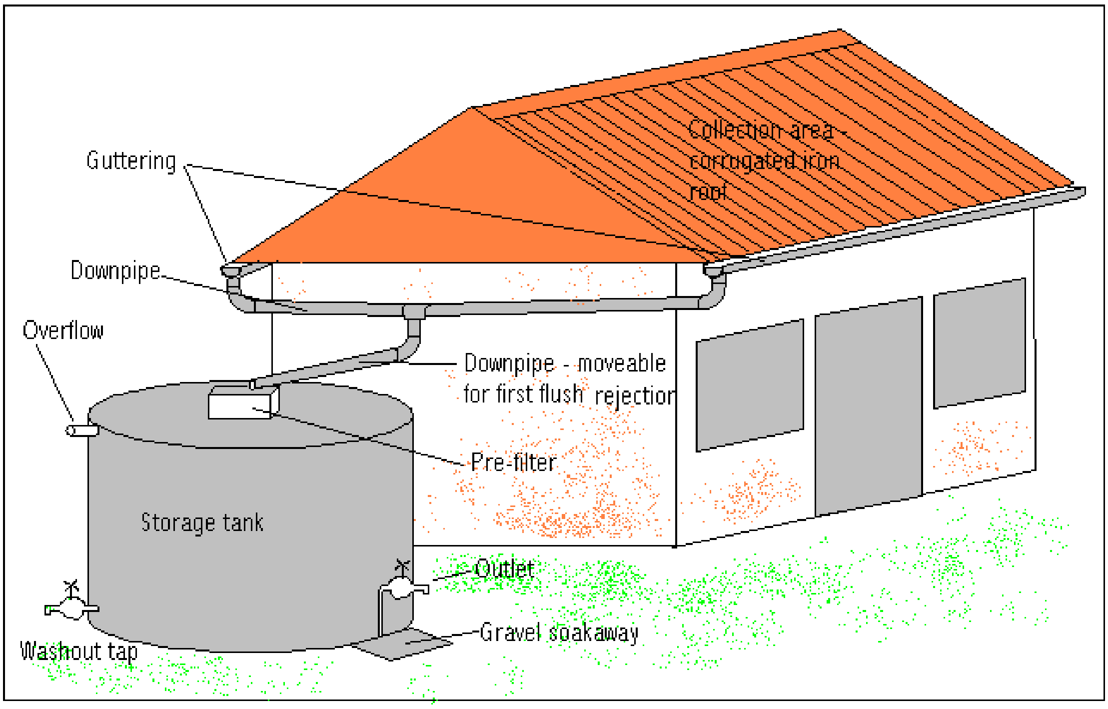

Figure 1 – Typical domestic roofwater harvesting system – showing the main components of the system

Storage tanks and cisterns

The water storage tank usually represents the biggest capital investment element of a DRWH system. It therefore usually requires the most careful design – to provide optimal storage capacity while keeping the cost as low as possible. The catchment area is usually the existing rooftop, and guttering can often be obtained relatively cheaply, or can be manufactured locally.

There are an almost unlimited number of options for storing water. Common vessels used for very small-scale water storage in developing countries include such examples as plastic bowls and buckets, jerrycans, clay or ceramic jars, cement jars, old oil drums, empty food containers, etc.

For storing larger quantities of water the system will usually require a tank or a cistern. For the purpose of this document we will classify the tank as an above-ground storage vessel and the cistern as a below-ground or under-ground storage vessel. These can vary in size from a cubic metre or so (1000 litres) up to hundreds of cubic metres for large projects, but typically up to a maximum of 20 or 30 cubic metres for a domestic system. There is a mind-boggling range of options open to the prospective rainwater harvester, with a wide variety of shapes, materials, sizes and prices on offer. The choice will depend on a number of technical and economic considerations. Some of these are listed below:

- Space availability
- Options available locally
- Local traditions for water storage
- Cost – of purchasing new tank
- Cost – of materials and labour for construction
- Materials and skills available locally
- Ground conditions
- Style of RWH (see link to this section)

One of the main choices will be whether to use a tank or a cistern. Both tanks and cisterns have their advantages and disadvantages. Table 1 summarises the pros and cons of each.

	Tank (above ground)	Cistern (below ground)

Pros	Above ground structure allows for easy inspection for cracks or leakage Many existing designs to choose from Can be easily purchased ‘off-the-shelf’ in most market centres Can be manufactured from a wide variety of materials Easy to construct for traditional materials Water extraction can be by gravity in many cases Can be raised above ground level to increase water pressure	generally cheaper more difficult to empty by leaving tap on require little or no space above ground unobtrusive surrounding ground gives support allowing lower wall thickness.
Cons	Require space Generally more expensive More easily damaged Prone to attack from weather Failure can be dangerous	water extraction is more problematic – often requiring a pump leaks or failures are more difficult to detect contamination of the tank from groundwater is more common tree roots can damage the structure there is danger to children and small animals if tank cover is left off flotation of the cistern may occur if groundwater level is high and cistern is empty heavy vehicles driving over a cistern can cause damage

Table 1. Pros and Cons of Tanks and Cisterns

Much work has been carried out on the development of the ideal tank for DRWH. The Case Studies section of this Web Site show a wide variety of tanks that have been built in many countries throughout the world.

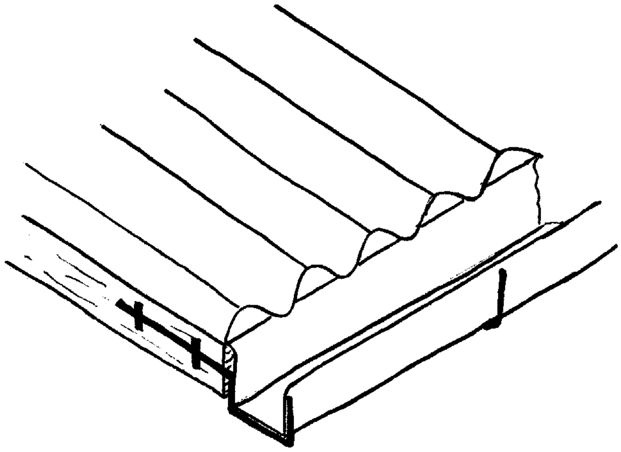
Collection surfaces

For domestic rainwater harvesting the most common surface for collection of water is the roof of the dwelling. Many other surfaces can and are used: courtyards, threshing areas, paved walking areas, plastic sheeting, trees, etc. Most dwellings, however, have a roof. The style, construction and material of the roof affect its suitability as a collection surface for water. Typical materials for roofing include corrugated iron sheet, asbestos sheet; tiles (a wide variety is found), slate, and thatch (from a variety of organic materials).

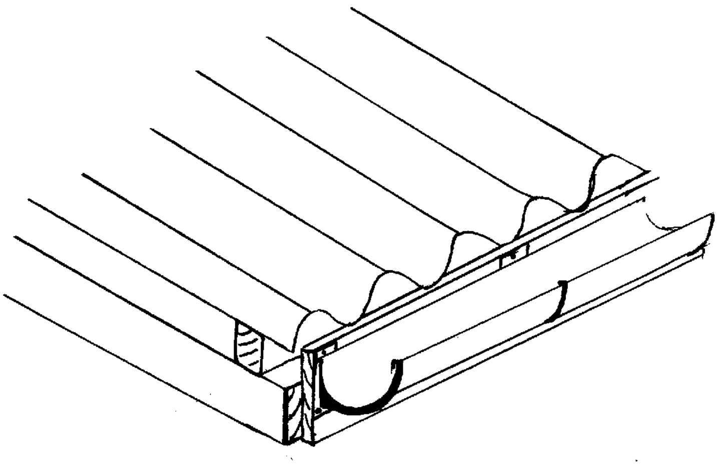
Guttering

Guttering is used to transport rainwater from the roof to the storage vessel. Guttering comes in a wide variety of shapes and forms, ranging from the factory made PVC type to home made guttering using bamboo or folded metal sheet. Guttering is usually fixed to the building just below the roof and catches the water as it falls from the roof. For a detailed analysis of the performance of various types of guttering see the DTU working paper titled ‘Guttering Design for Rainwater Harvesting – with special reference to conditions in Uganda’.

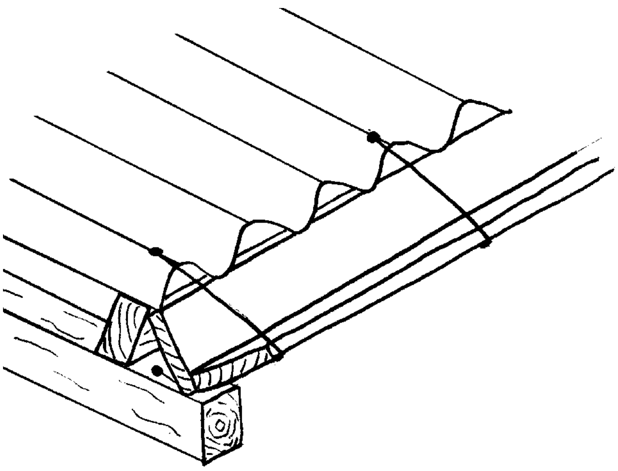
Below are shown some of the common types of guttering and fixings.



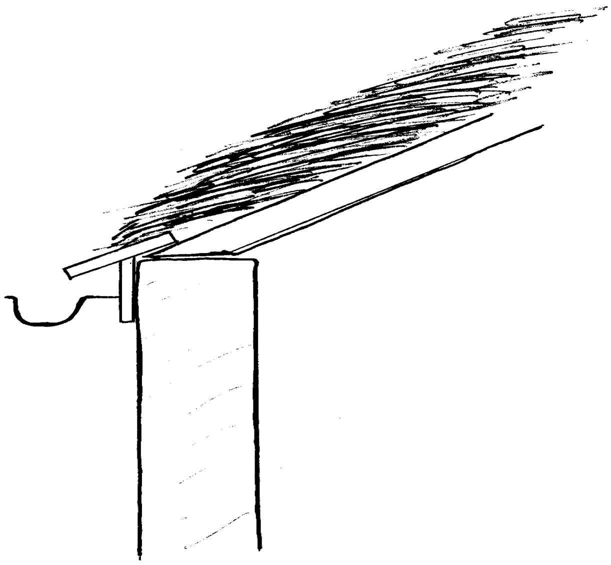
2a - rectangular section guttering fixed to rafter



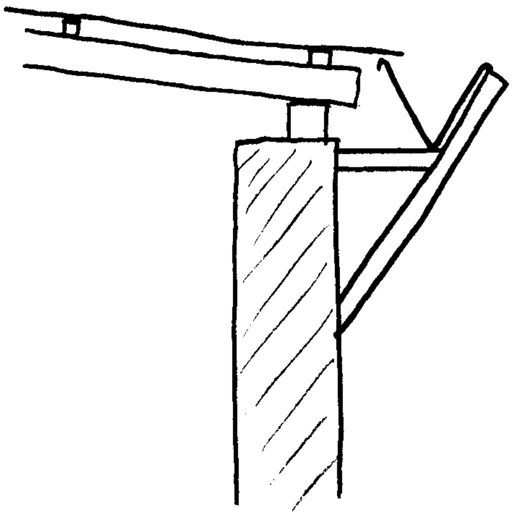
2b - semi circular trough gutter fixed to facia board



2c - timber V-shaped trough fixed with wire to rafter



2d - one configuration for guttering with thatch roof



2e - V-shaped gutter with wall mount

Figure 2 – a variety of guttering types showing possible fixings

Manufacturing low-cost gutters. Factory made gutters are usually expensive and beyond the reach of the poor of developing countries. They are seldom used for very low-cost systems. The alternative is usually to manufacture gutters from materials that can be found cheaply in the locality. There are a number of techniques that have been developed to help meet this demand; one such technique is described below.

V- shaped gutters from galvanised steel sheet can be simply made by cutting and folding flat galvanised steel sheet. Such sheet is readily available in most market centres and can be worked with tools that are commonly found in a modestly equipped workshop. One simple technique is to clamp the cut sheet between two lengths of straight timber and then to fold the sheet along the edge of the wood. A strengthening edge can be made be folding the sheet through 90o and then completing the edge
with a hammer on a hard flat surface. The better the grade of steel sheet that is used, the more durable and hard-wearing the product. Fitting a downpipe to V-shaped guttering can be problematic and the V-shaped guttering will often be continued to the tank rather than changing to the customary circular pipe section downpipe. Methods for fixing gutters are shown in figure 4.

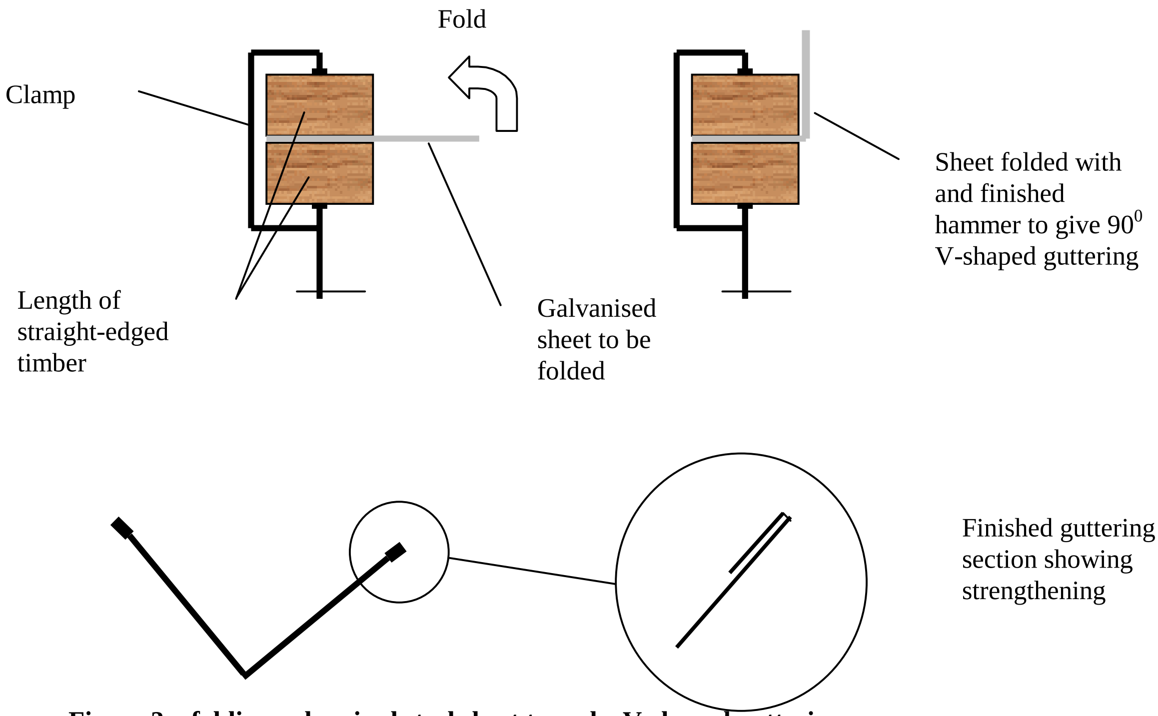


Figure 3 – folding galvanised steel sheet to make V-shaped guttering

Rectangular section gutters can be made in a similar way. It is somewhat easier to fit downpipes to rectangular section guttering.

First flush systems

Variations in Rainwater Quality from Roof Catchment

The quality of rainwater from a tile and a galvanised-iron type roof catchment were analysed over a period of 5 months. Examination of staggered 1 litre samples collected during a rainfall event showed that the concentrations of various pollutants were high in the first litre but decreased in subsequent samples with few exceptions. Faecal coliform and total coliform counts ranged from 8-13 (tile roof) and 4-8 (iron roof) to 41-75 (tile roof) and 25-63 (iron roof) colonies per 100 ml, respectively. However, no faecal coliforms were detected in the fourth and fifth litre samples from both roofs. The pH of rainwater collected from the open was acidic but increased slightly after falling on the roofs. The average zinc concentrations in the run-off from the galvanised-iron roof was about 5-fold higher compared to the tile roof, indicating leaching action but was well below the WHO limits for drinking water quality. Lead concentrations remained consistently high in all samples collected and exceeded the WHO guidelines by a factor of 3.5. For the roof area studied, a ' foul flush ' volume of 5l. would be the minimum to safeguard against microbiological contamination but the high metals content in the water indicate the need for some form of treatment. Rainfall intensity and the number of dry days preceding a rainfall event significantly affect the quality of run-off water from the catchment systems.

Debris, dirt and dust will collect on the roof of a building or other collection area. When the first rains arrive, this unwanted matter will be washed into the tank. This will cause contamination of the water and the quality will be reduced. Many RWH systems therefore incorporate a system for diverting this ‘first flush’ water so that it doesn’t enter the tank.

There are a number of simple systems which are commonly used and also a number other, slightly more complex, arrangements. The simpler ideas are based on a simple manually operated arrangement whereby the inlet pipe is moved away from the tank inlet and then replaced again once the initial first flush has been diverted.

This method has obvious drawbacks in that there has to be a person present who will remember to move the pipe. Slightly more sophisticated methods include arrangements such as those shown in Figure 4 below, where the stopper in the inlet chamber can be removed to allow the first flush to be diverted.

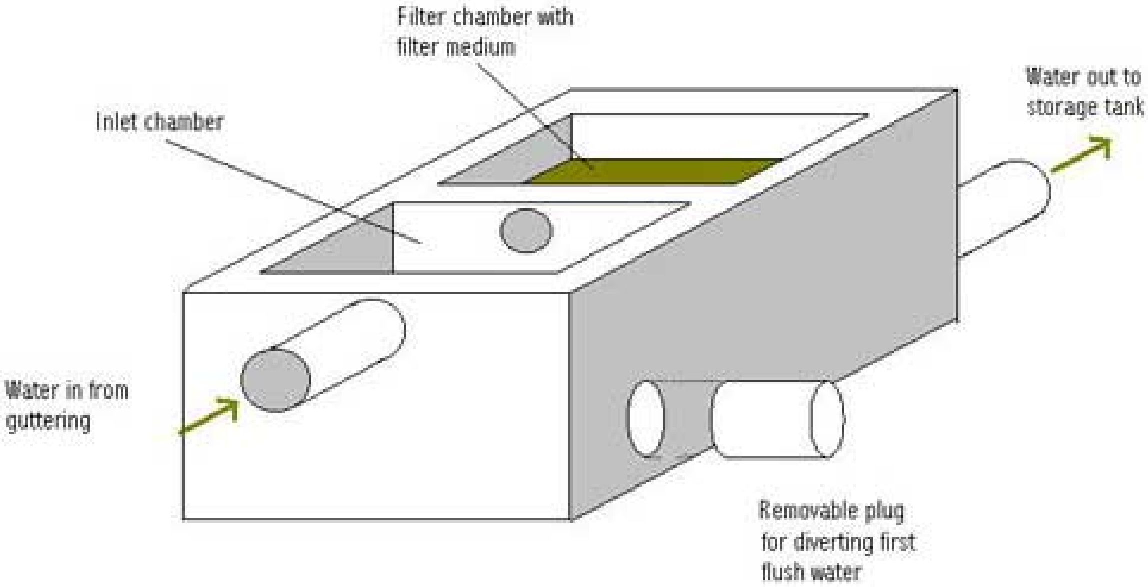

Figure 4 – First flush device using removable stopper in bottom of inlet chamber (above) and using diversion pipe (below)

Other systems use tipping gutters to achieve the same purpose. The most common system (as shown in Figure 5 below) uses a bucket which accepts the first flush and the weight of this water off-balances a tipping gutter which then diverts the water back into the tank. The bucket then empties slowly through a small-bore pipe and automatically resets. The process will repeat itself from time to time if the rain continues to fall, which can be a problem where water is really at a premium. In this case a tap can be fitted to the bucket and will be operated manually. The quantity of water that is flushed is dependent on the force required to lift the guttering. This can be adjusted to suit the needs of the user.

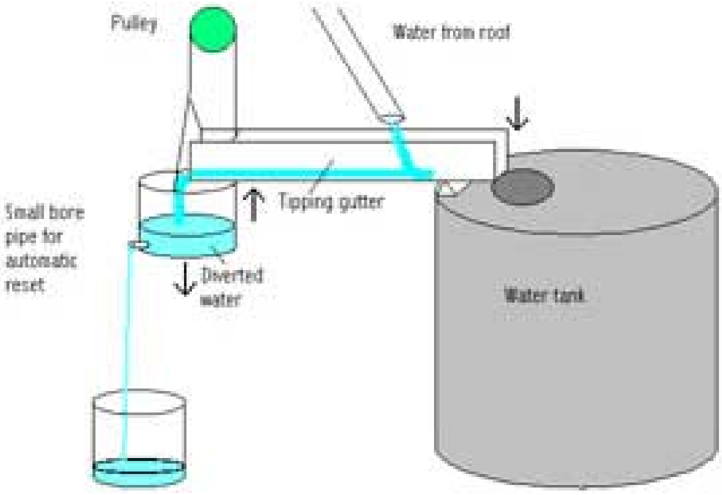

Figure 5 – the tipping gutter first flush system

Another system that is used relies on a floating ball that forms a seal once sufficient water has been diverted (see Figure 6 below). The seal is usually made as the balls rises into the apex of an inverted cone. The ball seals the top of the 'waste' water chamber and the diverted water is slowly released, as with the bucket system above, through a small bore pipe. Again the alternative is to use a tap. In some systems (notably one factory manufactured system from Australia) the top receiving chamber is designed such that a vortex is formed and any particles in the water are held in suspension in the vortex while only clean water passes into the storage tank. The 'waste' water can be used for irrigating garden plants or other suitable application. The debris has to be removed from the lower chamber occasionally.

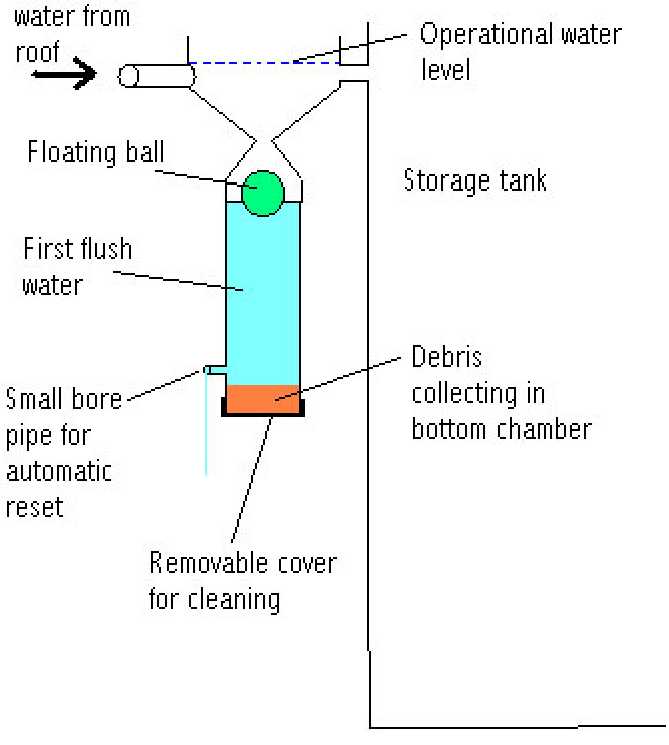

Figure 6 – the floating ball first flush system

Although the more sophisticated methods provide a much more elegant means of rejecting the first flush water, practitioners often recommend that very simple, easily maintained systems be used, as these are more likely to be repaired if failure occurs.

Filtration systems and settling tanks

Again, there are a wide variety of systems available for treating water before, during and after storage. The level of sophistication also varies, from extremely high-tech to very rudimentary. A German company, WISY, have developed an ingenious filter which fits into a vertical downpipe and acts as both filter and first-flush system. The filter cleverly takes in water through a very fine (0.17mm) mesh while allowing silt and debris to continue down the pipe. The efficiency of the filter is over 90%. This filter is commonly used in European systems.

The simple trash rack has been used in some systems but this type of filter has a number of problems attached: firstly it only removes large debris; and secondly the rack can become clogged easily and requires regular cleaning.

The sand-charcoal-stone filter is often used for filtering rainwater entering a tank. This type of filter is only suitable, however, where the inflow is slow, and will soon overflow if the inflow exceeds the rate at which the water can percolate through the sand.

Settling tanks and partitions can be used to remove silt and other suspended solids from the water. These are effective where used but add significant additional cost if elaborate techniques are used.

Post storage filtration include such systems as the upflow sand filter shown in Figure 7. Many other systems exist and can be found in the appropriate water literature.

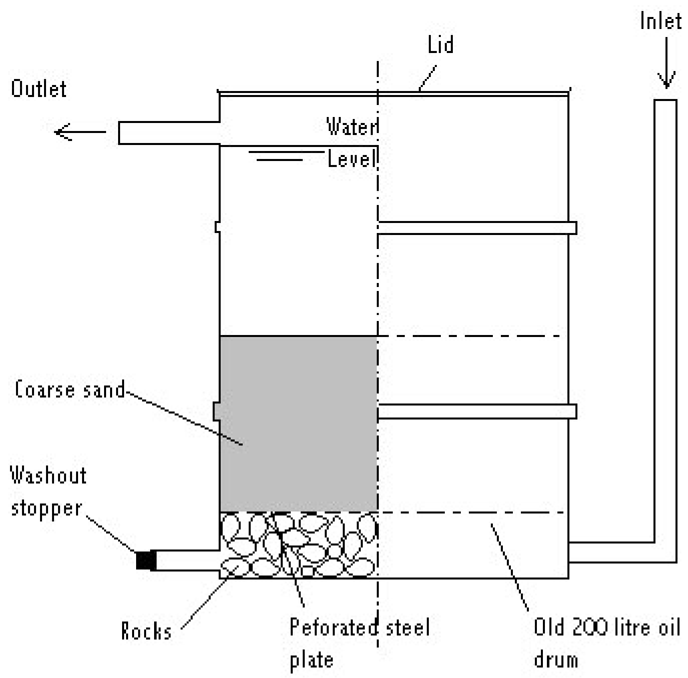

Figure 7 – Upflow sand filter for post treatment of stored water.

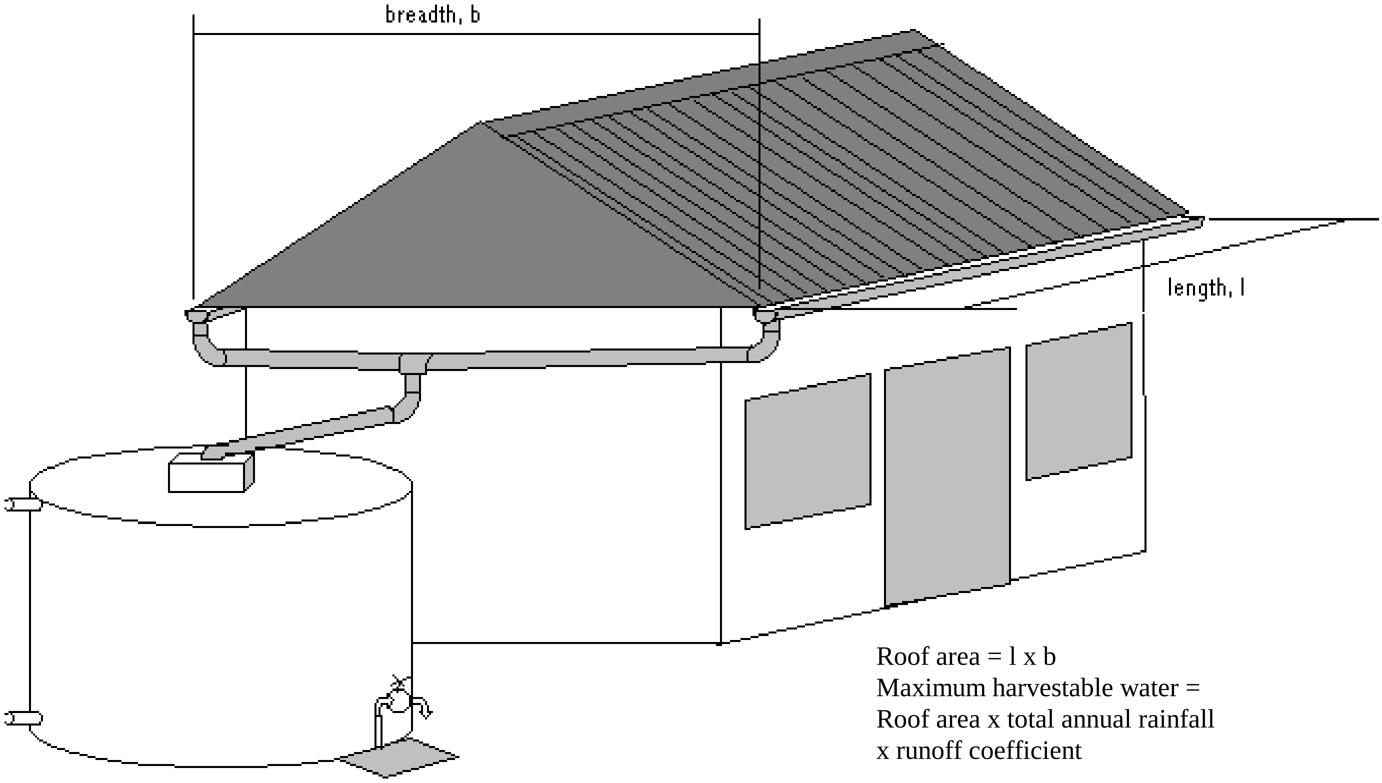
4. Sizing the DRWH system

Usually, the main calculation when designing a DRWH system will be to size the water tank correctly to give adequate storage capacity. The storage requirement will be determined by a number of interrelated factors. They include:

- local rainfall data and weather patterns
- roof (or other) collection area
- runoff coefficient (this varies between 0.5 and 0.9 depending on roof material and slope)
- user numbers and consumption rates



Roof area = l x b
Maximum harvestable water =
Roof area x total annual rainfall
x runoff coefficient

The style of rainwater harvesting (see Rainwater Harvesting Styles) will also play a part in determining the system components.

There are a number of different methods for sizing system components. These methods vary in complexity and sophistication. Some are readily carried out by relatively inexperienced first-time practitioners; others require computer software and trained engineers who understand how to use this software. The choice of method used to design system components will depend largely on the following factors:

- the size and sophistication of the system and its components
- the availability of the tools required for using a particular method (e.g. computers)
- the skill and education levels of the practitioner / designer

Below we will outline 3 different methods for sizing RWH system components.

Method 1 – demand side approach

A very simple method is to calculate the largest storage requirement based on the consumption rates and occupancy of the building.

As a simple example we can use the following typical data:

Consumption per capita per day, C – 20 litres
Number of people per household, n – 6
Longest average dry period – 25 days

Annual consumption = C x n x 365 = 43,800 litres

Storage requirement, T = $\frac{43{,}800 \times 25}{365}$ = 3,000 litres

This simple method assumes sufficient catchment area and rainfall and catchment area which is adequate, and is therefore only applicable in areas where this is the situation. It is a method for acquiring rough estimates of tank size.

Method 2 – supply side approach

In low rainfall areas or areas where the rainfall is of uneven distribution, more care has to be taken to size the storage properly. During some months of the year there may be an excess of water, while at other times there will be a deficit (see figure 1 below). If there is sufficient water throughout the year to meet the demand, then sufficient storage will be required to bridge the periods of scarcity. As storage is expensive, this should be done carefully to avoid unnecessary expense.

The example given here is a simple spreadsheet calculation for a site in North Western Tanzania. The rainfall statistics were gleaned from a nurse at the local hospital who had been keeping records for the previous 12 years. Average figures for the rainfall data were used to simplify the calculation, and no reliability calculation is done. This is a typical field approach to RWH storage sizing.

Example

Site: Medical dispensary, Ruganzu, Biharamulo District, Kagera, Tanzania (1997)
Demand:
Number of staff: 7
Staff consumption: 45 litres per day x 7 = 315 litres per day
Patients: 40
Patient consumption : 10 litres per day x 40 = 400 litres per day
Total demand: 715 litres per day or 260.97m^3 per month

Roof area: 190m^2
Runoff coefficient (for new corrugated GI roof): 0.9
Average annual rainfall: 1056mm per year
Annual available water (assuming all is collected) = 190 x 1.056 x 0.9 = 180.58m^3
Daily available water = 180.58 / 365 = 0.4947 m^3 / day or 494.7 litres per day or 150.48m^3 per month

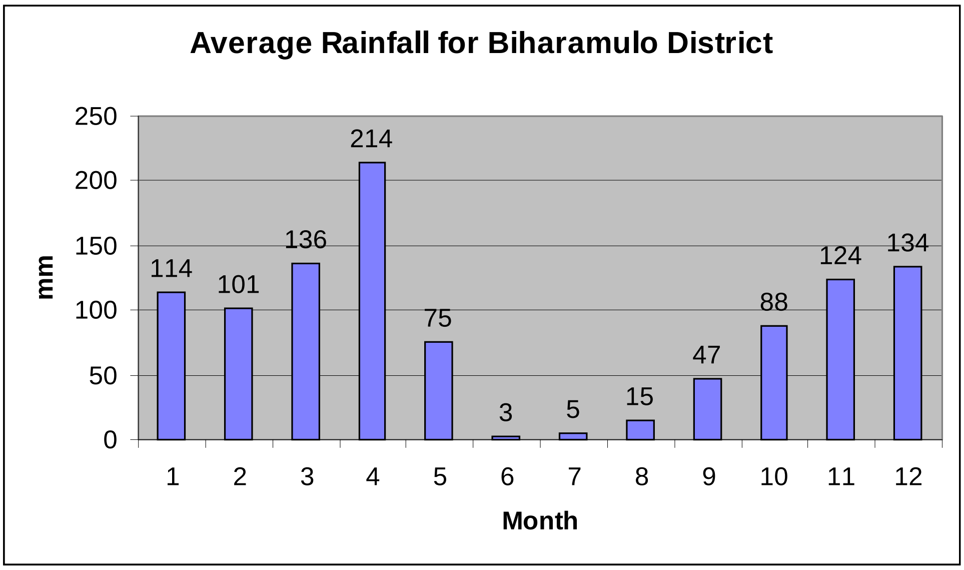


Figure 8 – average annual rainfall for the District of Biharamulo.

So, if we want to supply water all the year to meet the needs of the dispensary, the demand cannot exceed 494.7 litres per day. The expected demand cannot be met by the available harvested water. Careful water management will therefore be required.

Figure 9 below shows the comparison of water harvested and the amount that can be supplied to the dispensary using all the water which is harvested. It can be noted that there is a single rainy season. The first month that the rainfall on the roof meets the demand is October. If we therefore assume that the tank is empty at the end of September we can form a graph of cumulative harvested water and cumulative demand and from this we can calculate the maximum storage requirement for the dispensary.

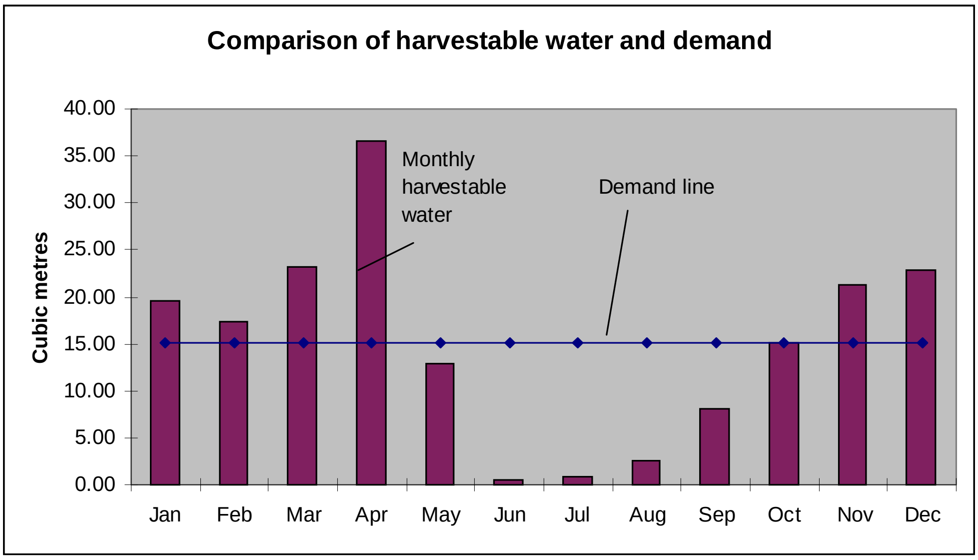

Figure 9 – comparison of the harvestable water and the demand for each month.

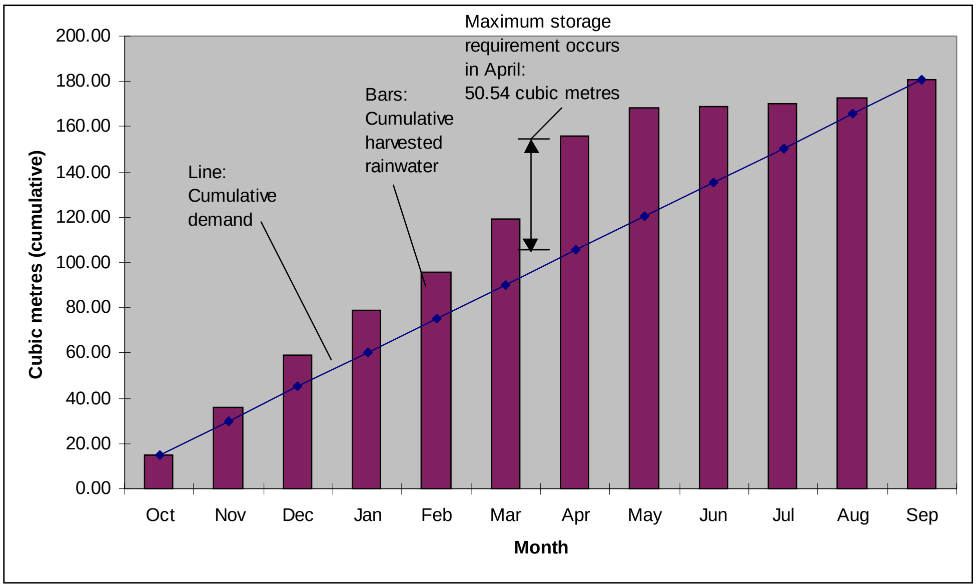

Figure 10 – showing the predicted cumulative inflow and outflow from the tank. The maximum storage requirement occurs in April.

Month	Rainfall (mm)	Rainfall harvested (cubic metres)	Cumulative rainfall harvested (cubic metres)	Demand (based on total utilisation)	Cumulative demand (cubic metres)	Difference between column 4 and 6
Oct	88	15.05	15.05	15.05	15.05	0.00
Nov	124	21.20	36.25	15.05	30.10	6.16
Dec	134	22.91	59.17	15.05	45.14	14.02

Jan	114	19.49	78.66	15.05	60.19	18.47
Feb	101	17.27	95.93	15.05	75.24	20.69
Mar	136	23.26	119.19	15.05	90.29	28.90
Apr	214	36.59	155.78	15.05	105.34	**50.45**
May	75	12.83	168.61	15.05	120.38	48.22
Jun	3	0.51	169.12	15.05	135.43	33.69
Jul	5	0.86	169.97	15.05	150.48	19.49
Aug	15	2.57	172.54	15.05	165.53	7.01
Sep	47	8.04	180.58	15.05	180.58	0.00
Totals		180.58		180.58		

Table 1 - shows the spreadsheet calculation for sizing the storage tank. It takes into consideration the accumulated inflow and outflow from the tank and the capacity of the tank is calculated as the greatest excess of water over and above consumption. This occurs in April with a storage requirement of 50.45 cubic metres. All this water will have to be stored to cover the shortfall during the dry period.

Method 3 – computer model

There are several computer-based programmes for calculating tank size quite accurately. One such programme, known as SimTanka, has been written by an Indian organisation and is available free of charge on the World Wide Web. The Ajit Foundation is a registered non-profit voluntary organisation with its main office in Jaipur, India and its community resource centre in Bikaner, India.

SimTanka is a software programme for simulating performance of rainwater harvesting systems with covered water storage tank. Such systems are called Tanka in western parts of the state of Rajasthan in India.

The idea of a computer simulation is to predict the performance of a rainwater harvesting system based on the mathematical model of the actual system. In particular SimTanka simulates the fluctuating rainfall on which the rainwater harvesting system is dependent.

Rainwater harvesting systems are often designed using some statistical indicator of the rainfall for a given place, like the average rainfall. When the rainfall is meagre and shows large fluctuations then a design based on any single statistical indicator can be
misleading. SimTanka takes into account the fluctuations in the rainfall, giving each fluctuation its right importance for determining the size of the rainwater harvesting system. The result of the simulation allows you to design a rainwater harvesting
system that will meet demands reliably, that is, it allows you to find the minimum catchment area and the smallest possible storage tank that will meet your demand with probability of up to 95% in spite of the fluctuations in the rainfall. Or you can use SimTanka to find out what fraction of your total demand can be met reliably.

SimTanka requires at least 15 years of monthly rainfall records for the place at which the rainwater harvesting system is located. If you do not have the rainfall record for the place then the rainfall record from the nearest place which has the same PATTERN of rainfall can be used.

The included utility, RainRecorder, is used for entering the rainfall data. Daily consumption per person is also entered and then the software will calculate optimum storage size or catchment size depending on the requirements of the user. SimTanka also calculates the reliability of the system based on the rainfall data of the previous 15 years.

SimTanka is free and is and was developed by the Ajit Foundation in the spirit that it might be useful for meeting the water needs of small communities in a sustainable and reliable manner. But no guaranties of any kind are implied.

For more information or to download the software see their website at
http://www.geocities.com/Rainforest/Canopy/4805/

(Source: the information given here is taken from this website).

Further comments

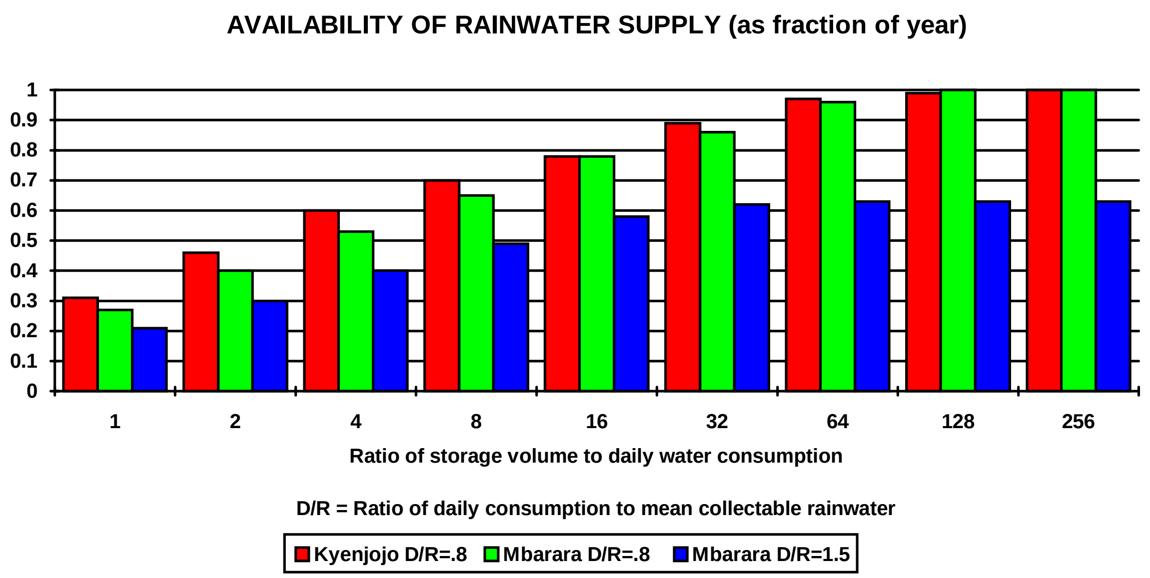
These methods outlined above can be further refined where necessary to use daily rainfall data. This is particularly important in areas where rainfall is more evenly distributed and more sensitive calculations are necessary.

Rainfall data can be obtained from a variety of sources. The first point of call should be the national meteorological organisation for the country in question. In some developing countries, however, statistics are limited due to lack of resources and other sources are often worth seeking. Local Water Departments or organisations, local hospitals or schools are all possible sources of information.

In reality the cost of the tank materials will often govern the choice of tank size. In other cases, such as large RWH programmes, standard sizes of tank are used regardless of consumption patterns, roof size or number of individual users.

Tank efficiency and the case for diminishing returns

On days when rainfall is heavy, the flow into a tank is higher than the outflow drawn by water users. A small tank will soon become full and then start to overflow. An *inefficient* system is one where, taken over say a year, that overflow constitutes a significant fraction of the water flowing into the tank. Insufficient storage volume is however not the only cause of inefficiency: poor guttering will fail to catch water during intense rain, leaking tanks will lose water, and an 'oversize' roof will intercept more rainfall than is needed.
Storage efficiency (%) =100 x (1 - *overflow / inflow*) provided that *inflow<demand*
System efficiency (%) = 100 x *water used / water falling on the roof*
In the dry season, a small tank may run dry, forcing users to seek water from alternative sources. *Unreliability* might be expressed as either the fraction of time (e.g. of days) when the tank is dry or the fraction of annual water use that has to be drawn from elsewhere. A RWH system may show unreliability not only because storage is small, but because the roof area is insufficient. The figure below shows how *reliability*, expressed as a fraction of year, varies with storage volume (expressed as a multiple of daily consumption) for two locations close to the Equator and therefore both with double rainy seasons.



From this graph one can see that increasing storage size, and therefore cost, gives diminishing returns. For example look at the left hand column of each triplet (Kyenjojo with roof sized such that average annual water demand is only 80% of average annual roof runoff). Assuming a say 100 litres per day demand, shows that increasing storage from 1 day (100 l) to 16 days (1600 l) raises the reliability from 31% to 78%, but storage has to be increased as high as 128 days (12,800 l) to achieve 99% reliability. Such high reliability is so expensive that it is an unrealistic design objective for a DRW system in a poor country. In any case, as we shall see below, users may change behaviour so as to reduce the effective unreliability of their systems.

System features (that affect tank sizing)

- An oversize roof slightly extent compensates for an undersize tank.
- If users are able and willing to adjust their consumption downwards during dry seasons, or when they find water levels in their tank lower than average, tanks can be sized smaller.
- ‘Partial’ RWH systems, either where it is accepted that RW will not meet needs throughout the year or where rainwater is only used to meet specific water needs like cooking/drinking, can be built with surprisingly small tanks.
- The reliability level appropriate to the design of a RWH system rises with the cost (in money, effort or even ill-health) of the alternative source that is used when the tank runs dry.

Rainfall data

Rainfall is very variable, especially where annual precipitation is less than 500mm. It also varies with location, so that data from a rain gauging station 20km away may be misleading when applied to the site of the RWH system. From the lowest to the highest quality of rainfall data we can think of at least 6 categories:

1. No numerical data available, but of course local people know quite well the seasonality of precipitation and which crops will grow (with what sort of water-stress failure rate).
2. There is no numerical data, but RWH has been practised for long enough locally for people to have a feel for what is an adequate tank size.
3. Only annual average rainfall is available, probably at a somewhat distant recording point, plus local knowledge of seasonality.
4. Monthly rainfall, averaged over at least 4 years, can be obtained.
5. Actual monthly rainfall records for at least 4 years, and preferably 7 years, are available for the site or for a location sufficiently nearby to give confidence or allow some systematic correction to be applied.
6. Daily rainfall data for a relevant location and lasting at least 4 years is available.

Daily data is adequate for all design methods except perhaps the optimisation of gutters for which *rainfall intensity* data is useful (e.g. the fraction of annual precipitation falling at a rate faster than say 1mm per minute). Rainfall data can be expensive to purchase and is often hard to locate even where it exists. Obviously methods of sizing tanks that require as an input rainfall data of a sort that is not locally available should not be used.

Possible methods for estimating likely future RWH system performance with a tank of given size

1. Ask local people with existing RWH systems and a comparable roof size what tank size they used and what has been their experience with it.
2. Mean dry season duration x daily dry season consumption. This may define an ‘ideal’ below which the designer chooses the ‘biggest affordable’.
3. Model *reliability* or *efficiency* using mean monthly rainfall data. (One variant of this is to compare the cumulative supply and usage loci to determine the maximum deviation of the former below the latter)
4. Test different tank sizes against actual *monthly* rainfall data over several recent years (or for tanks equivalent to less than 2 months water demand actual *daily* data) and thereby deciding the best reliability v cost trade-off.

5. Reasons for the current interest in DRWH

In the last decade there has been a large increase in the amount of interest in, and application of, DRWH in both developed and developing countries. There are a number of reasons for this growth. In developing countries these include: disillusionment with traditional technologies, which have failed to meet the needs of the people; a growing number of problems with groundwater sources; a realisation that DRWH is a viable alternative which gives the user autonomy and independence. In the industrialised countries the motivation has been: to reduce water bills, which have grown in some countries at alarming rates; to meet the ever growing needs (particularly for non-potable water) of ever more demanding societies; to offset the huge demand on depleted or polluted groundwater resources.

The following is a small collection of articles, reports and comments which illustrate these issues:

Rainwater Cistern Systems as an Alternative Drinking Water Source in Regions of Inadequate or Unsuitable Groundwater

The Canadian Province of Nova Scotia includes a population of approximately 850,000 persons in an area of 52,840 sq km. Approximately 320,000 persons are served by private well supplies. The quality of groundwater in Nova Scotia is generally good. However, there are areas of the province in which adequate reliable supplies of groundwater of acceptable quality are not available to individual dwellings. In these situations rainwater cistern systems have been used or proposed for use. An estimated total of up to 500 dwellings in Nova Scotia are now served by rainwater cistern systems. The rainwater system consists of a roof , which serves as a collection surface, and gutters and down-spouts that are connected to a storage reservoir located in a basement or underground. Treatment devices for disinfection and/or filtration have been installed by some owners on the household side of the cistern. The largest single reason for use of these systems is their location in areas where groundwater is completely unacceptable for domestic purposes because of local gypsum deposits. Other reasons include unsatisfactory well water caused by salt water intrusion, iron and manganese, or inadequate groundwater yield. Studies have indicated that a rainwater cistern can provide a reliable and effective method for the supply of water to an individual dwelling, provided that the size of the roof surface is adequate to meet the long-term demands of the occupants, and that the owner is prepared: (1) to install a cistern of adequate size; to provide a method for disinfection; and, (2) deal with routine maintenance in the form of cleaning of gutters and the cistern interior.

Symposium on Hydrogeology of Cold and Temperate Climates and Hydrogeology of Mineralized Zones. Proceedings of the Symposium held May 1-5, 1988, Halifax, Nova Scotia, Canada. (1989). pg 247-255, 1 fig, 7 tab, 14 ref.

The town of Avadi in Tamil Nadu, India, is using rainwater harvesting to augment its scarce groundwater resources. Not only were groundwater levels dropping but also groundwater quality has deteriorated, limiting water availability to only 4 litres per capita per day (lpcd). A consultant calculated that supply can be at least be doubled by channelling rainwater collected from roof tops and vacant areas around houses via percolation pits and a filter into household wells. Total costs for a system are INR 5,000 (US$ 118) of which INR 3,000 (US$ 71) for piping and the remainder is for sinking percolation pits. So far 10 houses have employed a rainwater harvesting system. The recharging method can be modified to tap water from storm-water drains, canals and boreholes.

Source: The Hindu, 21 September 1998

A survey of 3014 people across South Australia was undertaken to determine the sources of water for drinking and cooking. Overall, rainwater was found to be the main source of water for drinking – 42.2% of households used tank water for drinking, followed by mains supply at 40.3%. For cooking, mains supply was used by 64.3% of households, followed by 29.9% of households using rainwater from tanks. In the Metropolitan area, on average 25.6% of households used rainwater for drinking, whereas in rural areas, on average 81.5% of households use rainwater with use in some areas approaching 100%.

Source: Water – Journal of the Australian Water and Wastewater Association, January/ February 1998

The Tokyo Metropolitan Government is also promoting the use of RWH in the city, and have included for RWH in the Water Policy Guidelines. This is in response to an inability to meet urban demand because of inadequate sources of water.

In Germany there are increasing concerns about nitrates and pesticides in ground water. The concentrations of both of these is growing notably. Also an increased demand for drinking water (e.g. 1200% increase in consumption between 1975 and 1994 in the Oberfranken area of Northern Bavaria) is causing a major headache for water supply companies and the government.

Arsenic poisoning in Bangladesh and India

An estimated 18 million people in Bangladesh and West Bengal (India) are poisoning themselves by drinking arsenic-contaminated groundwater. Victims suffer a painful death, from one of several forms of cancer, with skin lesions on hands and feet as advanced signs of poisoning. The crisis is a result of extensive UNICEF and government-sponsored well drilling programs for over 25 years which successfully cut mortality rates attributed to diarrhoea but did not carry out water testing. Despite continued warnings by analytical chemist, Dr. Dipankar Chakraborty, as far back as 1988, government officials generally dismissed him as an alarmist. In late August 1998, the World Bank announced a US$ 32.4 million loan for the Bangladesh Arsenic Mitigation Water Supply Project (BAMWSP). The IRC International Water and Sanitation is helping prepare the operations steps and manuals for BAMWSP.
New York Times, 10 November 1998

An estimated 100 people in Bangladesh have died of arsenic-related diseases so far in 1998 and 1,000 have become ill. Most deaths are not known, however, because the problem was not officially recognised until 1993 [1]. In one of several articles on the arsenic crisis, journalist Sylvia Mortoza mentions that over 2,500 have died in Bangladesh over a few months [2]. Now major donor help is underway, nowhere near the 70 million people potentially at risk will fall ill. The issue has also raised awareness of arsenic poisoning in the US where environmentalists took the Environmental Protection Agency to court for dragging its feet on the adoption of the World Health Organization (WHO) arsenic guideline value of 10 ppb [3]. An overview of current arsenic research projects can be found at the West Bengal and Bangladesh Arsenic Crisis Information Centre site: http://bicn.com/acic/

Process and Progress
Where they have been installed, government tubewells and handpumps have been poorly maintained in rural areas and delays of several months before repairs are carried out are not uncommon. The urban context differs in that water infrastructure exists with both intermittent and unreliable supply.

Benefits from government sanitation programmes to rural communities in the project areas visited have been limited, and sanitation and drainage in the urban project area were inadequate before the project intervention.

Rainwater harvesting-Kibwezi project
This project includes the provision of guttering and the construction of rainwater storage tanks at 46 schools in the area. The purpose of the programme is to provide sufficient water throughout the year for the pupils, both for drinking and for cooking their midday meal. The work is carried out under KWAHO supervision with the assistance of parents who excavate the pit in which the ground tank is cast, and provide sand for its lining. At the time of evaluation, this installation had been completed in 27 schools, of which 10 incorporated ferro-cement tanks above ground with a capacity of 30 cubic metres and 17 are below ground with a capacity of 75 cubic metres. It is possible that low lift pumps installed in certain schools may not be suitable, in that they are mounted at about 45 degrees to the vertical.

Mfangano Island Project
Shallow wells constructed on Mfangano Island were intended to respond to endemic cholera, dysentery, diarrhoea and billharzia found in the Lake water from which inhabitants draw their supplies. To provide sources of safe water for inhabitants who tend to cluster around the lake shore, a trial programme for the construction of ten shallow wells has been carried out but with very limited success. In almost all cases, the water was saline and unacceptable to villagers.

Ngusuria Project
In Ngusuria, villagers have laid 12 km of 50 mm diameter GS pipe to supply three villages from a spring and impoundment high up on the side of the escarpment surrounding the area. Service mains, storage tanks and break pressure tanks have also been installed serving some 25 stand pipes and private connections. The discharge from the spring often reduces to zero at the end of the dry season. In this event, supplies are provided from a deep, copious borehole in which an electro-submersible pump has been installed. This was unserviceable at the time of the visit. Arrangements to lift the pump and motor for repairs were being made.

6.Criteria for the analysis of DRWH systems

The possible applications of rainwater harvesting are endless. For each circumstance, be it an affluent South Australian urban dwelling or a poor African rural household, there will be a desirable solution. The requirements of each individual will be different. For some, space will be limited, while for others cost may be the over-riding factor. It is therefore impossible to suggest a suitable DRWH system without knowing the context for which it will be used. We can however carry out a broad analysis for the systems considered here.

To facilitate such an analysis to be carried out we have developed a set of criteria by which the DRWH systems can be assessed by the reader. The list is by no means exhaustive and in most cases is purely subjective. Where actual facts and figures are available, they are given in the Case Study and the reader can judge him/herself the suitability of the system in question. The table shown below is completed for each example and shown at the end of each Case Study.

A cost analysis of DRWH systems is somewhat meaningless when the value of world currencies varies so widely. We have therefore considered not only local costs (and converted this into US Dollars for easy reference, but also considered this cost as a percentage of the average monthly income for the region in question.

Material requirement and costs

7.Health and DRWH

The literature on health aspects of RWH is surprisingly sporadic Gould & McPherson 1987, S Australia 1981, even in countries where RWH use is widespread and of long standing. We are interested in the mineral quality of roof run-off, in its bacteriological quality, in the connections between RWH and the breeding of disease vectors (especially mosquitoes), and in the risk of accidents such as children drowning. We would like to know not only how new systems might perform and do actually perform, but also whether that performance declines with the age of a RWH system. On the positive side, we should like to be able to quantify the undoubted health benefits of women spending less time collecting water - benefits such as fewer accidents to unattended infants, better nutrition, less female back injury and of course the hygiene benefits of greater water consumption which introducing RWH sometimes brings.

RWH may not be competing on a 'level playing field' when it comes to health criteria. Because there are few specific health standards defined for harvested run-off, there is the danger that inappropriate norms will be demanded of it. Competently harvested roofwater generally has negligible levels of pollution by minerals and low levels of bacterial pollution. In almost all developing country situations its quality is likely to be superior to that of such alternatives as discontinuously-pressured piped water, shallow well water and even deep well water. Conversely it may not achieve the bacteriological quality of treated water entering mains from a water works, or that of delivered water in rich countries. Roofwater that is incompetently collected or stored may indeed be turbid and a possible source of pathogens.

There have been concerns that rain may pick up unhealthy substances whilst falling through the atmosphere, whilst running down a roof or whilst resting in a store. The danger from the first of these, namely atmospheric pollution, seem slight. Measurements of precipitation even in industrialised areas Thomas & Greene 1993 indicate a fairly low take-up of heavy metals from the air and wholly tolerable levels of acidity; however no doubt it would be unwise to harvest rainwater immediately downwind of say a smelter. The probability of finding truly-airborne ingestible pathogenic viruses or bacteria seems low and of finding larger airborne pathogens negligible. Interest therefore focuses mainly upon contamination of roofs and the performance of water stores in reducing or increasing pathogens.

Roofs and gutters are made of a variety of materials. For most practical purposes we can exclude discussion of 'organic' roofs such as grass, reed and palm because they yield such dirty run-off that they are rarely used for RWH. The common materials of interest are ceramic, cementitious, rock and metallic (plastic roofs being neither cheap nor durable). Contamination of water might arise from the roofing material itself or from substances that have accumulated on a roof or in a gutter.

Metal roofs are normally of treated steel or less commonly of aluminium. Aluminium is very inert unless in contact with very acid water. However the effect on health of ingesting tiny amounts of aluminium are controversial; there has been some debate in Europe about a possible link between such ingestion (from the aluminium saucepans popular up to 1960) and the development of Alzheimer's Disease that causes premature senility. Corrugated steel roofing employs mild steel protected by hot-dip or electrolytic galvanising or by painting, since stainless steel is too expensive to use. Galvanising entails zinc compounds: fortunately zinc has a low toxicity, so that roof run-off water does not exceed WHO-permitted zinc levels. Roof paints including bitumen may entail some risk to health and/or may impart unpleasant taste to roofwater and should probably be avoided for RWH. More seriously although no one can now afford lead sheeting on roofs, localised lead 'flashing' is still used at joints. One study in Malaysia Yaziz 1989 reported lead levels of up to 3.5 times WHO limits in roof runoff but this is not a general finding and seems to have arisen from lead in dust deposition rather than the roofing material since it reduced rapidly with storm duration. Not surprisingly the safety of water harvested from 'asbestos' (= asbestos-reinforced cement mortar) roofs has been queried, but the consensus is that the danger of developing cancer from ingested asbestos is very slight Campbell 1993. The danger from inhaled asbestos dust is however sufficiently high that working with asbestos sheeting, for example sawing it, without special protection is now generally banned in industrial countries. The iron in a rusting roof will also enter the runoff, but in such small quantities that it does not prejudice either health or taste.

Metal roofs are comparatively smooth and are therefore less prone to contamination by dust, leaves, bird-droppings and other debris than rougher tile roofs. They may also get hot enough to sterilise themselves. However contamination may be substantial on all roof types and it has been common for many years to design 'first-flush diverters' into RWH systems. During a dry spell debris builds up on roofs, so that the initial run-off during the first following rainfall event can be full of sediment and highly turbid. Overhanging trees, especially coconut palms, make this sediment problem worse, as well as increasing the likelihood of bird and rodent droppings. A common strategy therefore is to divert to waste the first say 5 litres of runoff at the beginning of each rain event. This can be done automatically using proprietary devices, or where the seasons are well defined it can be done manually by temporarily displacing the pipe connecting gutter to storage tank. If this first flush is excluded, we have a water source with modest levels of turbidity and typically medium levels of bacterial contamination (e.g. <10 FC per 100ml). Modern 'no-maintenance' separators, or more traditional screens, cloth or sand filters will reduce turbidity and contamination further and any good tank design will reduce it further still.

Not all tanks are however designed, made and maintained well. One can commonly see tanks which offer access to insects, lizards and rodents and which permit enough light to enter that algae can grow. Such tanks take longer to lower the contamination level of the entering flow and may even permit new infection for example by pathogens carried on the feet of cockroaches. Water abstraction is occasionally by lowered bucket - with all the opportunities for contamination that offers - and not uncommonly by a tap set too low in the tank so that tank-bottom sediment may be drawn into the outflow. However tests in even poorly designed tanks commonly give levels of bacterial contamination (rarely over 5 FC per 100ml) that compare well with those in competing water sources in developing countries. The technique of filling a RWH tank then sealing it for a month or more produces excellent water quality. It seems it is possible even without such steps to meet the highest international standards for bacteria and dissolved substances with well-made RWH systems incorporating effective prefiltration and careful in-tank flow guidance. Cleaning tanks, say annually, should improve water quality, provided any remaining disturbed sediment is allowed to resettle for several days before the tank is used again. With the best pre-tank separators however, the rate of entry of organic material is so low that (provided no photo-synthesis occurs) such material can be entirely removed by aerobic bacterial action and no cleaning is required.

Water tanks are close to houses. Moreover they usually contain water during some or all of any dry season, a time when alternative breeding grounds for mosquitoes dry up. For both these reasons it is important that they do not act as significant breeding sites. The design of tanks and guttering to exclude insect breeding requires a mixture of common sense and professional engineering or entomological knowledge. It is common sense to so align gutters, and keep them clear of blockages, that they do not hold stagnant pools after rainfall finishes. It is engineering expertise or long experience that generates good designs for self-clearing gutters or filters. It perhaps requires entomological expertise to identify tank shapes that lower the chance of successful larval development. Mosquito eggs are sufficiently small that they could pass through most filters with entry water: such filters cannot be very fine if they are to be able to handle the sudden and large flows during intense tropical rainfall of up to 1 millimetre per minute. Mosquito control is therefore a matter of preventing the entry and exit of adult insects and interfering with larval growth. The former may be difficult to achieve if tank maintenance is poor or if users place greater importance on maximising tank inflow than on maintaining mosquito defences. It is therefore attractive to have the ‘defence-in-depth’ of larval control. This may take the form of active control with fish predators, surface oil films and suchlike but a more rewarding general policy is to starve larvae. Maintaining darkness in a tank prevents photo-synthesis and the growth of algae. Preventing the entry of suspended materials reduces the general nutrient levels supporting any biological chain. Research is underway into these factors and it seems likely that fairly straightforward measures can render a tank unsuitable for dry-season breeding of anopheles, aedes and culecine mosquitoes. Moreover, broadly speaking, if mosquitoes can be controlled it should be relatively easy to control larger disease vectors like cockroaches.

If a child falls into a tank, even if that child can swim, there is a real danger of drowning. Many existing tanks have no covers or easily displaced covers and stories of children deliberately bathing in free-standing RWH tanks are to be heard. Perhaps of most concern are underground tanks whose covers have been opened for inspection, maintenance or even for drawing water. It is not normal to fence underground tanks, to extend them above the ground high enough to deter access by crawling babies or to socially control children from playing on them. However fencing and/or partial raising could have advantages including reducing danger of contamination by surface water and lowering the chance of cover damage by vehicles as well as reducing the risk of children or night-moving adults falling in. Accidents like drowning are most likely where a new technology is being introduced and therefore should be the particular concern of technology-change agents.

Every technology has its obscure and rarely-met failure and danger modes. Clearly any aspect of RWH that involves human activity on high roofs, handling rusty metal or working ‘underground’ involves some risk of accident. A particular danger, known to have asphyxiated at least one builder recently, is the possibility of deoxygenation within a closed tank during the process of mortar setting and curing.

Finally, under health considerations, one might mention floods. If flood levels are higher than the entry point of RWH tank entrances, there is the real danger of serious contamination of the stored water. This danger may be avoided by suitable tank location or by the permanent presence of a say slow-sand entry filter.

Report A1 –Current Technology for Storing Domestic Rainwater (Part 2)

The work in this report forms the basis for the current DTU roofwater harvesting Web Site. The site can be found at:

http://www.eng.warwick.ac.uk/DTU/rainwaterharvesting/index.html

The work in this document is on-going and will be added to as the programme progresses. The aim is to collect examples of DRWH practice from around the world and to provide a useful resource for practitioners of DRWH. Many of the graphics shown in the Web Site are not shown in this document due to electronic storage requirement limitations. The report is in two parts so that the document remains manageable. This is Part 2.

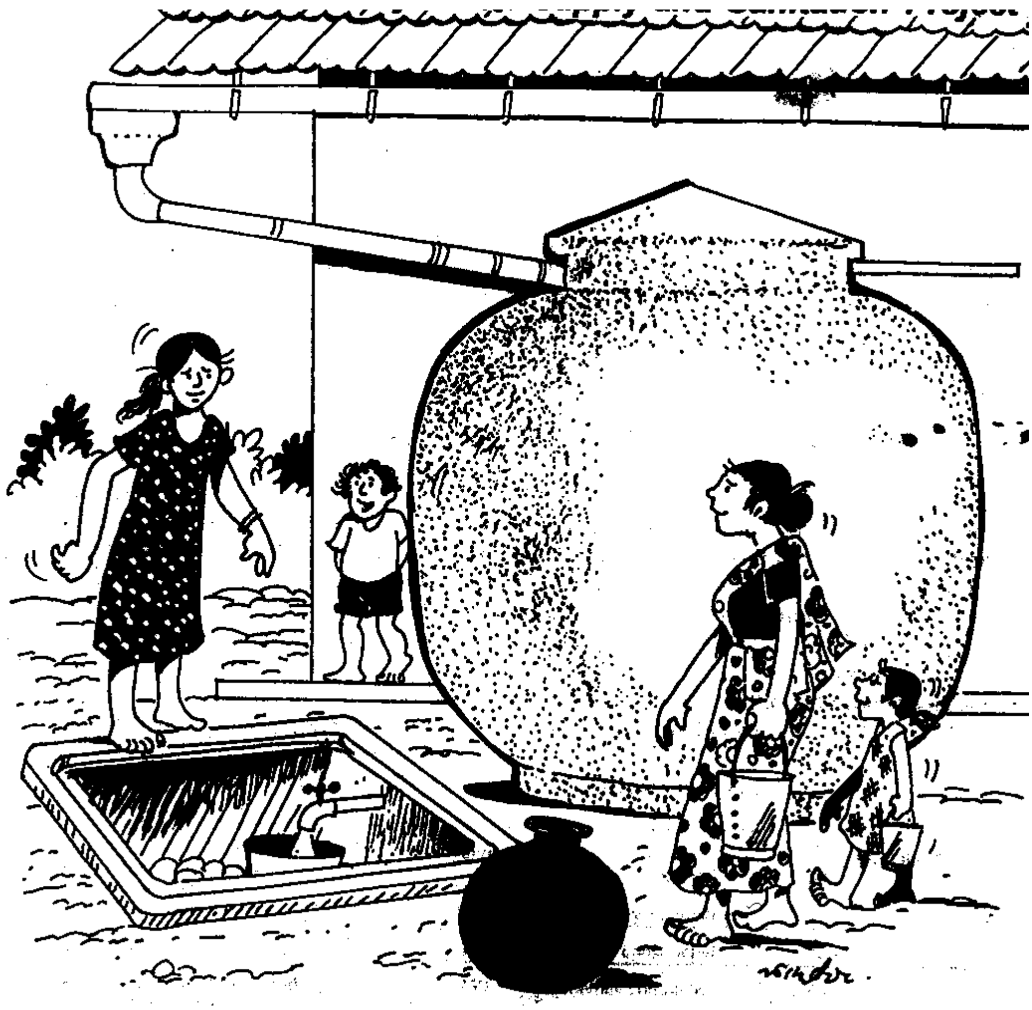
Contents of report (Part 2)

Case study 1 - The Sri Lankan Pumpkin Tank

Background Information

The Sri Lankan Pumpkin Tank, and the associated construction technique, was developed as part of a World Bank sponsored Water and Sanitation Programme which was implemented in the country between 1995 and 1998. The Community Water Supply and Sanitation Programme (CWSSP) covered 3 districts within the country – Badulla, Ratnapura and Matara Districts. Hundreds of these tanks were built in areas where conventional supply schemes, such as piped supplies or groundwater supplies, were difficult to provide. In some areas members of the target community were given the choice of a RWH system for individual households or a groundwater supply for a group of households. The choice varied. In all cases there was a choice of type of tank – either the Pumpkin tank or an underground tank which is described in Case Study 2. The choice was usually a function of ground conditions rather than personal preference. Both tanks have a capacity of approximately $5m^3$.

The Abikon family of Demetaralhina in Badulla District chose a pumpkin tank. Their village is in a rural highlands area of the country and the ground conditions were not suitable for a groundwater supply or for digging a pit for a below ground tank. Average annual rainfall is 2250mm with a bimodal rainfall pattern and a dry period, usually between December and April. Their per capita consumption was well below the 20 litres per day that each family member now consumes. The water is used for drinking (but only after boiling), cooking, personal and clothes washing. Mr Abikon also uses the water from their tank to water their 4 cows. Only towards the end of the dry season does the tank sometimes dry and then the family has to walk to the spring, about ½ a mile from their home.



Technical details

Rainwater is collected from only 1 side of the pitched roof, a collection area of 32m^2. The roofing material is a mix of zinc and asbestos sheeting. The guttering is a PVC U-channel, factory manufactured, found commonly in the nearby town, fitted to a facia board with similarly manufactured brackets, spaced at 300mm centres. The downpipe is a standard 3” PVC pipe, although some of the neighbours use less costly downpipes made from string and plastic tubing. The cost of the guttering is approximatley SLR5,600, about Sterling £86.00.

This pumpkin tank was built 3 years ago and is in very good condition. The construction is of ferrocement. The construction detail is given later. The cost of the tank is approximately SLR5,000 or Sterling £77.00. The materials and specialist labour for the tank were provided by CWSSP and the guttering was purchased by the Abikon family.

Water extraction is through a tap piped to a point slightly away from the tank, where the ground falls away and allows a bucket to be placed easily under the tap. There is a first flush mechanism fitted in the form of a simple PVC elbow with a length of pipe which diverts the dirty first water away from the
inlet chamber. The inlet chamber also acts as the prefilter chamber. The chamber is approximately 600mm cubed and contains subsequent layers of stone, charcoal and sand, through which rainwater passes.

Construction details:

The following construction details are given in the instructions which are handed out to masons during their training session:

Pumpkin (Wataka) Tank – Construction details

1. Prepare skeleton / framework legs (see Figure 1) as shown in the drawing. 10 no. required. Prepare the crown ring. This can be used again for many tanks.

(Figure 1 photo – one of the 10 framework legs used as the skeleton for the tank – shown in Web Page)

2. Lay the concrete base using two layers of chicken wire as reinforcing. Allow 300mm of chicken wire to protrude all around the edge of the base. This will be connected to the wall mesh later. Lay 10 anchor bolts for the legs in the base while casting (the diameter will depend on the diameter of the holes in the legs).
3. Leave the base for 7 days to cure, wetting each day.
4. Secure the 10 skeleton legs using the bolts and the crown ring.
5. Take 6mm steel rod and wrap it around the outside of the legs, starting at the bottom and working up at 10cm intervals.
6. Fix 2 layers of chicken wire over the outside of the skeleton. The filter tower can be added at this point if a filter is to be fitted.

(Figure 2 photo – a Pumpkin tank under construction – shown in Web Page)

7. Plaster the outside of the mesh. Leave for 1 day.
8. Go inside the tank and remove the skeleton.
9. Plaster inside the tank and cure for 7 days.

Water proofing can be added to the mortar. This can be a specialist additive or liquid dishwashing soap.

Cure the tank by wetting for 7 – 10 days. Fill the gradually starting on day 7, filling at a rate of approximately 300mm per day.

(Figure 3 photo – a finished Pumpkin tank)

Materials and labour breakdown

Material	Unit	Qty	Unit Cost	Total cost
Cement	Bag	8	265	2120

Sand	ft^3	55	3.5	192.5
Metal	ft^3	6	18	108
½" Chicken Mesh	ft^2	366	4	1464
Mould		1	325*	325
Transport				500
Skilled labour	hr	56	22	1232
Unskilled labour	hr	112	12.5	1400
				7341.5

*Assuming mould is used for 10 tanks
All costs given in Sri Lankan Rupees

65 SL Rupees = Sterling £1.00

Case study 2 – Underground brick dome tank, Sri Lanka

Background

This is another RWH system, as with the previous case study, which was developed by the CWSSP programme in Sri Lanka (see Case Study 1 for more detail). The tank, a 5m^3 underground brick built tank, is based loosely on the design of the Chinese below ground biogas tank. Indeed, the Sri Lankan engineer who designed the system had studied for some years in China. This is a good example of cross fertilisation of technologies across cultures, as well as the application of appropriate technology.

Again, this system was introduced due to the difficulties faced in bringing water to this community in a conventional manner. There was a lot of opposition to the RWH technology in the area at first, as it was a technology which was not widely known in the. Now, after 2 years using the rainwater falling on her roof, Mrs. Emsayakar, of Batalahena Village near the town Matara, sees things very differently.

The alternative offered by CWSSP was a handpump per 10 households. This still means walking to collect water. Mrs. Emsayakar joked that they can still use the handpump of their neighbours when they wish. She has not, however, had to do so yet as the harvested water meet all the needs of the family of 5, as long as they conserve water carefully. She also said, however, that she would prefer a piped / pumped supply which would mean that they could use as much water as they wish.

Technical detail

The tank

The tank is a 5m^3 below ground cylindrical brick construction based on the design of a Chinese biogas digester (see Figure 1 below). It has a diameter of 2.5m and a height of 1.3m to the base of the cover. The cover is a constructed using a clever brick dome design which can be left open to provide access. Water extraction is either by bucket, by handpump (more detail later) or by gravity through a pipe / tap arrangement where the topography and ground conditions are suitable. The cost of the tank is in the region of Rps.6,500 (UK£100). The construction details given to local masons are given below.

Figure 1 – detail drawing of the Sri Lankan brick dome tank (see Web Site)

The Chinese Brick Dome Tank – Construction details

1. Find suitable site
2. Dig pit 0.5m larger than the tank diameter
3. Plant an iron rod in the centre of the pit, making sure it is vertical.
4. Construct concrete base.
5. Start constructing walls using wire from iron rod to maintain the radius.
6. Once walls are complete backfill the gap between wall and pit with sand.
7. Make concrete ring beam to the shape shown. No reinforcing is required. Fit overflow pipe at this point if required.
8. Prepare two wooden sticks – one end an 'L' shape and the other a 'V' shape. The length of the stick is 2/3 that of the internal diameter of the tank.
9. Keeping the 'L' shaped end of the stick to top of the tank wall, place the 'V' end against the iron rod and wrap string or wire around the rod to support the stick.
10. Start to build the dome shaped roof of the tank with dry bricks.
11. To start, stick the first brick to the lintel with mortar and support it with the first stick.
12. For the second brick, stick this to the lintel and the first brick and support it with the second stick.
13. Push the third brick into place (with mortar) next to the second brick and move the second stick to hold the third brick.
14. Continue the process as with brick 3 until the first course is almost complete.
15. The final 'key' brick should be shaped to fit tightly allowing for the mortar.
16. Remove the sticks once the first course is complete.
17. Continue in this fashion for the subsequent courses.
18. The dome mouth is constructed in a similar way, but using the bricks length-ways.

19. Plaster the outside of the dome, then plaster the inside of the dome.
20. Plaster the inside of the tank.
21. Plaster the floor o the tank
22. Cure the tank by wetting for 7 – 10 days. Fill the gradually starting on day 7, filling at a rate of approximately 300mm per day.

Water proofing can be added to the mortar. This can be specialist additive or liquid dishwashing soap.

Water extraction is performed, at this sight, by two methods. A tap is fitted which allows water to flow by gravity from the tank, as shown if Figure 2. The second option is a simple handpump which has been developed, as part of the CWSSP programme, for use with below ground tanks. The pump is known as the Tamana pump, after the Pacific island on which it's predecessor was originally observed.

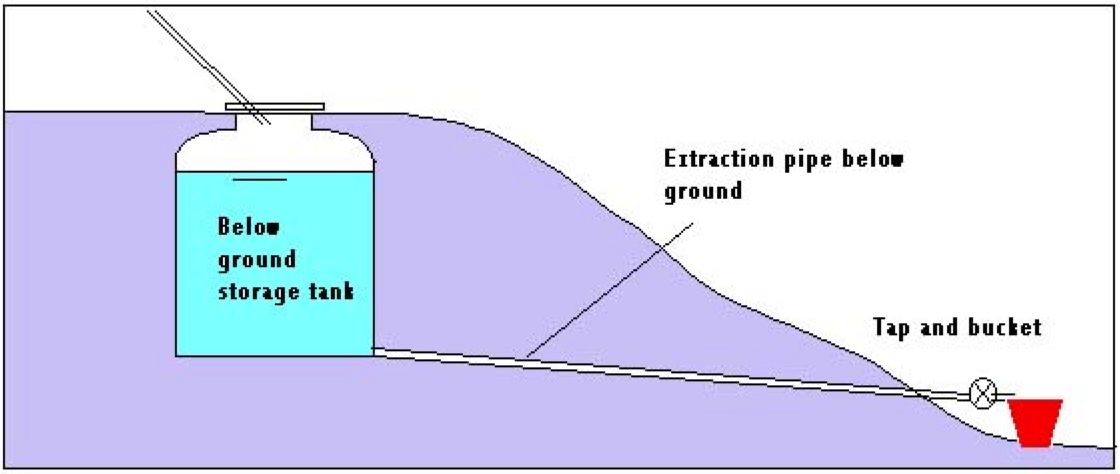


Figure 2 – Water is fed by gravity from the tank when the conditions are favourable

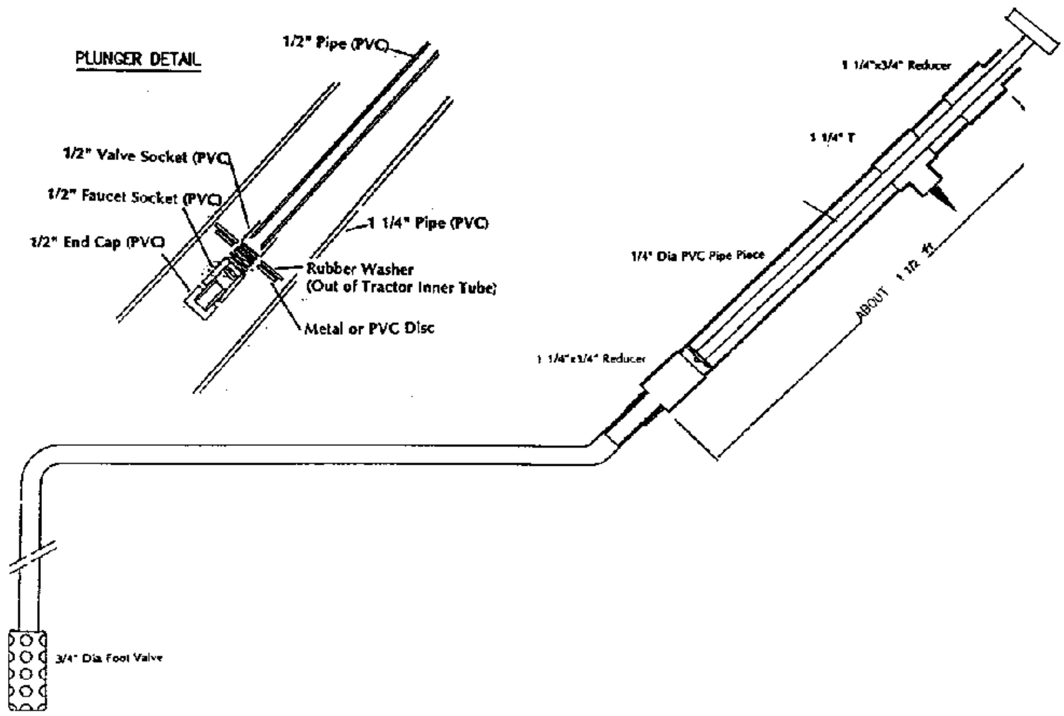

Figure 3 – The Tamana pump – design drawings

The Tamana pump is designed to be very low cost, approximately UK£5, using only locally available PVC fittings and rubber from a tractor inner tube. The location of the pump is shown in Figure 1 and technical details of the pump are shown in figure 3. This particular pump was fitted by the owners son, a mechanic, who has fitted many of these pumps for other community members. The pump has been brought via a ¾” PVC pipe to the kitchen of the house.

The first flush system is quite simple – the inlet chamber has a hole in its bottom, which is plugged with a bottle. When the bottle is removed water is allowed to flow away from the tank . The inlet chamber leads otherwise to a pre-filter chamber which contains layers of stone, charcoal and sand. The owner has experienced some problems with infestations of ants in this chamber. The inlet pipe to the tank has a protective mosquito mesh to stop mosquitoes entering and breeding in the tank.

Catchment area

The catchment area is the roof of the dwelling. This is a pitched roof of pan-tiles. Only one side of the roof is used. The other side is actually used to supply water for a neighbours tank which is situated at the other side of the house. The guttering is a factory manufactured U section type fitted to a facia board with specialist clips. The cost of the guttering is 1000 Rps. (UK£15.50). There is only about 8m of guttering for the 28m^2 of catchment surface.

User pattern

Average annual rainfall is 2600mm with a bimodal rainfall pattern and a dry season which lasts for 3 months. When properly managed the water collected can last throughout the dry period, with occasional trips to the nearby well for washing water. The average consumption rate for the whole family is about 75 litres per day but this is reduced during the dry season. The water is used for all domestic applications and there is no anxiety about the quality of the water, as is seen often where rainwater is used.

Item	Unit	Unit cost	Quantity	Cost (SL Rupees)
Cement	bag	310	8.5	2635
Sand	m^3	1700	0.4	680
¾ “ Metal bar	m^3	4000	0.1	400
Brick	Number	2.10	800	1680
Padlo cement	kg	100	0.5	50
Skilled labour	days	250	4	1000
Unskilled labour	days	150	12	1800
			Total	**8245**
The unskilled labour is often provided by the recipient hence reducing the cost of the tank.				

Case study 3

3.0m^3 brick built storage tank, Sri Lanka

Background

This case study is an example of local initiative in design and manufacture in DRWH. The tank in question was constructed in the village of Ahaspokuna, near Kandy, in the highlands area of Sri Lanka. The tank was built 10 years ago by a local mason for the Rajasomasari family and has since been copied so that there are now several of these tanks in the area. The setting is a high rainfall area (almost 3000mm annually) with a bimodal rainfall distribution. There is a dry season which lasts a maximum of 4 months. The Rajasomasari family fit the low to middle income range and their dwelling is a single storey bungalow with an electricity supply, latrine and shower room.

Technical detail

The tank

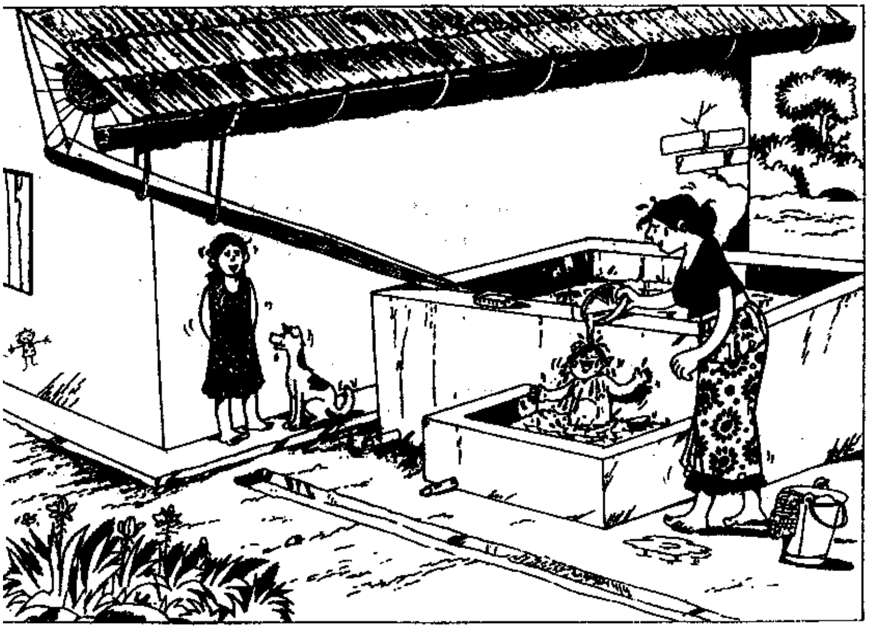
The tank is a simple brick built rectangular structure which has been cement rendered both inside and outside and sits at ground level. The tank has a concrete base. The cover is a removable wooden frame covered with a fine nylon mesh which filters out all larger debris such as leaves and twigs. The dimensions of the tank are 1.5 x 1.5 x 1.5m, giving a usable storage capacity of around 3m^3. The tank has an overflow and washout fitted. Small fish are kept in the tank, which helps to prevent algae growth and build up of organic materials. Water is extracted using a small bucket – there is a small removable section in the nylon mesh. The tank is usually cleaned when it is empty. The owner mentioned that the tank is very easy to clean because the top of the walls are only at chest height.

Catchment

The catchment area is the zinc sheet roofing of the house which totals about 90m^2. It is a pitched roof with a small gradient, say about 10^o. The guttering is, as is commonly found in Sri Lanka, S-Lon brand, U-channel, factory produced guttering as used for conventional rainwater protection /removal from houses. The cost of the guttering was approximately Rs. 5,000 (about £75.00). It is interesting to note that as much has been spent on the guttering as on the tank. Fittings for the guttering are also factory manufactured. The downpipe empties straight into the tank through the nylon mesh and can be diverted away from the tank as a first flush mechanism.

Water uses

The per capita consumption of water is in the region of 30 litres per day. They have a family of four people. The water is used for all domestic applications except drinking – water from the groundwater pump in the nearby valley is used for this purpose. The family is unsure of the cleanliness of the harvested water. The water in the tank lasts only about 15 days in the dry season, which is not very satisfactory in the eyes of the owner who would prefer a bigger tank.



Case study 4 – 10,000 litre partially below ground brick built tank, Sri Lanka

Background

This tank was built by Mr G. Victor A. Goonetilleke in the hill town of Kandy , Sri Lanka. Mr Goonetilleke decided to build his RWH tank after experiencing difficulty in sinking a well to sufficient depth to have a reliable perennial source of groundwater at the site of his newly built home. Drilling through the bedrock was too costly and there was no guarantee of securing a reliable supply. After 6 years of carrying water during the dry season Mr Goonetilleke started to research the idea of building a tank to store the rainwater that fell on his roof. There was very little encouragement from friends and neighbours who said that the water would provide an ideal site for mosquito breeding and algae growth. At the time there were no organisations to give advice on the benefits and drawbacks of roofwater harvesting. Three years after first contemplating the idea of a RWH tank, and after many helpful discussions with an Australian Radio Ham who convinced Mr Goonetilleke that RWH was a viable technolgy (and widely used in Australia), he decided to go ahead and build.

Technical details

The tank

Once the decision was made to build then certain design choices presented themselves. The determining factors for the tank capacity were:

sufficient capacity to store 100 litres of water for a period of 60 days
sufficient capacity to hold two bowser loads of water – during the dry season it is possible to purchase bowsers of water, but storage is required for this purpose. Each bowser contains 5,000 litres of water, but are not always available immediately upon request.

It was therefore decided to build a tank which would hold 10,000 litres. The next choice was what kind of tank to build. Mr. Goonetilleke had 3 obvious choices:

an underground tank - this type of tank needs excavation, care is needed to prevent roots penetrating the tank, contamination from ground can occur if not properly sealed, leaks are hard to detect and, finally, a strong cover is required to prevent children or animals from falling in. This type of tank does have the advantage, however, of being unobtrusive and benefitng from the support of the surrounding ground, making it cheaper to build.
a surface level tank – these require more space and can be ugly, but water is easier to extract under the influence of gravity and leakage is easier to detect. Covers need not be so sturdy, as little weight will be placed upon them.
an overhead tank – this type of tank is good in as much as little space is needed at ground level and the water is pressurised due to the ‘head’ of water. They are, however, expensive and it is difficult to transport water from the catchment system to the tank.

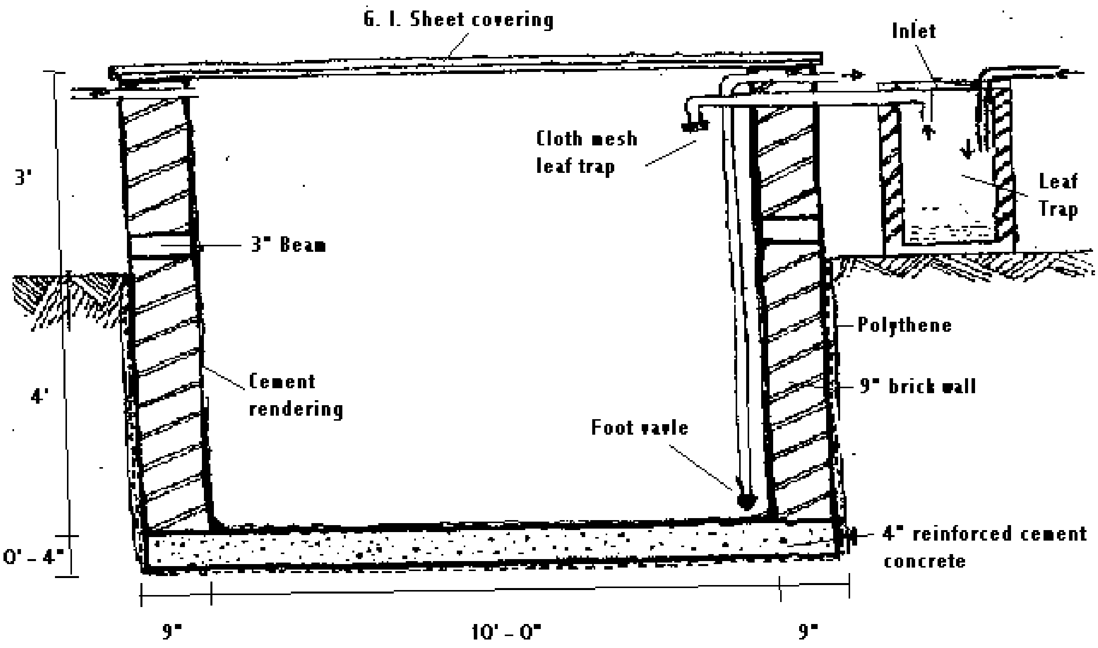


Figure 1 - sketch of 10m^3 brick-built tank.

The decision was made to build a tank which combined the advantages of the below ground and the surface tanks. Figure 1 shows a plan of the tank which was eventually built, partly below ground with 3 foot walls protruding from the surface of the ground. The next choice was what material to use for constructing the tank. Locally available plastic tanks were expensive and so Mr Goonitelleke decided to hire a mason to build a brick tank with a concrete base. Bricks are available locally.

The tank has a 4", 10 foot square, concrete base which is reinforced with ribbed steel bar. Polythene was laid underneath the concrete and brought up to ground level. The walls of the tank are of 9" brickwork. A 4" concrete ringbeam was cast at ground level to give added strength. The gap between the walls and the excavated pit were lined with concrete to allay fears of root penetration. The wall was then continued to 3 foot above ground level. The inside of the tank and exposed external walls of the tank were rendered – no waterproofing additive was added. The tank was covered with some galvanised steel sheets. A pump was fitted to pump water to a header tank situated in a tower near the house (which also houses an old 200 litre oil drum which collects rainwater for irrigating the garden). The overflow from the main tank goes into a shallow ditch where there is a flourishing stand of bamboo.

The total cost of the system was around Rs. 25,000 (US$550), but Mr Goonetilleke says that minimum cost was not the primary objective.

The roof and guttering
The roofing material is asbestos sheeting with an area of about 2000 square feet being used for catchment which is half the total roof area. S-lon brand, PVC, U-channel guttering is used to catch the water and the downpipe leads to a 1" PVC pipe (not ideal but it was freely available at the time) which then transports the water to the tank. The first flush system is a simple connector which enables the pipe to be diverted to the garden pond. The filtration system is simply a piece of mesh and some discarded mosquito net, but the aim is to improve on this.

Maintenance
During the 4 years the tank has been in use there has been no need for any major repair. The tank is cleaned once or twice a year and the cover is swept of leaves and dust regularly. Internal inspection of the tank is easy because of the low walls.

Uses for the harvested water
The water is used for mainly for washing and bathing and is occasionally used for drinking, but is then boiled. During the dry season waste (grey) water is used for watering the plants. There is little need to be overly conservative with the water because it is possible to order a bowser when the water level gets low (4500 litres at a cost of approximately US$7.00), although so far this has not been necessary.

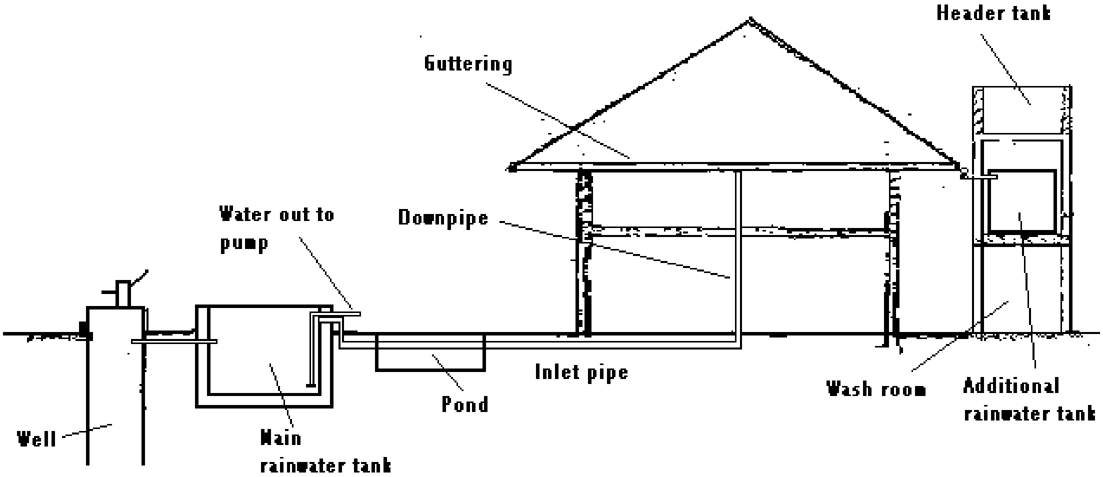

Figure 2 – Sketch showing the whole scheme including the water tower

Mr. Goonetilleke gives the following suggestions for improved awareness of RWH techniques:

- better information dissemination and educational awareness should be carried out at all levels.
- where possible, credit and technical advice should be made available in conjunction with other incentives.
- more concern should be given to the improper application of treated water – there is no need for water to be of exceptionally high standards if it to be used for clothes washing or bathing.
- architects should be aware of the principles of RWH and incorporate the technique in the house design where this is appropriate.
- care and attention are necessary (moreso than money), to maintain and improve the quality of harvested water.
- there are many myths associated with the concept of RHW which can be easily dispelled when the technology is put into practice.

Case study 5 – 10m^3 ferrocement tank, Nagercoil, India

Introduction and background

This RWH system is an example of a suburban solution to inadequate water supply from the municipal authorities. Although the family have a piped supply connected to the main town supply, the reliability of this supply is very poor – the piped supply provides water only every 8 to 10 days and the quality of the water is questionable. The family also has a groundwater supply but this, too, is unreliable. Their solution was to construct a RWH tank and harvest water from their roof. The traditional Nalluketta building style of this area, as shown in Figure 1, lends itself well to RWH. The central rooftop courtyard above a single storey dwelling makes an ideal collection area.

The system was installed as part of a programme run by the Centre for Appropriate Technology, an n.g.o. based in the town of Nagercoil. They have installed more that 100 such systems in the area.

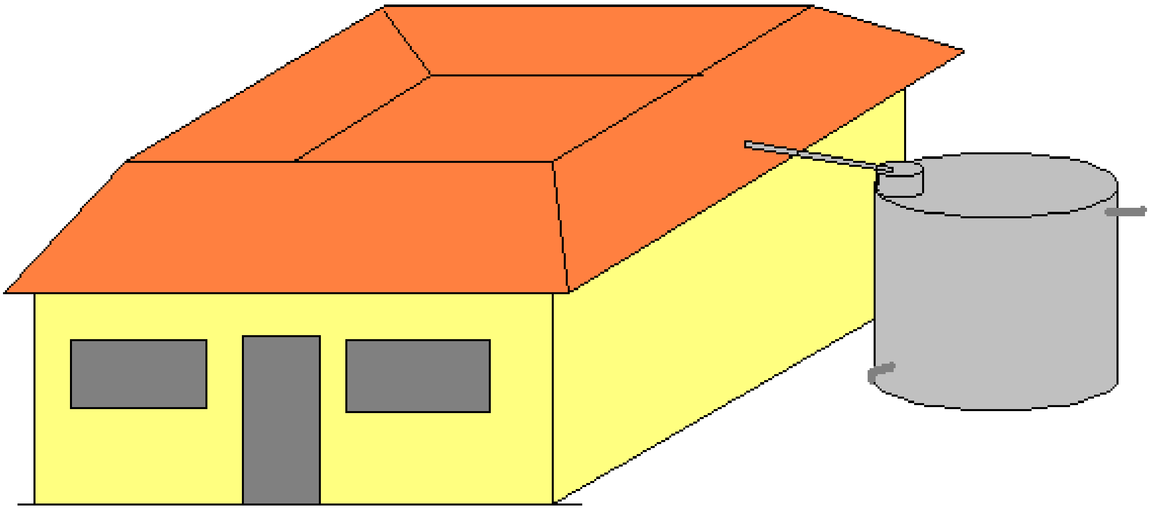

Figure 1. Traditional Nalluketta building style

Technical detail

Tank details

The tank is a cylindrical ferrocement structure, with a diameter of 2.5m and a height of 2m. There was little detail available regarding construction details but it appears from the corrugations on the exterior that a zinc sheet mould had been used to cast the tank. The tank is set on an 18” concrete plinth which means that a bucket can be placed comfortably under the extraction tap while still keeping the extraction pipe near the bottom of the storage area, therefore not wasting any storage capacity. The tank cover is formed using corrugated asbestos sheets. The tank is fitted with an overflow pipe near cover level.

First flush is achieved by simply moving the down pipe away from the inlet basin. There is a pre-filter basin which sits on top of the cover. It contains a plastic bowl which has been punctured repeatedly to allow water to pass through, as with a sieve. The bowl is filled with small stones and sand which acts as a filter. The bowl and basin have been cemented in place to prevent water entering the tank through the joints. A water level ‘sight tube’ has been fitted but is too discoloured by sun and silt to be of any use.

Catchment area

The catchment area, as mentioned earlier, is the rooftop of the house. Because the rooftop is rather unusual in design (see Figure 1) and the collection area is the internal rooftop courtyard, it is required that the downpipe pass through the roof structure (see Figure 3). This can present problems if sealing is not effectual. The catchment could take place on the outer faces of the pitched roof but this would entail fitting guttering and facia board, all extra expense. The catchment area is approximately 100m^2.

The pitched section of the roof slopes at approximately 35^o and is of pantiles. The central rooftop courtyard area is mostly flat with a a vriety of tiled and cement rendered surface. There are many trees overhanging the roof and it quickly becomes covered in leaves which could block the downpipe.

(Figure 2 photo – catchment area)

Annual rainfall in the region is about 1200mm. Normally there is a single wet season with a dry season which lasts about 4 months.

User pattern
The catchment is about twice the size required to fill the tank, so the tank can be filled early in the rainy season. The families procedure during the rains is:
to sweep the roof clean and divert the first rain runoff
to fill the tank early in the wet season
to then seal the tank (e.g. tape up the entry against mosquito entry)and divert flow away from it
to use the water for premium quality purposes only during the following dry season: the stored water usually lasts until the next rains

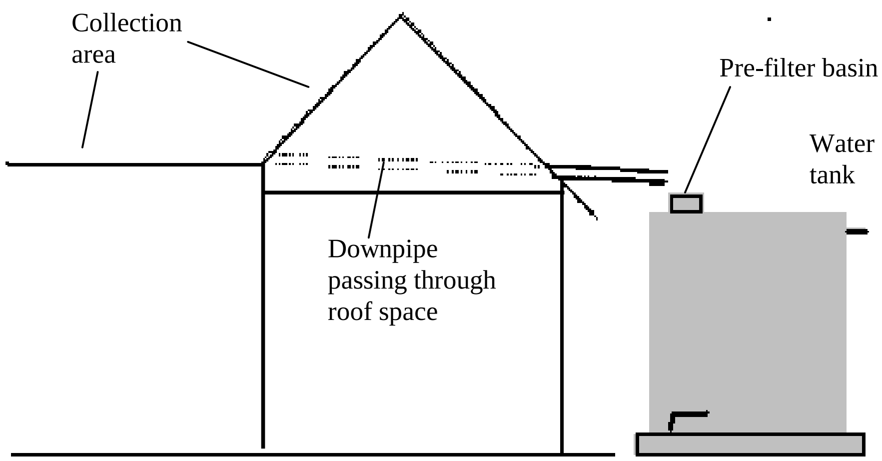

Figure 3. Cross section of the building showing the downpipe passing through the roof structure

Case study 6 – Below ground low-cost water storage cistern – 4 to 10 m^3 – Uganda

Introduction

This tank (or cistern) was developed in Uganda by members of the Development Technology Unit, Warwick University and members of the Uganda Rural Development and Training Programme (URDT), between 1995 and 1997. Work is still continuing on the refinement of the tank. URDT is a service NGO located at Kagadi in Mid-Western Uganda. Several of these cisterns were built and tested with the aim of developing a low-cost (under US$150), all-year, domestic, water storage technology for the surrounding region. The information for this Case Study is taken from a document titled 'Underground storage of rainwater for domestic use' by T. H. Thomas and B. McGeever, which is available as a working paper from the Development Technology Unit (see the list of partners on our home page).

Uganda is well suited to RWH practice for several reasons:
rainwater harvesting is a technology which is traditional to Uganda, albeit on a very ad hoc, very low-tech basis, e.g. buckets under the eaves to catch water during storms, or old 200 litre oild drums used for short term storage.
it has a bimodal rainfall pattern with very short dry seasons which are rarely completely dry.
annual rainfall in many parts of the country is in excess of 1200mm, which means that even the smallest house would have sufficient roof collection area to provide sufficient rainwater to meet demand (based on 15litres per capita per day).
corrugated iron roofs are becoming common, even in rural areas .
the lateritic soils in the area make well sinking a difficult task (yet provide ideal ground conditions for below ground tank construction).
there are many hilly areas where water (for irrigation and domestic use) has to be carried uphill from the valleys.
gravity-fed piped water is rare outside the main towns both because it is technically difficult (absence of strong high level springs, lack of mains electricity) and because the organisation to install and operate gravity water supplies is lacking in rural areas.

Ntale[1996] carried out a study of costs of existing water storage technologies based on a tank capacity of 8000litres. The results are shown below.
$340 in total for unreinforced mortar jars (at least 4 jars),
$390 for a brickwork tank, 50% more if reinforcing is deemed necessary,
$450 for a galvanised iron tank,
$1432 for a PVC tank,
$480 to $880 (various sources for E Africa) for a ferrocement tank,
$182 (quoted from Brazil) for a plastered tank of stabilised rammed earth, a material currently hardly known in Uganda..
These sums seem generally beyond the purchasing capacity of Ugandan rural households where even finding $200 for an iron roof is often not possible, although the last technique has promise.

Technical detail

Materials, tools and skills

The paper describes how to make a 6,000 to 10,000 litre underground cistern, suitable for construction where the soil is firm and hard but not rocky. *Variant A* has a 20 mm thick cement-mortar dome (mix = 1:3), a 25 mm cement mortar lining to its Chamber, and employs a little chicken mesh reinforcing. *Variant B* has a 20 mm cement/lime-plastered Chamber. Both variants have similar shapes and construction procedures. The materials necessary for the tank's construction meet the test of ready availability even in African small towns. They are, for an 8,000 litre cistern:

Material	Quantities	
	Variant A	Variant B
bags (ea. 50 kg) cement	$5^1/_2$	$3^1/_2$
bags (ea. 25 kg) lime	0	3
wheelbarrows of sand	15	15
lengths (ea. 12m) of 6mm reinforcing bar	1	1

chicken mesh (1.8m width)	1.5m	0
plastic bucket, say 10 litre	1	1

(also wood to make the template mentioned under *Step 1* below - 130 cm x 100 cm thin ply or 3m x 300 mm x 20 mm plank - and a large plastic washing bowl)

The tools needed for tank production are:

- ♦ digging and plastering tools
- ♦ a large plastic basin (say 45 cm diameter)
- ♦ a bucket on a rope for lifting out soil
- ♦ a spirit level
- ♦ a template for the dome (see *Step 1*)

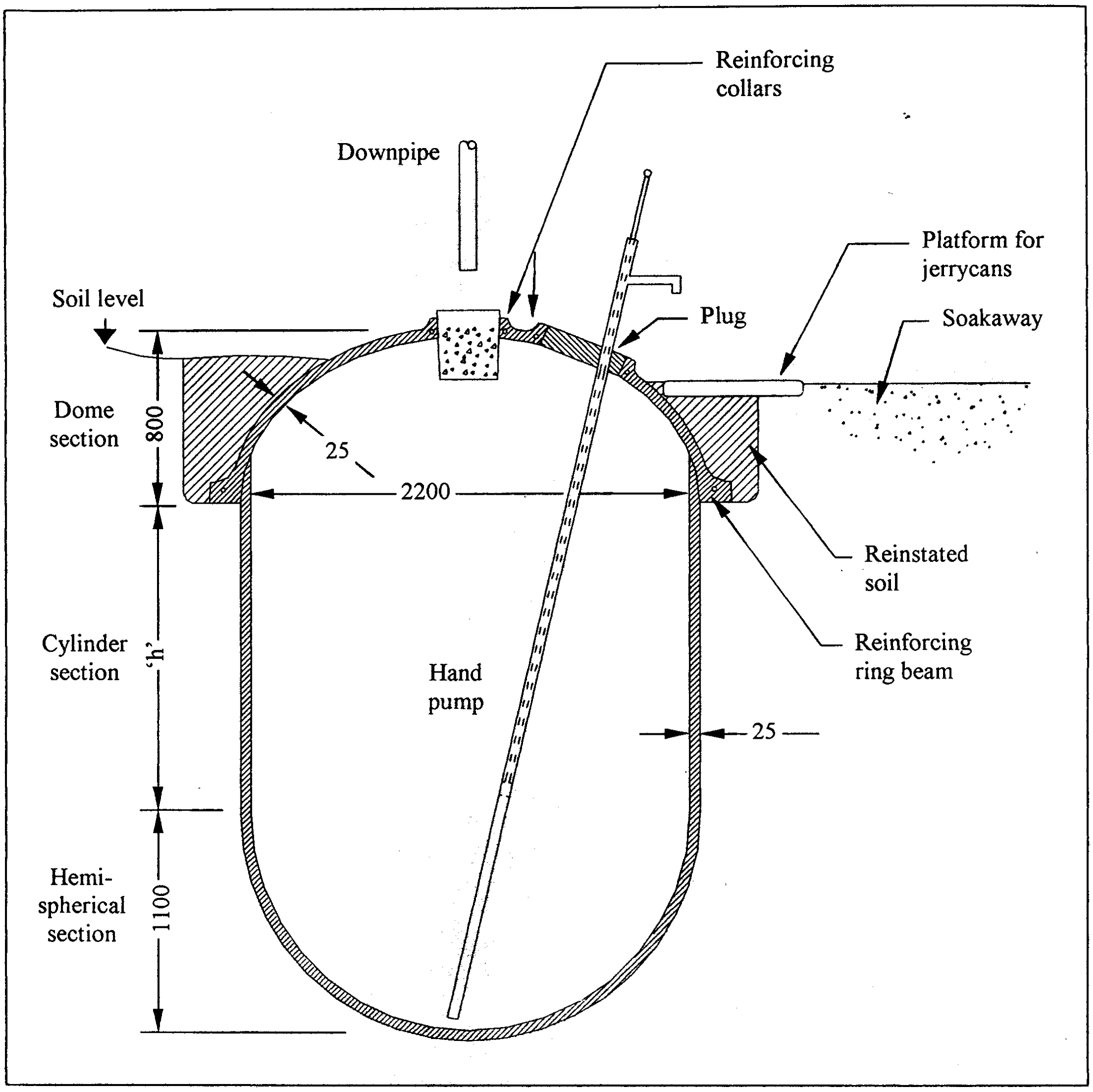

Figure 1 - General side view of cistern with pump

Parts of the DTU/URDT rainwater storage cistern and steps in its construction

The cistern is divided into four parts, namely the Chamber, the Cover, the Pump and Extras. Figure 1 shows a sectioned-elevation view of the tank and pump (what you would see if you could dig it out and cut it in half from top to bottom).

The Chamber has to have adequate volume and be waterproof. Because the overall cost of a cistern is dominated by the cost of the walls and cover, these should be as small as possible. For a given cistern volume, their total area is a minimum, for either a rectangular or cylindrical tank, when the tank's depth equals its width.

However for certain sorts of cover it is difficult to span widths of more than say 7 feet (2.2 meters). The cistern we are about to describe has a rounded Cover and a rounded bottom and has an internal diameter of 2.2 meters. The depth of the straight part of its sides for different capacities is as follows:

usable capacity in litres	4,000	6,000	8,000	10,000
depth of cylindrical sides	0 meters	0.5 m	1.0 m	1.5 m
depth from dome to bottom	1.9 m	2.4 m	2.9 m	3.4 m

The Cover has to stop the water from evaporating, keep the water clean, prevent anyone falling into it and keep out light and mosquitoes. It has to be pierced by a big hole to let the rainwater in very rapidly and smaller hole through which water can be pumped out. These holes must also be mosquito and light proof, and at least one of them must be large enough for a man to squeeze through in order to inspect or replaster the inside of the tank. It is recommended that the Chamber is excavated through the main hole in the Cover. This method allows the cover to be cast easily in situ without the need for shuttering or special tools. An earth mound is constructed for this purpose below ground level, as shown in Figure XX. The Cover should be shaped so that it leads any run-off from nearby ground away from its inlet. It must be strong enough to bear the weight of many people, provided that it has been covered with earth so that only the top of the dome is above the ground.

The pump. Thomas and McGeever discuss the requirements of a handpump for poor rural communities in Uganda:

A pump for a household cistern should

be cheap (in Uganda a ceiling price of USh.15,000 = $US15 was chosen);

permit an adult to raise 10 litres per minute (a rate generally obtained from protected wells) from a depth of 4 meters without undue effort and also be usable by a child of 6 years;

be 'self-priming', delivering water within a few strokes of starting to pump even when the pump has been out of use for some days;

reach water within 20 cm of the bottom of a tank;

fit into the mortar plug in the cover (dome) of a cistern so that light, mosquitoes and surface water cannot enter, yet permit the riser pipe and foot valve to be withdrawn through that plug whenever they need any maintenance;

lift at least 100,000 litres under household conditions of use before requiring replacement;

lift at least 10,000 litres before requiring maintenance, all such maintenance being possible using skills and materials available in most African villages;

be economically manufacturable in each country of use;

discharge conveniently into a jerrycan or other collection vessel.

In addition it is desirable that

♦ the foot valve does not leak faster than 0.1 litre per minute, so that if the pump is used twice within say 10 minutes it does not have to be (self) re-primed for the second use;
♦ the intake is constrained to avoid drawing up sediment in the tank by being located say 10 cm above the tank bottom; however for cleaning purposes it is helpful if dirtied wash water can be lifted from as little as 2 cm from the tank bottom.

Some development of a handpump which aimed at achieving this specification was carried out, but the authors feel that it was far from ideal. We will not, therefore, consider this pump in this case study.

The Extras include some means of seeing the water level inside the tank without having to open the Cover, a coarse filter for water entering the tank and provision for safe disposal of any overflow water. There is some interest in putting a layer of sand at the bottom of the tank as an output filter, however this would require the pump intake to be connected to a perforated pipe running under the sand. (Experiments to test such a filter's performance have yet to be done.)

During construction of any cistern, there are three choices in how one might combine the Cover and the Chamber. In some cistern designs, the Chamber is dug first and then the Cover built over the Chamber. In other designs the Cover and Chamber are made side-by-side and then the cover is lifted onto the top of the Chamber. For our design, we recommend a third method: the Cover is made first (in its final position at ground level) and then the Chamber is dug through an access hole in the Cover. It is not too difficult to do this if excavation is manual (although the procedure effectively excludes mechanical excavation and is therefore not recommended for high-wage countries) and it allows the use a cheaper dome-shaped Cover than if the cover had to be lifted. So the sequence for construction is as follows:

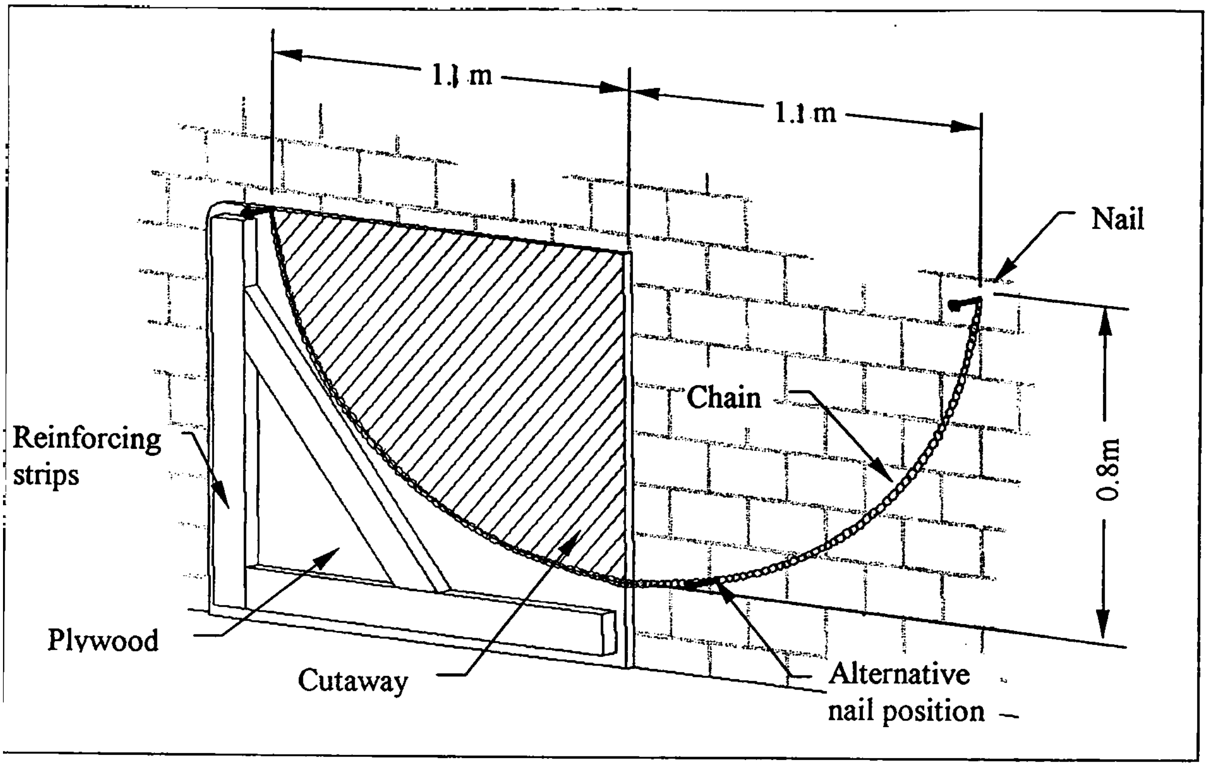

Figure 3 Making the template

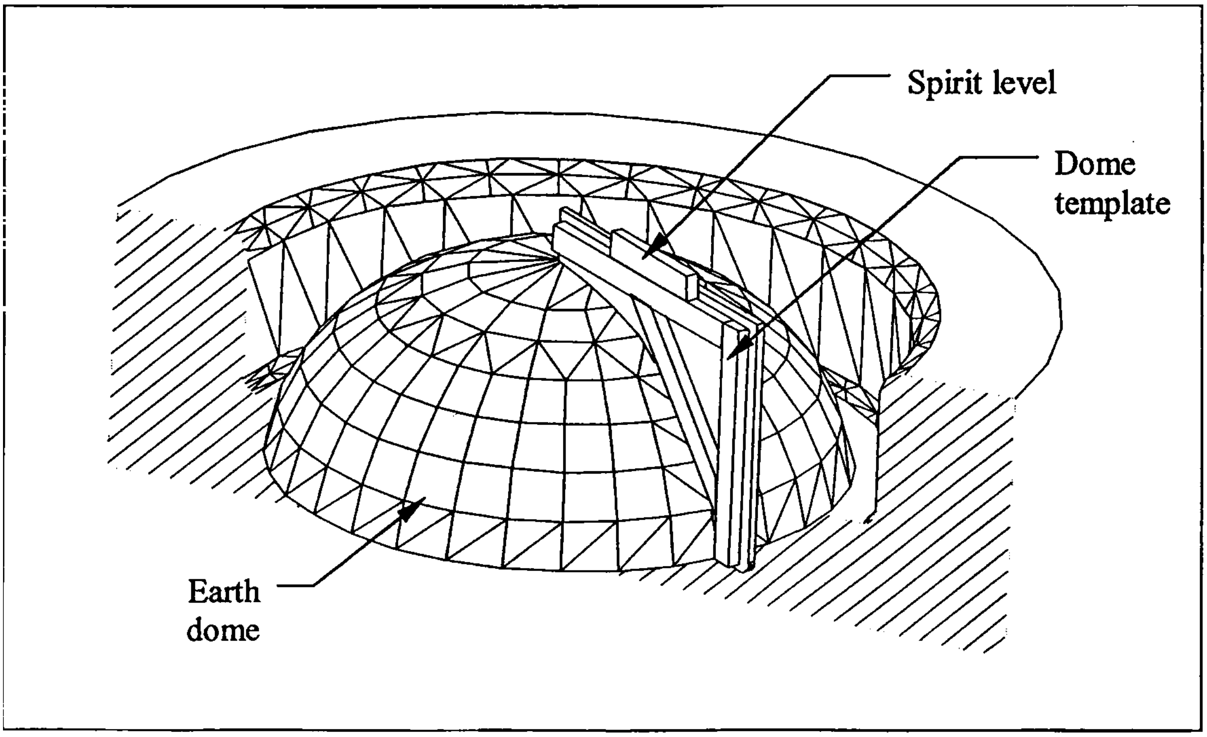

Figure 4 Forming the earth dome-mound

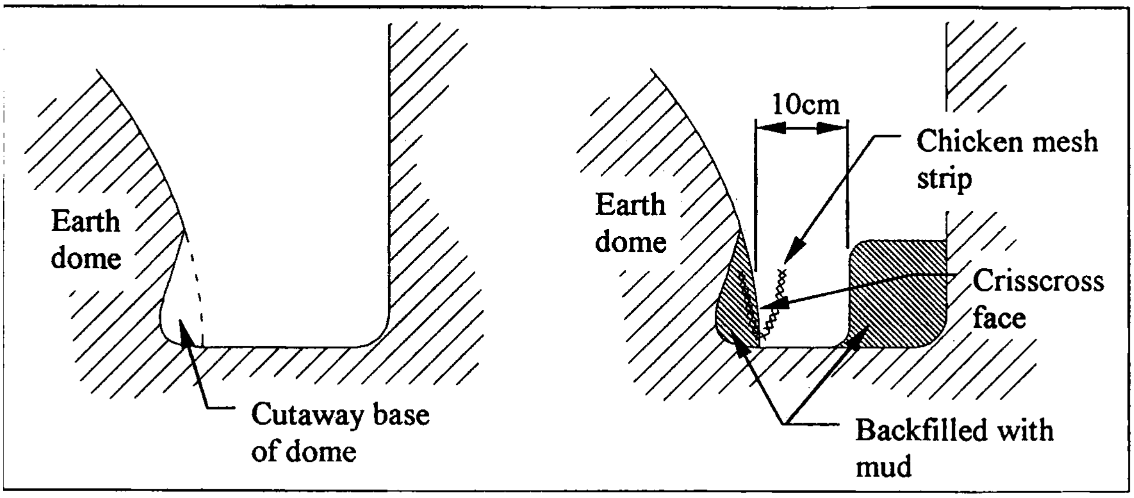

Figure 5 – Detail of joint between dome and wall

- Prepare reinforcing bar (and perhaps mesh) to place in the trench and round each hole in the dome
- Place mortar to form the ring beam and the dome with its two holes
- Cure the mortar then cover the dome with soil
- Through the larger hole dig out the Chamber
- Plaster the inside of the chamber and allow this plaster to cure
- Make the pump
- Set the pump into the dome
- Construct the tank inlet with its gravel filter

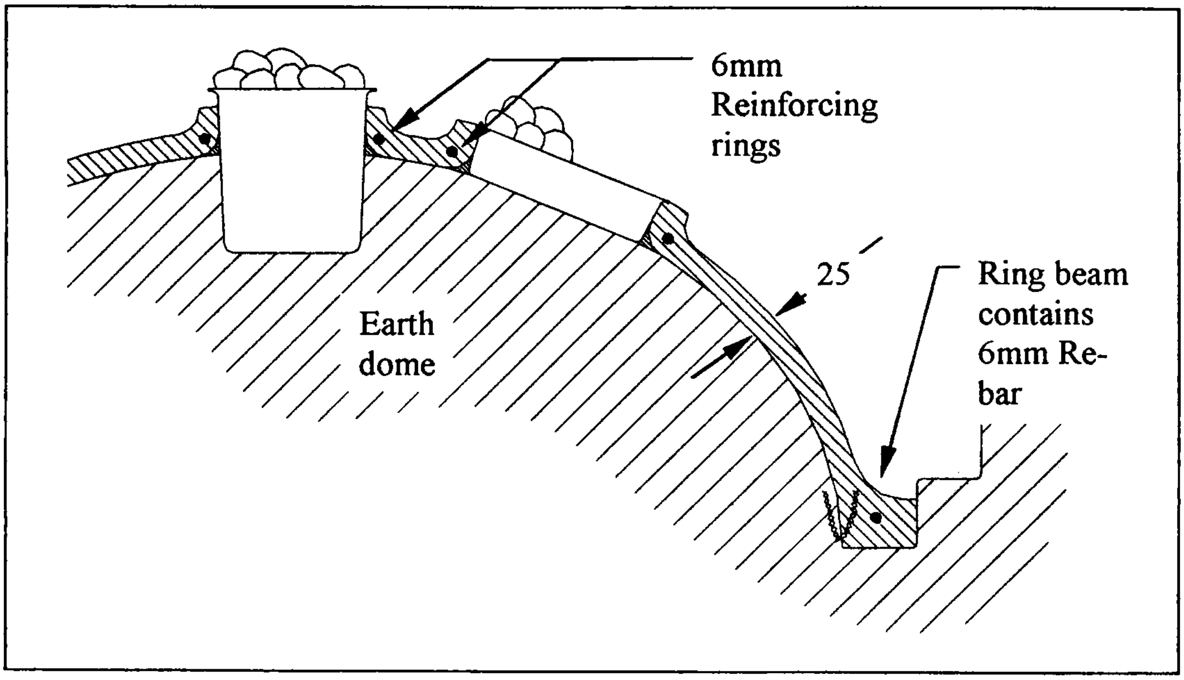

Figure 6 - Water inlet with coarse gravel filter

Provide drainage and arrange the hard-standing for pumper and water containers

The tank takes about 24 ‘man-days’ to construct. However the mortar dome and later the plaster in the chamber should each be left to cure for 2 weeks, so it needs a minimum of 6 weeks from when construction starts to when the tank can be used. Most of the work is digging but for 2 days an experienced plasterer is required. The pump can be made in a few hours.

Further work and field trials

Three tanks of 8000 litres were built and tested in the town of Kagadi. Tests on dome strength, leakage and chamber integrity and flexure were carried out and the results were very reassuring. Tests were also carried out a very low-cost pump design which proved to be unreliable and has therefore not been included in this Case Study.

Tank costs

Cistern costs (8,000 litre capacity with 20 mm dome and 2-coat chamber lining)

Item	*Quantity*	*Cost (US$)*
Cement/lime (including transport)	250 kg	65
Sand (assumed from a nearby source)	18 wheel-barrows	3
6 mm reinforcing bar	12m	5
Chicken mesh	3 m^2	4
PVC Bucket + 0.5 m of 50 mm piping		3
Unskilled labour for digging (9 m^3) etc.	20 person days	40
Plasterer	2 person days	8
Supervisor + say 25 km travel	1 person day	10
Tools (say)		5
	Total	143

Design variants

Some design variations have been discussed in this paper.
The dome of the tanks built in 1996 were 25 to 30 mm thick. Those recently tested for strength were 20 mm thick and performed well. 20 mm will be used henceforth as a norm. Moreover both mortar and concrete have been used for the dome. Concrete uses less cement, but requires fine aggregate (which is not widely available in rural areas) and is much harder to work smoothly as a plaster. There is some danger that these workability problems could lead to serious cracks in inexperienced hands. The mortar dome looks better. Mortar is more vulnerable than concrete to shrinkage during curing, but this should not matter in a largely unconstrained dome. On balance we recommend mortar despite the 33% higher cement requirement.
The chambers of the 1996 cisterns were single plastered to a thickness of 30 mm. The later tanks are using 20 mm applied as two layers (e.g. 15 mm plus 5 mm) rather than one. The tank most in danger of earth tremors has just been plastered with a 2-layer lime-cement mortar; it may take some years before the benefits of using this slower curing but more flexible plaster can be assessed.

Case study 7 – 10m³ ferrocement water tank using former

Introduction

This example has been taken from 'Ferrocement water tanks and their construction' by S. B. Watt and published by Intermediate Technology Publications (more information about this book and this publisher is given in the information section later in this document). All figures in the Case Study are taken from this book.

Watt states that these tanks have been used for many years in parts of Africa and have been designed to be as simple as possible to build in self-help programmes. The users, who are at first unskilled in this sort of construction, can contribute their time and efforts in collecting sand and water, digging the foundations and preparing the mortar under the general guidance of a trained builder. With experience they quickly learn how to make the tanks without further guidance.
A trained builder with 5 helpers takes approximately 3 days to complete the tank. The users often contribute some money towards the cost of the tank, which helps to cover the builders' wages, the cement, reinforcement and the hire of the formwork.

Design

The tanks have been designed for construction by relatively unskilled workers. They have a diameter of 2.5m, a height of 2m, giving a capacity of 10cubic metres. The final wall thickness will be about 4cms. The tanks are built on site and should not be moved.

Formwork

The 2m high formwork is made from 16 sheets of standard galvanised roofing iron, 0.6mm thick with 7.5cm corrugations rolled into a cylinder with a radius of 1.25m. Steel angle iron (40 x 40 x 5mm) is bolted vertically on the inside face at the ends of each set of 4 sheets – this allows the sheets to be bolted together to form a circle. Between the edge of each section is placed a wedge which is pulled out to allow the formwork to be dismantled (see Figure1).

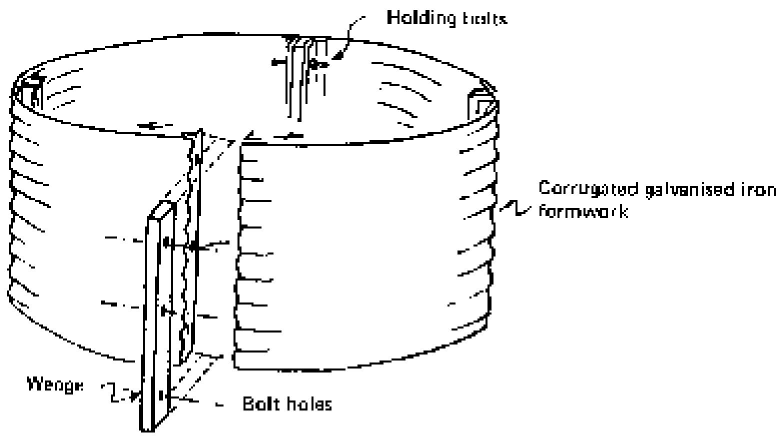

Figure 1 – Assembling the formwork

Construction

A circular area 2.8m in diameter is cleared at the required site for the tank and excavated down through the loose topsoil. A 10cm layer of sand is laid evenly over the excavation and a 7.5cm layer of concrete mix of 1:2:4 (cement:sand:gravel by volume) will form the foundation slab under the tank. Into this concrete foundation is cast a 1m length of 20mm bore steel water pipe with a tap on the outside end. The pipe is curved so that it projects 10cm above the floor of the tank; a piece of wire is threaded through the pipe to act as a pull through after the tank has been built (see Figure 2).

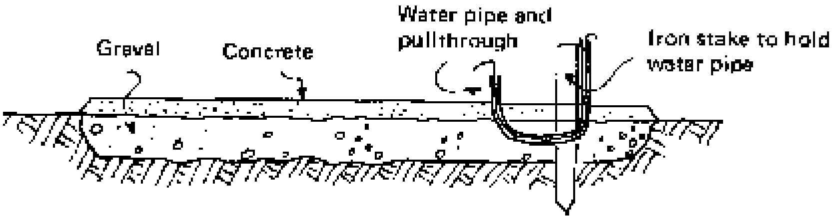

Figure 2 – Foundation of tank

When this concrete slab has hardened the formwork of the tank is erected. The bolts passing through the angle iron and wedges are tightened to provide a rigid cylindrical form. This is cleaned free of cement and dirt, oiled and the wire netting wrapped around it to a single thickness and tucked under the forms. The netting has a 50mm mesh, and is made from 1.0mm wire.
To form the hoop reinforcements, the straight galvanised iron wire, 2.5mm diameter, is wound tightly around the tank from the base at the following spaces:
2 wires in each corrugation for the first eight corrugations
1 wire in each corrugation for the remaining corrugations
2 wires in the top corrugation

About 200m of 2.5mm diameter wire will be needed, weight 8 kg. The netting provides vertical reinforcement to the tank and also holds the hoop wire out of the corrugations. The outside is then plastered with a layer of mortar made from a mix of 1:3 (cement : sand by volume)and as soon as this has begun to stiffen a second layer of mortar is trowelled on to cover the reinforcing wire to a depth of 15mm. The surface is finished smooth with a wooden float.
After a day or so the formwork is dismantled by removing the holding bolts and by pulling out the wedges which will leave the shuttering free to be stripped away from the inside mortar wall. The sections are lifted clear of the tank to be thoroughly cleaned of any mortar or cement. A 20cm length of 8cm diameter downpipe is built into the wall at the top of the tank to act as an overflow and the inside of the tank of plastered with mortatr to fill up the corrugations. When this has hardened sufficiently, a second final coat is trowelled onto the inside and finished with a wooden float.
A 5cm thick layer of mortar is next laid onto the floor of the tank and the junction of the floor with the walls built into a coving. The floors are not reinforced and so the tank wold fracture if it were moved. Take care that the mortar does not fill up the outlet pipe. Before the mortar on the floor has stiffened, form a shallow depression in the middle; this will allow the tank to be cleaned at a later date – the sediment can be brushed to the hole and cupped out (see Figure 3).

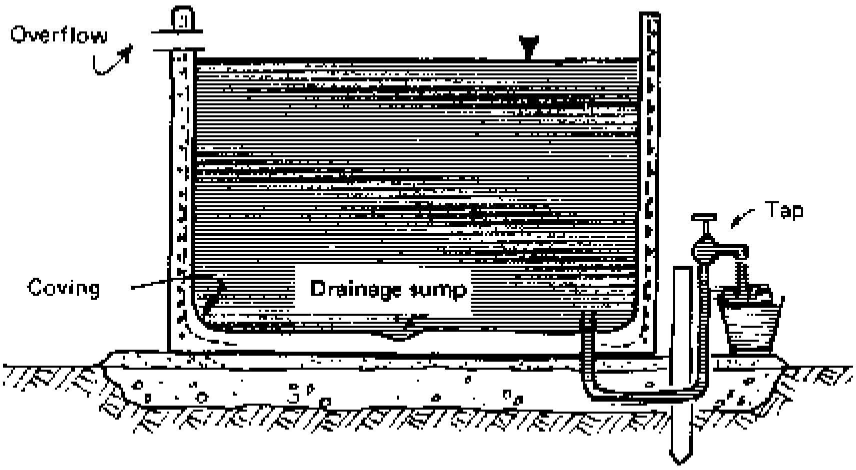

Figure 3 – The completed tank

The inside of the tank is painted with a thick cement slurry to seal the inside of the tank the a small of water is allowed to stand in the bottom of the tank and the tank is covered and cured for seven days.

Roof

The tank is covered with sheets of 0.5mm galvanised sheeting supported on two lengths of angle iron. Alternatively, a reinforced mortar roof may be built in the way described in Case Study 8 (Factory Made Tanks – New Zealand). Building a mortar roof is not difficult but does require more formwork.

Materials

Materials required for a 10m^3 tank with galvanised iron roof.

Cement	600 kg
Plain wire 2.5mm diameter	200m
Chicken mesh – 1m wide	16m
Water pipe – 20mm bore	1m
Water tap	1 No
Overflow pipe – 8cm bore iron or concrete	0.2m
Sand	1.0m^3
Gravel	0.5m^3
Galvanised iron sheet and angle iron	

Case study 8 – Factory made tanks, 1 to 25m³, New Zealand

This example has been taken from 'Ferrocement water tanks and their construction' by S. B. Watt and published by Intermediate Technology Publications (http://www.oneworld.org/itdg/publications.html). All figures taken from this publication also.

Introduction

Ferrocement tanks have been made commercially in New Zealand for many years and have now largely replaced the traditional corrugated galvanised iron tanks. They are used mainly to store water for domestic and dairy purposes on the farm but they are also winning acceptance for industrial liquid storage. The cost of the smaller tanks is comparable with that of tanks made from other materials such as galvanised iron; the cost per unit volume decreases rapidly with increase in size.

Tank sizes

The tanks are constructed in various sizes, with capacities from $1m^3$ to $25m^3$, diameters from 1m to 3.6m, and heights from 1.3m to 2.9m. With specially built formwork and machine mortar mixers each tank takes 2 – 5 person days to build. There are several manufacturers producing such tanks in New Zealand. The high wage costs in New Zealand are reflected in the prices of the tanks.

Design

The water pressure in a tank full of water generates stresses in a tank that are difficult to calculate structurally. The tanks have been designed to resist only hoop stresses and a layer of woven netting is included as nominal reinforcement; this netting in fact provides the only reinforcement at the base of the wall where it joins with the floor – the point of greatest stress. This section is thickened during construction and from information given by the manufacturers there is no evidence that cracks appear under normal loads. The only causes of failure have resulted from damage during delivery.
All the tanks are built with an integral roof and a covered access hatch.

Capacity (m^3)	Diameter (m)	Height (m)	Weight (tonne)
0.9	1.2	1.3	0.25
1.8	1.55	1.3	0.3
2.7	1.85	1.3	0.45
3.6	2.0	1.45	0.8
4.5	2.0	1.95	1.25
9.0	2.9	1.95	2.1
13.5	2.9	2.6	3.0
18.0	3.65	2.6	4.0
22.5	3.65	2.9	5.0

Table 1 – Size and weight of New Zealand tanks

Cement	740 kg
Sand	$1.0m^3$
Plain wire – 4mm diameter	330m
Wire mesh – 1m wide	28m
Weld mesh for slab	$7m^2$

Table 2 – Materials needed to make a $9m^3$ tank

The quantities shown in Table 2 are higher than a comparable tank, which would be built in situ. The tanks described here have to be stronger than the self-help tanks to be able to withstand the extra stresses during transportation

Construction

The tanks are constructed on special fabricated steel formwork which is quickly erected (see fig 1), or on a temporary timber formwork. Usually, the floor of the tank is cast first; this is reinforced with welded steel mesh made from 8mm diameter rods at 20cm centres with a floor thickness between 6cm and 10cm, depending on the size of the tank. Loops of 8mm steel are allowed to project from the base to allow for easy handling; this also reduces the stresses that will be set up in the tanks as they are being lifted or winched. A strip of chicken wire is also cast into the sides of the floor and is bent up into the walls.

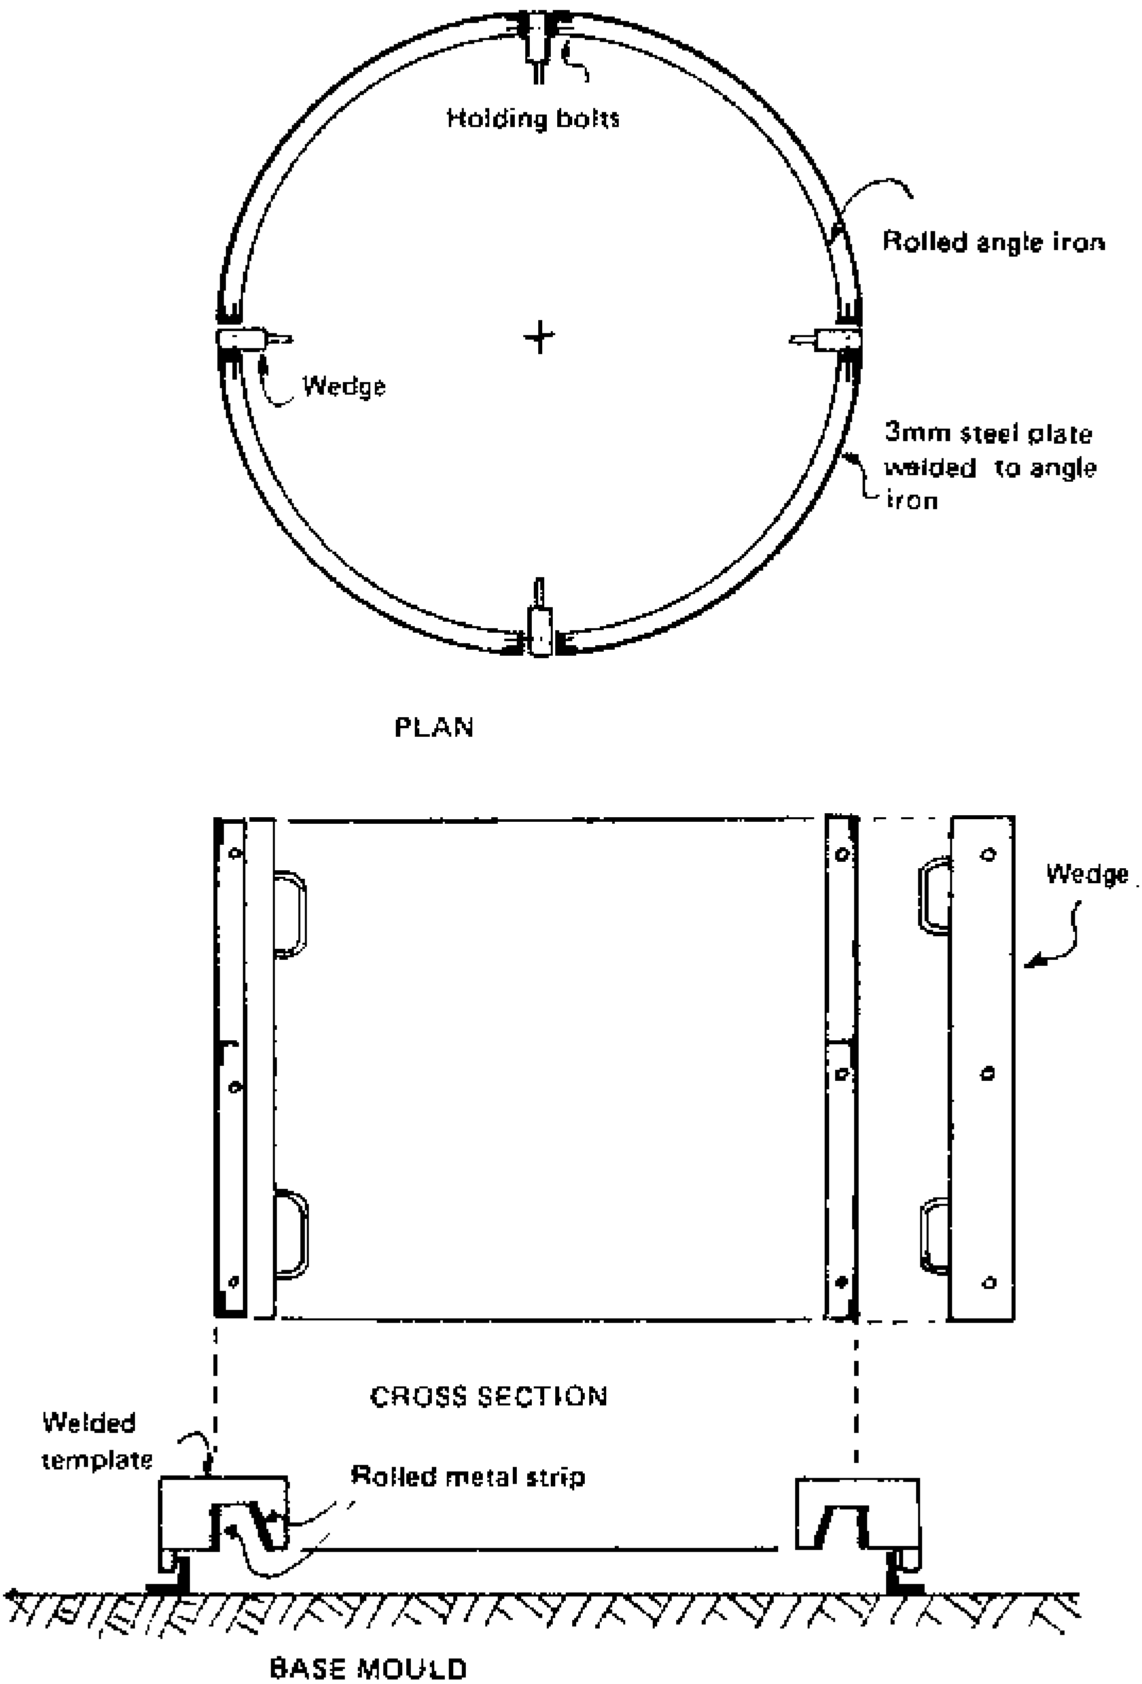

Figure 1 – formwork used for tank construction

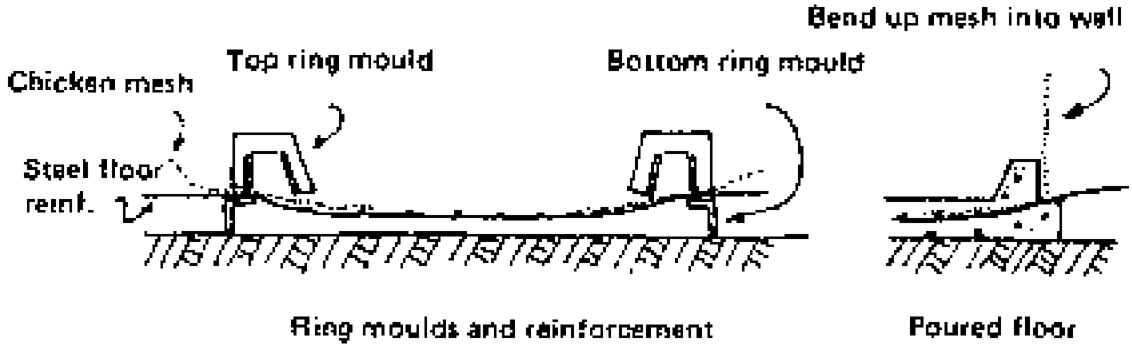

Figure 2 – Casting the base slab

When the floor slab has been cast, the formwork is erected and the chicken wire folded up against the shuttering. A layer of chicken wire or weld mesh made from 2mm wire at 5cm centres is wrapped around the tank to cover the shuttering from top to bottom (see Figure 3).

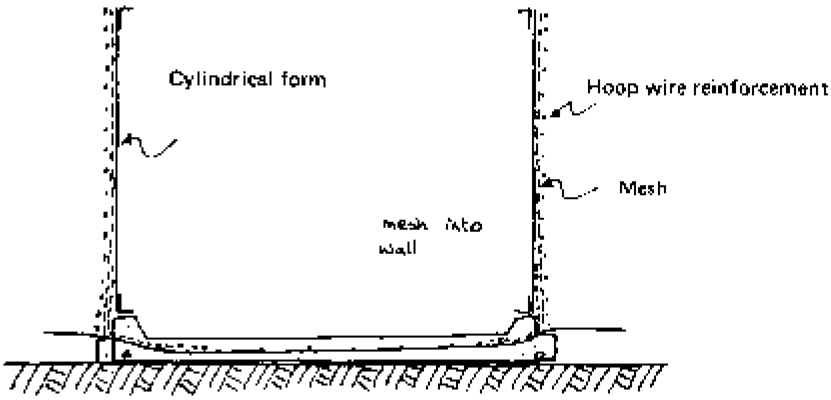

Figure 3 – Assembling the formwork and reinforcement

The main reinforcement, 4mm diameter straight wire, is wrapped tightly around the tank in a spiral with a 5cm gap between the wires. Theoretically this gap should be much smaller at the bottom of the tank than at the top to take the extra stresses, but in practice the spacing is left constant. This prevents mistakes during construction and does not add appreciably to the overall cost. The same spacing is often used on all of the tanks, both small and large.

The first mortar layer (1:3 cement:sand by volume)is trowelled onto the tank 1cm thick and given 24hrs to harden. A second layer of mortar is then trowelled on and finished smooth with a plasterer's float; this is also given 24hrs to harden.

The formwork is now carefully stripped and removed from inside the tank and a third layer of mortar is trowelled onto the inside of the tank to completely cover up the reinforcement. A thick un-reinforced coving is added to strengthen the joint between the floor and the tank.

Finally, the roof is built onto the tank y laying mortar onto shaped formwork which is propped from underneath. the roof is reinforced with two layers of wire mesh, which is tied onto the mesh protruding up from the walls (see Figure 4).

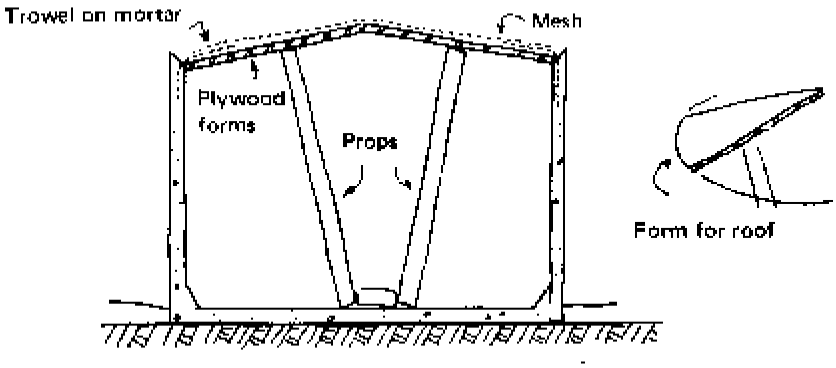

Figure 4 – Constructing the roof

A prefabricated angle iron frame is set into the wire mesh to provide formwork for an access hatch into the finished tank. This is removed after the mortar has set (see Figure XX5). Mortar is trowelled on in a 3cm layer and allowed to cue for 3 days. When it is strong enough the roof and access hatch formwork is stripped and a layer of mortar trowelled onto the inside of tank roof.
The tank is finally painted on the inside with a coat of cement and water slurry, a small volume of water is allowed to sit in the bottom of the tank and the tank is covered and cured for at least 7 days.

Transporting the tanks

The factory tanks of less than 25m^3 capacity are light enough to be carried by lorry. They are taken to the prepared site and joined directly to the necessary pipe connections; tanks of larger capacity are usually built on site.
The smaller, lighter tanks are lifted onto and off of the lorry with a truck-mounted hoist. The larger tanks are winched onto the truck with a sling. The first step is to jack one edge of the tank clear of the ground. The truck is then so positioned so that a pair of steel runners resting on its carrying platform can be placed under the tank to form a ramp. A wire rope sling is fitted around the tank, which is then drawn up the ramp by a winch mounted on the truck. Steel pipes are used as rollers when moving the tank.
For unloading the platform of the truck is raised slightly and the tank slides down the ramp. The steel pipes are again used as rollers and the downward movement is controlled by the winch.

Case study 9 – RWH in the barrios of Tegucigalpa

Introduction

This case study is drawn for a report produced by UNICEF in 1991. The 'Barrios' of Tegucigalpa, Honduras, are the low-income urban settlements that have developed around the city as tens of thousands of people move, each year, to the city from rural areas. They come in search of better living conditions but often end up in these barrios, where public services and amenities are poor or non-existent. Health statistics show that the residents of the barrios are suffering from a number of water related diseases that could easily be avoided with provision of a reliable, clean water supply. Unfortunately, more than 150,000 residents have to find their own water.

Water vendors sell water at extortionate prices, some families having to spend 30 or 40% of their income on water alone. In 1987, UNICEF, SANAA (National Water and Sewage Service) and UEBM (Unit for Marginal Barrios) started work on an integrated water supply project that would help the residents to direct their money into providing themselves with clean water. The programme studies several water supply options, including piped networks, groundwater wells, trucking of water and rainwater harvesting.

The report from which this Case Study is drawn studies the indigenous RWH systems in use in two barrios - Israel Norte and Villa Vueva. Although technically unsophisticated and lacking good health practice, the systems described here show what urban settlement have done to improve their own lot. Many of the systems make use of recycled or scavenged materials and some examples show high levels of initiative.

Water use

In the two barrios mentioned above, about 90% of the families collect rainwater. The quantity of rainwater collected varies from home to home. Figure 1 shows the percentage of needs met by rainwater in the barrio of Israel Norte.

Figure 2 shows the various uses of rainwater and the percentage of people who use the rainwater for a particular application.

Fig. 1 -Percentage of water needs met by Rainwater in the barrio of Israel Norte

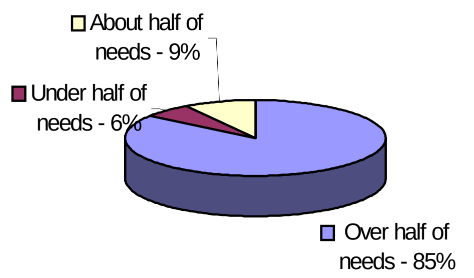

Fig. 2 - Rainwater uses in Israel Norte - %age of residents using rainwater for the following applications

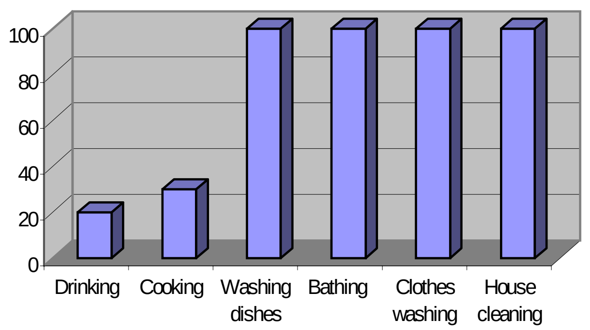


The deficit in drinking and cooking water is usually met by water which is purchased form vendors or from nearby standpipes in middle class residential areas. The rainwater is not seen as being a high-quality source of water.

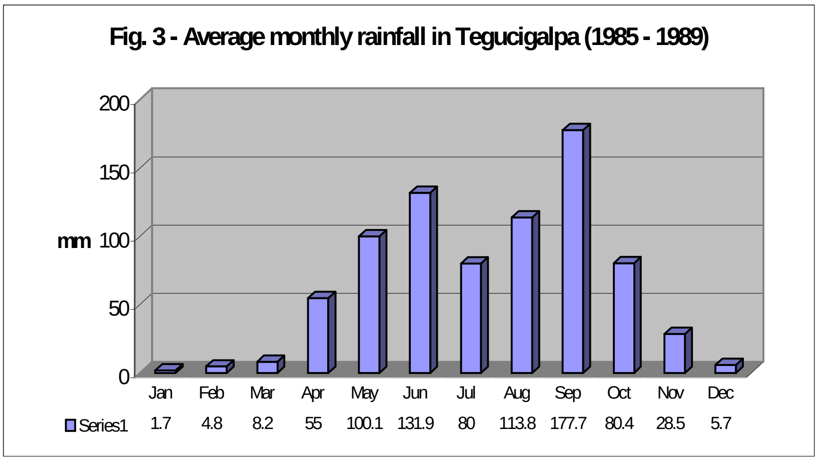
Rainwater harvesting is popular as there is a direct saving for every litre of water saved. For a household with a $45m^2$ collection surface (the average roof area) the saving is over US$100 annually.

Technical detail

The RWCS's used in the barrios are rudimentary. The basic system usually has the following components:

Roof – collection surface

The average roof area in the Villa Nueva barrio is $45m^2$, with typically half of this area being used for collecting water. The recommended roof area to provide adequate collection area for total rainwater harvesting is $100m^2$. The average rainfall in the area is 788mm, which is quite low and hence the large collection area requirement. The majority of the rainfall (as shown in Figure 3) falls between April and November with two peaks, one in June and one in September.



Roofing material varies, but by far the most commonly used material is iron sheet. Other materials used are asbestos/cement sheets, clay tiles, *techon* (a locally produced asphalt treated pressed paper sheet) and a variety of discarded plastics and sheet materials.

Gutters to collect the water from the roof

Again, a variety of materials have been used to make gutters. In the barrio of Villa Norte 75% of the gutters are made from sheet steel. The fabrication technique of steel gutters varies also – some have been made from scraps of steel sheet or old, flattened steel drums. Pre-fabricated gutters are also seen - these are rolled to give a semi-circular trough, and are fitted with a neck to attach the downpipe (where fitted), which can be of PVC. The authors state that the cost of these gutters was US$36 for a 20 foot length (1991). There are a number of different methods for fixing the gutters, but where high quality gutters are used the quality of the bracket is usually better also, being formed of wood or bent reinforcing bar. Some gutters were poorly mounted with depressions which allows water to stand and corrode the steel. Gutters are typically fitted to one side of the building only.

PVC gutters are formed from 8” PVC pipe which has been cut in half. The cost of a 20 foot length of PVC pipe is US$38 which provides 2 lengths of guttering when split. The PVC guttering is preferred because it is cheaper and lighter. Many other scavenged materials are used for guttering, including wood and asbestos sheeting.

Downpipe

In Israel Norte barrio, 90% of the systems have no downpipe. The water runs from the gutter directly into the storage vessel. The remainder used either plastic hose, PVC pipe or sheet metal to transport the water to a remote water storage container.

None of the systems studies were fitted with any kind of screen, filter or first flush mechanism.

Storage

Water storage facilities at the barrios are, again, basic. The majority are old 200 litre steel barrels. These are bought (the average price is US$13) or scavenged and most contained pesticides, chemicals or toxic materials – so are not well-suited to water storage. The second most common type of storage is the *pila, a* concrete water tanks of about 500 litre capacity which has an integrated washing board (see Figure 4). These are built by local masons and cost approximately of US$25. The tanks can be sized to suit the needs and means of the user. Fifteen to 30 % of the residents of the barrios have these pilas.

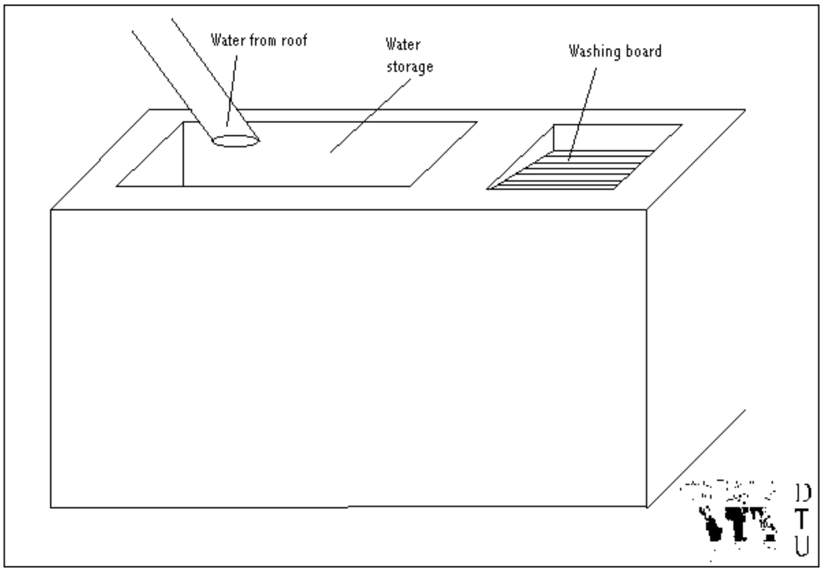


Figure 4 – The brick and mortar *pila*, as found in the barrios of Tegucigalpa

Some people have also acquired plastic barrels which may have contained paint, oil or other substance. Only very few of the systems studied had a cover fitted.

Water quality and alternative sources of water

The study team sampled the stored rainwater to find the level of bacteriological contamination present. It was found that where the water was used for drinking, 63% of the water samples taken contained E.Coli. Where the water was used for other domestic purposes only, 71% of the samples were contaminated. All sample were taken from the storage vessels.
The study team also sampled the alternative sources of water for the two barrios included in the study. Table 1 below shows the results.

Source	Number of Coliforms present (WHO guidelines recommend 0 coliforms in drinking water)
SANAA / UNICEF public taps	0 coliforms
Private water vedors – sample taken from hose	Uncountable
Unprotected superficial cells	varies between 650 and uncountable
Store reportedly selling water bought from SANNA truck	0 coliforms

Research into single skin, externally reinforced, brick tanks

Interim Report
April 1999
Mr. D. G. Rees
DTU, University of Warwick

Table of Contents

1. Introduction

1.1 Project background

This work is being carried out as part of a programme titled 'Domestic Roofwater Harvesting in the Humid Tropics', which is an international 3 year, four partner, European Union funded, programme which started in August 1998.

Warwick is leading the sub-programme titled 'Low cost storage', the aim of which is to develop a number of techniques for construction of low cost water storage tanks or cisterns. As part of the programme we will look at several techniques for reducing costs, improving quality and improving health through good design and construction practice.

One such possible low cost design that will be investigated in detail is the externally reinforced, single skin brick tank. This Interim Report discusses the early research work that has been carried out on this design idea with the aim of clarifying the findings of this work and the further work that is required to provide enough useful detail to confidently promote such a technology.

1.2 Brick tanks – design philosophy for Developing Countries

The design philosophy adopted for water storage tank design is one of local manufacture using materials that are available with relative ease in the locality. Cost control is of major concern in order that the technology becomes more accessible to the poor of developing countries.

Brick is one such locally manufactured, widely used, readily available material which is ideally suited to wall construction, but not quite so well suited to conventional larger volume tank construction. In this report we look at methods of improving the suitability of brick to low cost tank manufacture by using external steel reinforcing to give additional hoop strength to cylindrical brick tanks. We also look at methods of lining such tanks for water tightness – at this stage limited mainly to internal cement render. Plastic lining of tanks will be discussed in a later report.

2. The theory of stresses in cylindrical tanks

Cylindrical tank walls experience a ‘hoop stress’ which is proportional to the diameter, D, of the tank, the pressure, p, on the walls of the tank and the thickness of the tank wall, t (Equation 1). The stress on a cylindrical tank wall is also affected by

$$\sigma_t = \frac{pD}{2t} \qquad \textit{Equation\_1 – Hoop Stress}$$

the type of joint between the tank base and tank wall. There are two obvious cases to consider as illustrated in Figure 1 below. Taking Case 1, if the tank wall is free to move at its base and still maintain a watertight seal, then the strain induced in the wall will cause the diameter of the tank to increase until the hoop stress is taken up by reinforcing in the wall (obviously the increase in diameter is exaggerated here for effect). In this case the force exerted by the water pressure on the tank walls will be taken up solely by the hoop tension in the walls. The maximum hoop stress will be experienced at the base of the wall and will decrease proportionally (linearly) according to Equation 1.

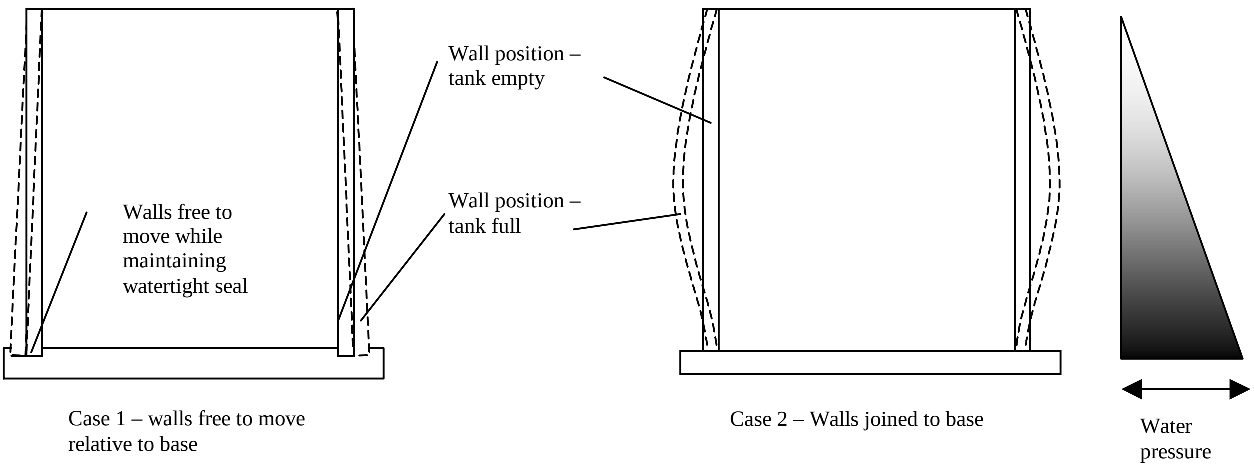

Figure 1 – The two cases for wall and base union in cylindrical tanks

Taking Case 2, if the wall and base are monolithic i.e. the wall and base are continuous, the situation becomes more complex as bending stresses are set up in the wall as a result of the restraining effect of the base slab. There now exists a complex combination of bending, shear and hoop stresses. Gray and Manning[4] suggest that if the wall is not free to move at its base, then the loading caused by the outward pressure is counteracted by a combination of hoop resistance and cantilever resistance. This is illustrated in Figure 2 which shows the load distribution diagram suggested by Gray and Manning. As the base of the wall is now restrained there is no freedom for the wall to move and take up the hoop stress and so the hoop stress there is reduced to zero. Maximum hoop stress is now experienced higher up the wall of the tank. All the restraining forces acting at the base are due to the cantilever.

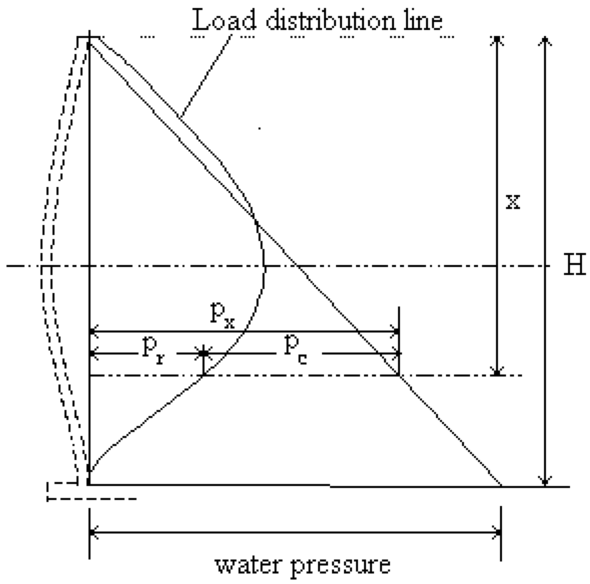

Figure 2 – Typical Load distribution diagram for a tank wall which is monolithic with base (modified slightly from Gray and Manning[4].

p_x – Total outward pressure load to be restrained
p_r – Portion of the load restrained by hoop stresses or radial constraints
p_c –Portion of the load restrained by cantilever
x – distance from top of tank
H – total depth of tank

As illustrated in Figure 2, the total pressure p_x at any depth of wall is composed of p_r (the portion of the load carried by the hoop restraints) and p_c (the portion of the load carried by the cantilever), such that,

$$p_x = p_r + p_c$$

The profile of the 'load distribution curve' is governed by the profile of the tank. Gray and Manning give a number of load distribution curves for a variety of tank profiles (see Figure 3). The tank profile is related to the distribution curve by Equation 2, all tanks with equivalent values of K having similar load distribution curves.

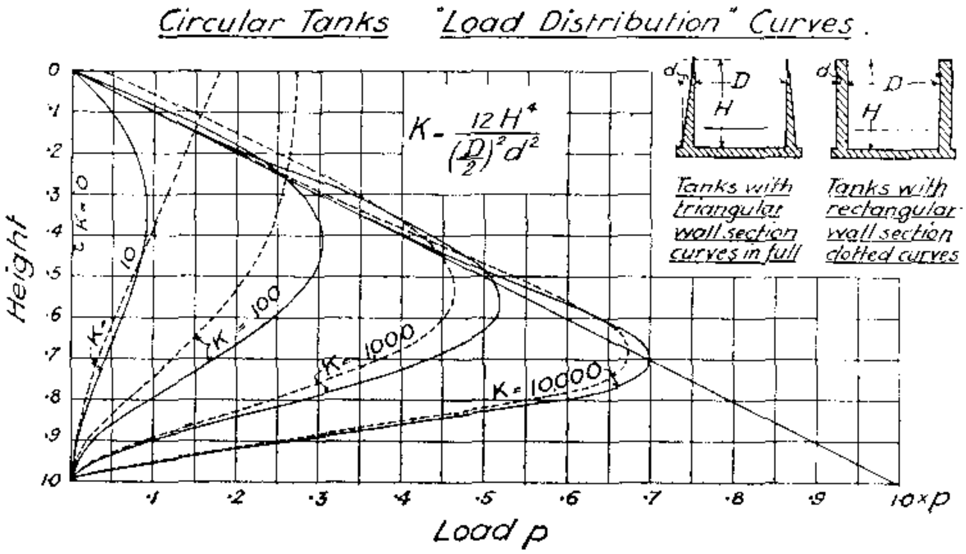

Figure 3 – Load distribution curves for a variety of K values (Gray and Manning[4])

$$K = \frac{12H^4}{\left(\frac{D}{2}\right)^2 d^2} \text{....................} Equation\_2$$

where,
H = height of tank
D = diameter of tank
d = thickness of wall at foot

It is noted that cantilever load increases for diminishing values of K. K is tightly controlled by the value of H such that K increases to the fourth power of H. We also see that K falls as tank radius and wall thickness increase.

If we consider a typical cylindrical single skin, brick tank with homogenous wall and base of diameter 2m, height 2m and wall thickness of 0.1m, then we obtain a value of K equal to 19,200. This is beyond the value shown in Figure 3 and suggests a regime where p_r dominates i.e. the outward pressure load is resisted predominantly by hoop stresses. Cantilever forces act only at the extreme base of the tank wall (within the bottom 20%). The tank can therefore be dealt with as if the hoop stresses induced are similar to those of a tank with a free base joint. This still leaves the high bending and shear stresses in the base of the wall to be evaluated. Watt[2] suggests that the maximum bending stress on the inside face of the tank wall will be almost double the induced hoop stress for a similar tank profile. This can easily be compensated by increasing wall thickness at the base of the tank. As demonstrated by Equations 3 doubling the wall thickness, d, effectively decreases the bending stress in the wall by a factor of four.

Bending stress, $$\sigma_b = \frac{M\left(\frac{d}{2}\right)}{\left(\frac{bd^3}{12}\right)} = \frac{6M}{b}\left(\frac{1}{d^2}\right) \text{ ....} \textit{Equation 3}$$

where, $\frac{bd^3}{12}$ is the Second Moment of area

and b is the width of a strip of wall carrying local bending moment, M

Shear stress is very small compared with the bending and hoop stresses (Watt) and can therefore be neglected for the sake of this analysis.

Work is currently being carried out to develop a computer software programme for a fuller analysis of stresses set up in a variety of tank shapes and sizes.

2.1 Calculating hoop stresses in reinforced brick tanks

The task of calculating hoop stresses in the tank under consideration now becomes a simple task. We treat the tank as if its walls were unconstrained at the base and can thus use Equation 1. We will then deal with bending stresses separately by increasing wall thickness locally at the base as required.

For a tank with a brick wall and external steel reinforcing we need to understand what stresses are induced in each material and what function each material is performing. Table 1 shows a hoop stress analysis for the two materials that have been used during tests at the University. These materials are high tensile steel packaging straps (of 13mm width x 0.5mm thickness), and brick masonry (in this case with cement mortar). If we analyse the two materials separately we can see from Table 1 that the ability of the brick masonry to withstand the imposed hoop stress is unpredictable due to the unpredictable nature of the quality of the material. High tensile steel, on the other hand, has reliable and predictable strength and will afford almost four times the required hoop strength. The steel, then, provides the tensile strength required to prevent failure due to excessive hoop stress.

The brick masonry, on the other hand, provides the stiffness required to prevent failure due to bending stresses. For the example shown below the stiffness of the brick is many orders of magnitude greater that the 'virtual' steel wall stiffness (virtual wall thickness is the thickness that would exist if the straps formed a continuous steel shell - the straps themselves actually provide no vertical stiffness).

We therefore see that one material compliments the other. The steel provides a hoop strength up to eight times that of the brick masonry whilst the brick masonry provides the stiffness that could only be achieved in a steel tank with hundreds of times the quantity of steel used in the example given.

Properties	**High tensile steel strap (13mm x 0.5mm) – two straps per course of bricks**	**Brick masonry**	**Units**
UTS (Mpa)	833	0.1 – 1.0	Mpa
Yield strength	450		Mpa
Youngs modulus	210	25 - 100	Gpa
Wall thickness (equivilant)	173×10^{-6}	0.1	m
Tank diameter	2	2	m
Water depth	2	2	m
Hoop stress exerted by water force	113.19	0.196	MPa
Safety factor	3.98	0.51 – 5.10	

Table 1 – Hoop stress analysis for steel and brick masonry in cylindrical tank of 2m diameter and 2m height

2.2 Construction and application regimes to ensure strength

Some thought has to be given to the interaction between the brick masonry and the steel strap. The two materials must interact in such a way as to enhance the properties of the other as explained in the previous section. This can only be achieved when the construction of the walls and application of the steel strapping is performed in a certain way. The steel is applied externally to the brick wall, using a tool specially designed for applying this kind of strap. The strap should be applied with sufficient pre-tension to be able to counteract the normal water force that will be exerted upon the wall upon filling the tank. In consequence, the masonry is initially put into compression and remains in compression as the tank is filled. This will protect the brick masonry against failure (cracking) should the hoop strength of the masonry be unable to accept the load (due to inferior workmanship or poor material quality). Referring to Table 1, the hoop stress exerted by the water force is 113.19 MPa (say 114 MPa). Experiments were carried out at the University to confirm that such a pre-tension can be applied to the tank and the description and results of these experiments are shown in a subsequent chapter.

2.3 Stresses in tank foundations and base

Little work has yet been done to calculate stresses in the tank base. This will be included in the next report.

2.4 Stresses due to other factors

Stresses due to other factors such as wind forces, cyclic loading and seismic activity have not been considered in this analysis.

3. The theory of cracking in cement render

(This section is the work of Dr. T. H. Thomas from a paper titled 'The Causes and Prevention of Leakage through Cementitious Renders in Water Tanks')

3.1 Cementitious renders

Renders of cement or lime mortar are commonly used in water tanks when the tank itself is constructed of rather permeable materials such as brick, stabilised soil or even (in the case of underground tanks) of unstabilised soil. The render's primary purpose is water-proofing, for which it should have a sufficiently low permeability to protect the main tank material and to reduce water loss through walls to a tolerable level. Thus we might demand that the render keep wall leakage in a 10 m^3 tank to under 1 litre per day. The render may have secondary functions such as reducing the roughness of a masonry surface so that it can be easily cleaned down, or even of providing a little stability to the wall behind it.

Cementitious renders are usually sufficiently impermeable in themselves, but are so brittle and so intolerant of *tensile* strains that they commonly crack. It is the cracks that leak and preventing cracks should be a focus of research effort.

3.2 Sharing out any shrinkage between 'many' cracks

Shrinkage of a render constrained by underlying masonry is the main mechanism for producing cracks. Tensile stresses in the render are relieved by cracking. Tensile strains are replaced by a combination of strain-free mortar interspaced by cracks carrying no tension forces. For a given shrinkage and a given material, the total volume or total width of cracks may be more or less fixed. However that total may be variously distributed between few or many distinct cracks. Consider for example the inside of a masonry tank of diameter 2 m where a render incapable of supporting any tensile strain has contracted by 1000 microstrain (0.1%) relative to the masonry. Around a circumference we might expect a total crack width of about 6 mm divided between say n individual cracks. We would certainly expect the leakage through an individual crack to be a rising function of its individual width. We might expect the total leakage to fall with rise in n - e.g. for two 1 mm cracks to leak less than one 2 mm crack.

Consider an individual crack of length L and width W penetrating a render of thickness T across which there is a pressure drop, from liquid to liquid, of p. The leakage velocities are very low and the key dimension (W) is small, so the Reynolds Number will certainly indicate laminar flow. As water behaves as a fairly Newtonian fluid, we can assume a viscous shear stress in the fluid proportional to the transverse velocity gradient in that fluid. Provided velocities are small compared with that corresponding to conversion of pressure head into velocity head, (i.e. $v^2 << 2p/\rho$) this gives a velocity profile of :

$v = \frac{p}{2T\mu}\left(Wy - y^2\right)$ where v is water velocity in the layer distance y from the side of the crack.

The consequent flowrate through the whole (assumed rectangular) crack is:

$Q = L\int_0^W v\,dy = \frac{pL}{12T\mu}W^3$ which is proportional to W^3, hence Q/W is proportional to W^2.

This suggests that replacing one large crack by two smaller (half-width) cracks will usefully reduce leakage by a factor of 4.

Inserting numbers: a 100 mm long crack of width 0.1 mm in a render 10 mm thick and subject to a water pressure of 10 kPa (1 m head) will leak 20^{o}C water (μ = 1 mPa s) at nearly 750 litres per day. Replacing this crack by ten 0.01 mm cracks will reduce leakage to 7.5 litres per day. Even this is usually unacceptable, so we are looking to get crack widths below 10 μm. However at these capillary sizes, surface tension effects become dominant.

Surface tension is likely to prevent *any* flow through a plane crack whose thickness W is less than $2\gamma/p$ where γ is the surface tension of water (in Nm^{-1}). Thus for water at 20^{o}C for which γ = 72.5 mN/m, a head of 1 m will not cause leakage through a gap smaller than 14.5 μm.

3.3 Prevention of cracking or of leakage through cracks.

Render cracks may form during ‘manufacture’ of a tank or when water pressure is first applied after manufacture or during moisture cycling through the life of a tank. We are studying the various shrinkage and crack-formation mechanisms associated with cementitious materials. Generally such materials experience shrinkage of up to 2000 μstrain.

Strategies to prevent or reduce leakage through cracks include:

	Approach	Technique
a	Use non-shrinking render	1. Use mortar with very low water content 2. Pre-shrink the render 3. Cure under water
b	Remove the constraint provided by underlying masonry/reinforcement	1. Add reinforcement after curing 2. Use flexible mortar to lay bricks/blocks 3. Use very-slow setting mortar to lay them 4. Masonry same as render
c	Reduce constraint of base plate	1. Flexible or sliding wall-base joint 2. Thicken wall to reduce bending stresses
d	Distribute cracks (convert into more but smaller cracks)	1. Reinforce with mesh 2. Reinforce with fibre 3. Manipulate bond with masonry
e	Stagger cracks in multi-layer render	1. Plaster, cure, replaster 2. Plaster, cure, groove, fill
f	Use a flexible render	1. More (hydraulic) lime in mix 2. Add polymers like latex to mix
g	Prevent cracks opening under stress (strain induced by water pressure)	1. Hoop tension the reinforcement after curing the render 2. Do so before curing the render. 3. Thicken the masonry to reduce changes in strain when under load.

Table 2 – strategies for preventing cracking in cementitious renders

4. Building materials

One of the aims of this research is to investigate the behaviour and suitability of the materials listed in this chapter for use in construction of a water storage tank and to make recommendations for tank construction techniques using these materials. Tests and test results are shown later in this document. Now we will discuss the general nature of the materials and the general theory postulated for design.

Fired clay brick is a rigid, brittle building material. It is usually used in conjunction with a cementitious binder (such as cement or lime mortar) to form a wall which is strong in compression but weak in tension. There are a number of techniques used to give extra strength where required: this usually takes the form of laying the bricks in a regular pattern to form an interlocking matrix of brick and mortar. Ties, buttresses, and other building aids and techniques give extra, localised strength where required. It is difficult to improve the tensile strength of brick masonry without creating a composite material by adding steel or timber.

The predominant stresses that will be set up in a tank wall are tensile stresses. As explained in an earlier section, these stresses are due to the water in the tank exerting hoop stresses and bending stresses in the structure. The brick and mortar construction alone cannot be expected to withstand these stresses and it is for this reason that steel strapping is used to take up the predominant tensile stresses. The brick gives rigidity (i.e. stiffness) and mass to the structure while the steel, with it's high tensile strength, performs the task of providing hoop strength. Together, using the cylindrical wall structure, they combine properties to provide a rigid structure with sufficiently high tensile strength.

A further requirement of the tank wall material is that it be watertight, and that it remain watertight for the lifetime of the tank. Brick masonry rarely achieves this requirement and so we will also look at methods of providing a waterproof membrane or lining within the tank. Therefore, we also look at cementitious renders which are applied to the inner surface of the tank wall to provide a continuous waterproof membrane. Later (in a later report) we look at low-cost plastic liners for water tanks.

We investigate the properties of these materials used together (brick masonry – steel – mortar render) to determine the optimum design specification that will give adequate strength, rigidity and watertightness, while minimising the quantity of material used (with the aim of keeping costs to a minimum). Each of the individual materials mentioned above has it's own unique behaviour and the biggest challenge comes in trying to match these materials in such a way that they act in synergistic fashion to provide a composite that gives the required properties.

Much thought has been given to the process required to achieve this synergy. A number of mortar and render types have been investigated and the methods of application and construction regimes have been considered carefully. In this report we will look in some detail at the following aspects of tank design and construction:

- behaviour of lime and cement mortars
- application of steel strapping to cylindrical steel tanks
- stresses in steel strapping in cylindrical brick tanks during application and under load conditions
- initial investigations into shrinkage and cracking in thin renders

4.1 Tank construction materials

Fired clay brick.

Low quality fired clay brick is a building material which is commonly found in many, many countries throughout the world. Brick masonry is a building technique that has existed for more than 4000 years. A variety of soils are available for the process of brick making and the process itself varies in complexity from small field based batch kilns capable of producing a few thousand bricks to large scale continuous mechanised technology capable of producing hundreds of thousands of bricks per day.

Cement mortar.
Nowadays, the most common methods of bonding fired clay bricks is with cement mortar. Cement mortar is a hydraulic binder made from a controlled mixture of sand and Ordinary Portland Cement (OPC), with or without a variety of admixtures that improve the properties of the mortar. Plasticisers are used to reduce the water requirement of mortar and hence improve strength, or to improve the workability for a given water content. Bagged lime is sometimes added to improve workability. A typical mortar would be made up of 1 part OPC to 4 parts clean, well-graded sand, although the quantity can vary enormously depending on strength requirements.

Lime mortar.
Lime has been used as a building material for over 2000 years. To make a lime binder or mortar, calcium carbonate (limestone) is burnt at a temperature of about 900^oC to drive off the carbon dioxide and produce calcium oxide (quicklime). The quicklime is then ‘slaked’ (water is added) to produce hydrated lime powder. If further water is added a lime milk is formed and this is allowed to settle and mature for some time (months) in a pit to form a lime putty. This can then be used for a variety of applications including mixing with sand to form a lime mortar.

Lime mortars have certain benefits over cement mortars. The lime mortar slowly absorbs carbon dioxide from the atmosphere and this causes the mortar to harden as it returns to it’s initial state as limestone. This process can take many years and in the meantime the mortar remains plastic. This can be beneficial where flexibility is required or where other less flexible materials are used in close proximity.

5. Reinforcing materials

5.1 Choice of reinforcing material

A number of materials were considered for use as external reinforcing for the tank. There are examples of similar designs from Thailand of brick masonry and steel wire tanks (Vadhanavikkit[6]), and from Uganda of stabilised soil cement blocks with barbed wire reinforcing (personal correspondence with Mr. Kimanzi Gilbert of the Uganda Rainwater Association) and other examples of brick and barbed wire tanks from Botswana.

As mentioned in the introductory chapter it is important that the materials used for the tank construction be available widely in the areas where they will be built (less developed tropical regions) and that the materials be of low cost. Those materials mentioned above i.e. steel wire and barbed wire, as well a number of other similar materials are readily found for other construction and agricultural applications.

In the cases mentioned above there is some concern (on our part) as to the control of the application of the reinforcing material and the amount of tension that can be achieved and maintained. Tying knots in wire, and maintaining tension at the same time, is a difficult business, especially when the wire needs to be tight against the surface of a wall. We are therefore considering packaging strap as an alternative for the following reasons:

- it is widely available in any country where there is a reasonable manufacturing base;
- the strap is ideally suited to this application with a high tensile strength and flat surface that lays flat against the brick face;
- it is cheap once the tools have been purchased (even the tools themselves are not prohibitively expensive for a mason of reasonable standing). More research is currently underway into prices of strap and tools in developing countries;
- application is easy with the dispenser, tensioning and crimping tool
- a high pre-tension can be easily applied to the strap applying compression forces to the masonry.

Depending on feedback from a number of countries (Sri Lanka, Uganda, India, Kenya in particular), we will later reassess the suitability of this material and possibly look at alternatives.

5.2 Spacing of steel straps

Following on from Chapter 2.1 we are now able to calculate the spacing for the steel strapping, assuming pure hoop stresses are induced by the outward water pressure.

Virtual wall thickness, $t = \frac{w \times t_s}{s}$ .... *Equation 5*

where, w = strap width
t_s = strap thickness
s = maximum strap spacing

Maximum strap spacing, $s = \frac{2\sigma_{ma} w t_s}{\rho g H d}$ .... *Equation 6*

For the tank considered in Table 1, we can rearrange Equations 1 and 5 to give Equation 6. If we specify a value for maximum acceptable hoop stress in the strap, $\sigma_{ma,}$ of say 150 Mpa (one third of the yield strength of the steel), we can easily calculate the strap spacing using a simple spreadsheet calculation. Table 3 below is the data output from such a spreadsheet calculation for a small variety of tanks of a similar size and profile to that being considered.

	Distance from top water level						
Tank diameter (m)	<0.5m	0.5m - 0.75m	0.75m - 1.0m	1.0m - 1.25m	1.25m - 1.5m	1.5m - 1.75m	1.75m - 2.0m
1.00	398	265	199	159			
1.25	318	212	159	127			
1.50	265	177	133	106	88		
1.75	227	151	114	91	76	65	
2.00	**199**	**133**	**99**	**80**	**66**	**57**	**50**
2.25			88	71	59	50	44
2.50				64	53	45	40

Table 3 – Maximum strap spacing for a variety of tank diameters and depths

It can be seen that the minimum strap spacing (at the base of the wall) is less than the thickness of one course of bricks (80mm) and so two straps will be used on each course of bricks, giving a spacing of approximately 40mm.

6. Laboratory experiments

6.1 Introduction

The experiments described in this chapter were carried out at the University of Warwick between January and April 1999. Forming the basis for the tests were a number of brick masonry cylinder specimens built on a civil engineering 'strong floor'. Such a specimen is shown in Figure 4 below. The specimens were of internal diameter 1.5m and varying height. These specimens allowed experimentation and observation of mortar behaviour, cracking of renders with a number of different additives, application and loading of steel packaging strap, as well as providing through practice an insight into the merits of the construction technique.

Figure 4 – Brick masonry cylinder specimen

6.2 Mortar observation – lime and cement mortars

Two types of mortar were used for constructing the cement mortar specimens; cement mortar and lime mortar. The main purpose of this test was to observe the following:

- the plasticity of the mortar and the associated ability of the brick masonry to ‘move’ in compression;
- the behaviour of the brick masonry under load – particularly the load transfer characteristics of the masonry;
- render behaviour (particularly cracking) when applied to each type of brick masonry.

The cement mortar is composed of the following:

Sand cement ratio	5:1
Water cement ratio	0.5 (i.e. water content 50% by weight of cement)
Mortar plasticiser	10% of water content

The lime mortar is made up of 3 parts well-graded sand to one part lime putty. No water is required.

The first part of the experiment consisted of simply observing the brick masonry when applying the steel strap for signs of movement and, secondly, observing the tension in the strap to determine the ability of the masonry to go into compression without distortion (i.e. that the masonry is sufficiently rigid). Early in the experiment it was decided that the lime masonry was insufficiently rigid in the early days after construction and that, without further investigation of its properties it would be unwise to use this material for this application. Although the characteristic property of lime mortar to remain plastic can, in some cases, be a positive advantage (we subsequently see that render cracking is greatly reduced - almost eliminated even - when using lime mortar), it does mean that a wall built using lime mortar will be far less rigid than its cement mortar equivalent.

Cement mortar gives a strong, rigid wall with no sign of movement during application of the strapping. The load that can be applied to a cement mortar, brick masonry tank is outlined in Graphs 1 and 2. The figures shown in this graph demonstrate the rigidity of the material at characteristic loads (and beyond). Detailed tests of this nature have not been carried out to date on the lime mortar specimen, but visually the wall of the lime mortar specimen can be seen to move when strapping is applied.

The behaviour of renders on each of the specimens is detailed in the following chapter.

6.3 Render – shrinkage and cracking

A number of tests were carried out to observe cracking of renders of different types on specimens constructed with two different mortar types (cement and lime mortar). The base render was made up of 4 parts sand to one part OPC and a water content of 0.4 (this was slightly exceeded in most cases to provide a workable render) Mortar plasticiser was added in all cases at 10% of water content. The render thickness varied due to the uneven surface onto which it was being applied, but in general the thickness remained within 5 – 15mm. After a day the wall was painted with a thin white paint to help with the location of cracks (see Figure 5 below). Any visible crack was measured using a hand held x20 microscope. Shrinkage was measured by observing the separation of the render from the wall at the top of the specimen. In

Table 5, separation is indicated as a percentage of the visible joint line over which separation occurred and the minimum and maximum value of separation width (in mm).

Figure 5 – Cracks in renders

The additives used during the tests are shown below:

- **Mortar plasticiser** – a proprietary plasticiser used for mortars and renders in the building industry.
- **Re-in fibre** – a polypropylene fibre of 50 micron square cross-section and 6mm in length. This is a UK construction industry building material used for preventing cracking in thin renders and screeds.
- **Febond SBR** – a proprietary waterproofing solution for use in renders and for other application. It is a styrene-butadiene co-polymer latex specifically designed to improve water resistance and durability.

Five render types were tested. All were cement based renders. These are listed below in Table 4.

Render type number	Sand : cement ratio (by weight)	Water cement ratio (by weight)	Mortar plasticiser content (as %age of water)	Other additive	Curing regime
01	4:1	0.4 – 0.5	10%	none	basic*
02	4:1	0.4 – 0.5	10%	none	7 days**
03	4:1	0.4 – 0.5	10%	re-in fibre	basic*
04	4:1	0.4 – 0.5	10%	re-in fibre	7 days**
05	4:1	0.4 – 0.5	10%	sbr	7 days**

01	No test				
02	0	0	0	0	no separation
03	No test				
04	0	0	0	0	no separation
05**	69.33	2207	0.32	1.3	no separation

Table 5 – Cracking in cement renders – values for a number of test results after 7 days
*** Separation given as a percentage of separation at the visible joint around the perimeter at the top of the specimen wall. Variation in crack width also given.**
**** although manufacturers instructions were followed carefully there is some concern about the validity of these results – possibly an incorrect quantity of SBR was added to the render.**

The results given in Table 5 lead us to a number of tentative conclusions:

- the re-in fibre (renders 03 and 04) significantly reduces cracking in renders;
- improved curing of renders on cement mortar wall (renders 02, 04 and 05) helps prevent separation at the cost of increasing cracking i.e. adhesion to the wall improves causing greater cracking – this is advantageous if we then seal the cracks with a nil coat (cement slurry) or other proprietary sealant ;
- separation of render is much greater on cement mortar walls due to the rigidity of the wall. In the case of lime mortar, the wall moves as the render shrinks, preventing cracking – as mentioned in an earlier chapter this is very beneficial for achieving crack-free renders but not so beneficial in terms of loss of rigidity.
- no conclusions are made about the characteristics of SBR render due to uncertain results

Further work is required to gain a better understanding of renders and their behaviour on internal tank walls. This work is outlined in the final chapter of this report.

6.4 Reinforcing straps – initial tensile strength tests

Initial tensile strength tests were carried out on a number of packaging straps to determine the strength of each (manufacturers specification was not available for all). The aim of the tests were to investigate the strength of woven polypropylene strap and the effect of crimping steel straps. The tests were carried out at the Universities civil engineering laboratory using the tensometer machine (see Figure 6).

Without going into detail here it can be stated that the *polypropylene* strap was insufficiently strong for the application under consideration with an Ultimate Tensile Strength half that of steel with ten times the strain.

In all cases the singly crimped steel band broke at the crimp at well below maximum UTS. During practical tests on the brick specimens, in which the strap had been fitted with two crimps, the strap broke remote from the crimp at a value close to UTS.

6.5 Reinforcing straps – applying the strap

This experiment aimed to investigate:

a) the pre-tension set up in the reinforcing straps during application with the tensioning tool - as mentioned in chapter 2 it is necessary that sufficient pre-tension exists in the strap after application to support the masonry in compression and prevent cracking when the tank is initially (and subsequently) loaded.
b) the distribution of the tension in the strap upon application – this experiment was to test the assumption that circumferential tension in the strap would vary due to the friction between the wall and the strap, from a maximum near the tensioner, to a minimum on the opposite side of the tank.

The experiment involved measurement of the strain in the reinforcing strap using strain gauges. The strain gauges had been calibrated beforehand (see Figure 6 below) so that the load in the strap could be derived directly and accurately from the strain values. Three strain gauges were placed on a single strap, at 0, 90 and 180 degrees around the specimen circumference, and readings taken as the strap was applied (see Figure 7).

Figure 6 – Calibration of strain gauges using tensometer

Figure 7 – Showing strain gauge fitted to the steel strap

Box 1

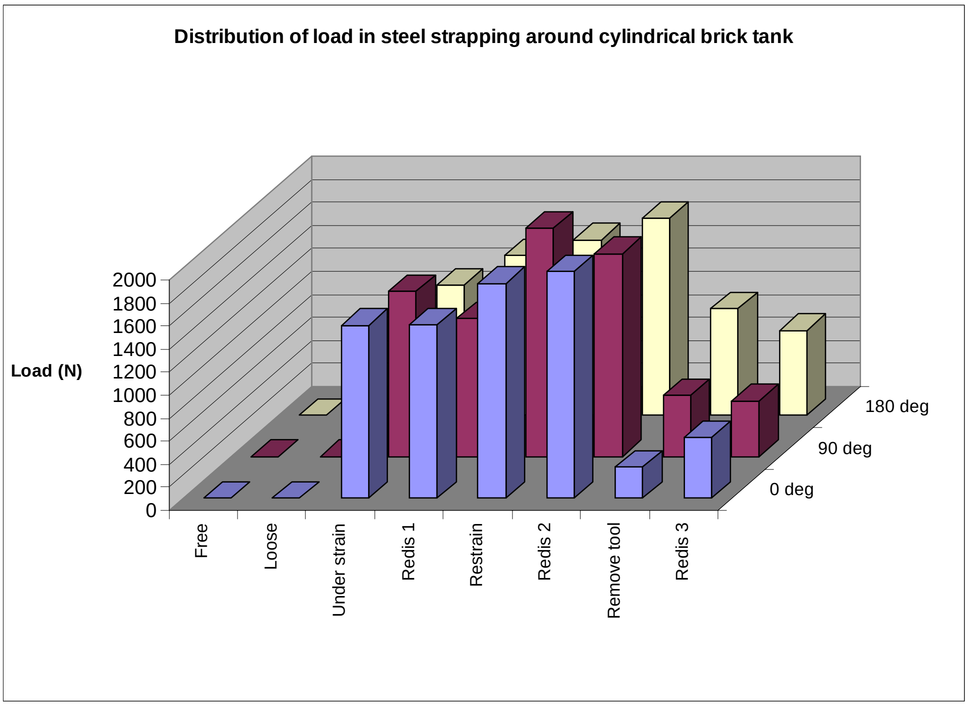
Applying the steel strap
The strap is applied to the brick masonry specimen using a manually operated tensioning tool. Once fully tensioned the strap is crimped (see Figure 9 below) using specially designed crimps and crimping tool and then the tensioning tool is removed. It can be seen from Figure 8 below that the tensioning tool holds the strap away from the wall in order to allow access for the jaws of the crimping tool. After initial experiments there was some concern about the loss of tension when the tool is removed.

Graph 1 shows the steps taken during the experiment and the load registered by the strain gauges. The term 'redis' in the graph means redistribution of the load. This was achieved by using a screwdriver to prise the strap away from the masonry slightly (moving around one brick at a time) to allow the tension in the strap to be redistributed.

Box 2

Strap pretension required to balance water pressure forces and prevent tensile stress being set up in masonry
- From Table 1, maximum hoop stress in steel due to water pressure is 114 Mpa
- Area of cross section of steel strap = 6.5mm^2
- Tension required in strap = 6.5 x 114 = 741 N

An analysis of the graph clearly shows the increase of tension in the strap as the strap is tightened and also shows that a certain amount of redistribution of that load takes place during the 'redis' phase. The drop off in tension during removal of the tool without packing (as illustrated in Figure 8) is completely unacceptable with the final tension being a small fraction of the tension created by the tool and insufficient to put the masonry into compression (see Box2). We see, however, that the tool is capable of tensioning the strap sufficiently – values of almost 2000 N being achieved during the tensioning phase.



Graph 1 – Distribution of load in steel strap around cylindrical brick tank during application

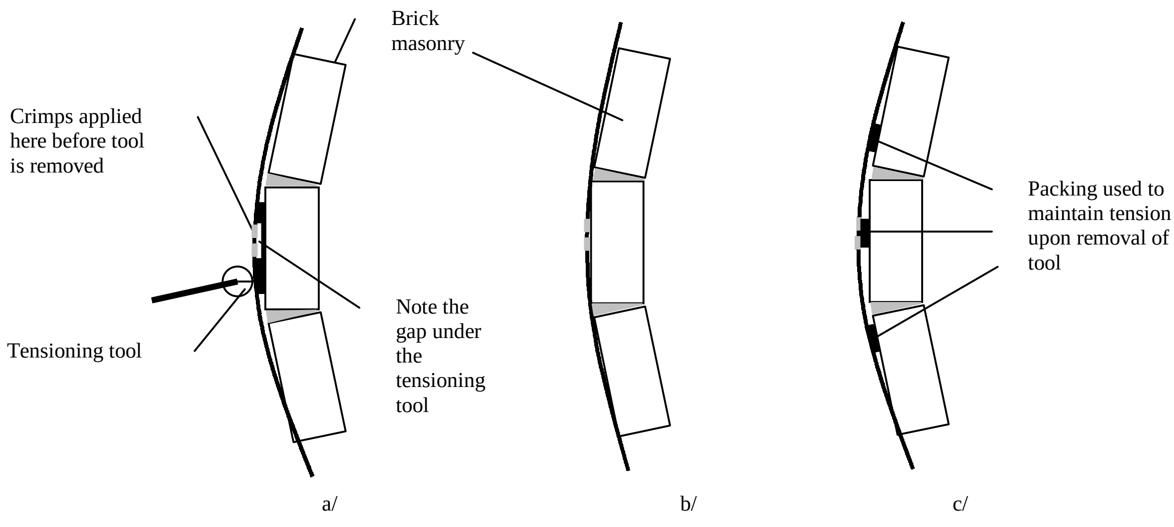


Figure 8 – showing tensioning and crimping arrangement for steel strapping a/ during the tensioning and crimping process b/ when crimping is complete and the tensioning tool has been removed and tension reduced c/ maintaining tension by using packing

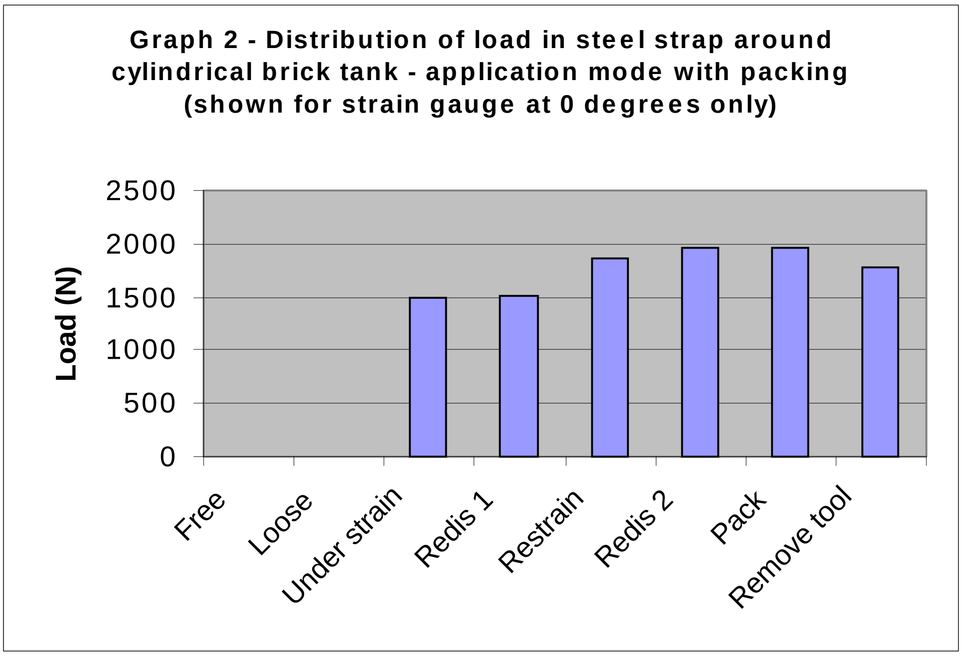
Figure 9 – photograph of straps showing crimps

Figure 8 shows the method used to pack the strap to prevent loss of tension upon removing the tensioning tool. If this process is carried out the tension can be maintained as shown in Graph 2. In this case the tension, at 1777 Newtons, is more than double that required to prevent the masonry going into tension upon pressure loading. Practically, this involves placing some packing material behind each strap as it is applied. Further work is needed to define a practical method and a suitable material for this purpose.



Graph 2 - Distribution of load in steel strap around cylindrical brick tank - application mode with packing (shown for strain gauge at 0 degrees only)

6.6 Reinforcing straps – loading and ultimate tensile strength

A test was carried out to determine the maximum load that can be applied to an externally reinforced brick tank. The aim of the test was to simulate water pressure acting on the wall of the tank and to observe the behaviour and failure mode of the tank as pressure was increased. Ideally the test would have been carried out using a sealed tank that could be pressurised to the point of failure but this was not practical at the University, especially indoors on the civil engineering strong floor. To simulate water pressure a steel expansion ring was manufactured as shown in Figure 10 below. The ring was made from 3mm mild steel to provide enough rigidity to prevent buckling but enough flexibility to take up the shape of the interior surface with which it came into contact. The ring was expanded using two 1 tonne hydraulic jacks, as shown in Figure 11. A load cell was placed in series with the jack to measure the applied load and is also shown in Figure 11 (this had been calibrated earlier). The ring spanned 2 courses of bricks that with hindsight, should have been free floating, but were not. The straps on the specimen were fitted with strain gauges at 0^o, 90^o, and 180^o to measure the stress induced in the strap. Thus we could monitor the increase in load in the strap due to increased (simulated) water pressure.

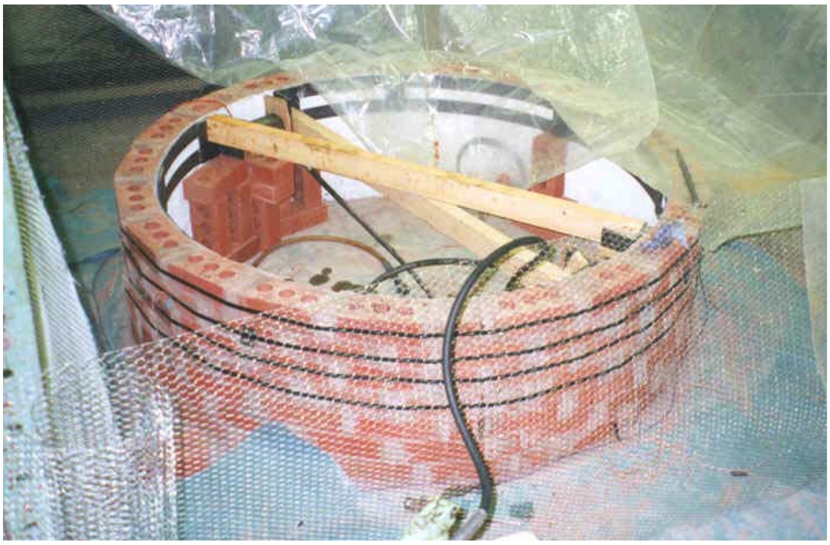


Figure 10 – Specimen under test, showing expansion ring

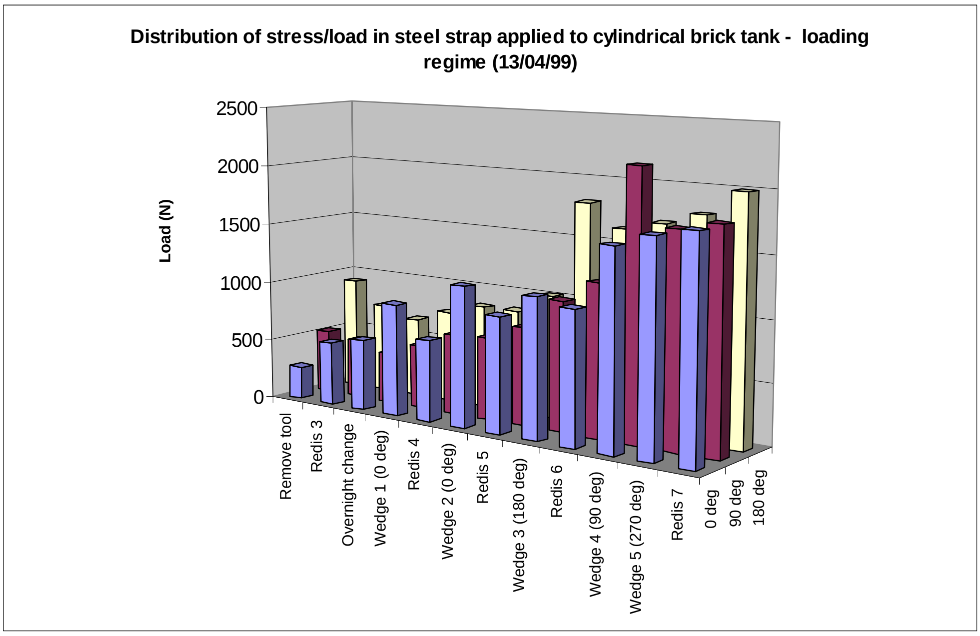
As the hydraulic jacks were extended the ring slowly expanded putting the strap into tension. The jacks continued to be extended until the straps failed and the masonry broke. During this time observations were made of the following:

- the applied load
- the cracking of the render
- the cracking of the masonry
- the strain (and hence load) in the strap

Graph 3 (histogram) shows the general trend of increased load in the straps as the expansion ring is opened. Noting the horizontal axis of the histogram we see that jack pressure in the expansion ring is not rising continuously. Graph 4 shows a clearer representation of what is happening in one of the straps – namely the strap at 90^o. There are some interesting phenomenon to observe:

1. Firstly, the force in the expansion ring is much greater that the force in the strap. There are a number of possible explanations for this:
    - the two courses of brick under test are not free-floating and so some energy is being required to stress the lower courses of bricks
    - in the early stages of the test, until the masonry fails, some of the load is taken by the masonry itself
    - there are four straps fitted on the specimen, all of which are accepting some of the load – two strap are directly under load

2. We see two distinct regions (see Graph 4 below), one where the pressure in the ring rises linearly with the load in the strap (region 1) and then a region where the pressure in the ring rises little, and indeed starts to fall, as the load in the strap increase and the ring continues to expand (region 2). This can be explained as follows (either or both of the following acting at any time):
    - as the cracking in the specimen worsens, the energy that was taken up 'bending' the lower part of the wall is now redistributed in the upper part of the wall (the test area) as the joint between the two fails.
    - the masonry breaks locally, and there is a significant repositioning of the brick (local to the ring) within the masonry as the ring expands further.

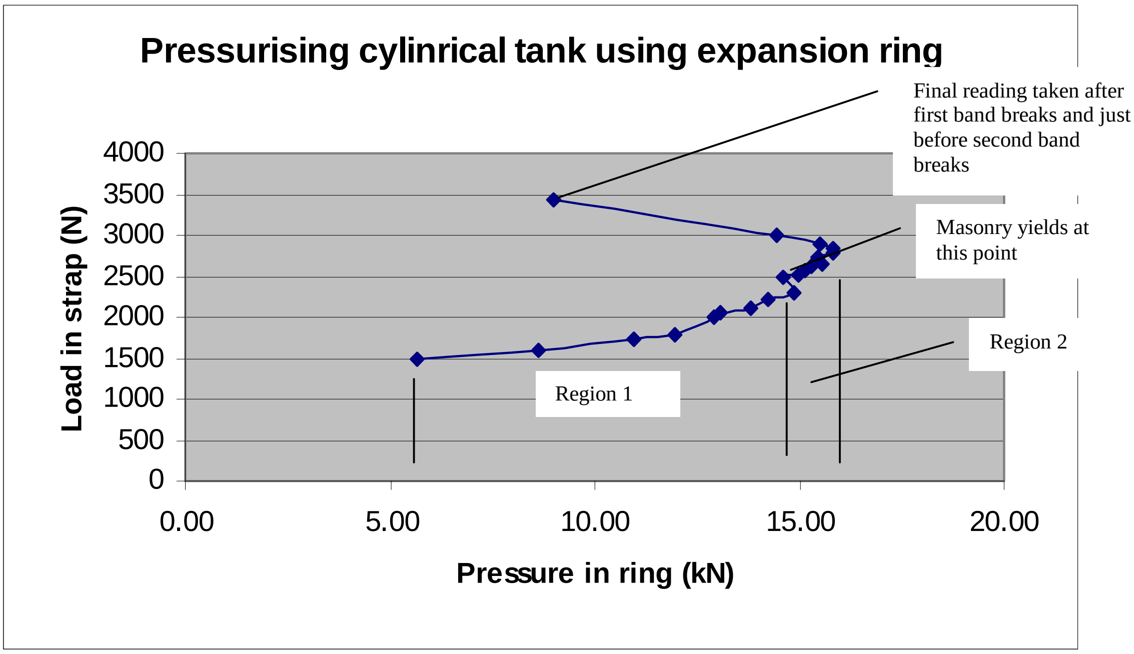


Graph 3 – Loading cylindrical tank using expansion ring

3. Large vertical and horizontal cracks appear (see Figure 12):
    - the horizontal cracks are due to shear as the upper section of the specimen wall shears away from the lower section
    - the vertical cracks are obviously the result of tension as the pressure is applied to the ring

Figure 11 – Specimen under test, showing close up of hydraulic jack and load cell

Figure 12 – Cracking in specimen after pressure test



Graph 4 – Pressurising cylindrical tank using expansion ring – strain gauge readings at 90 degrees

In conclusion it should be strongly noted that although what we see is a realistic representation of what was going on in the test specimen during the test, and is of some value to us in understanding the behaviour of cylindrical tanks, it is not what we were looking for! This was due to improper experimental design. A further test will be carried out on a free-floating specimen i.e. a specimen set on a sliding ring to simulate an elemental horizontal slice of tank. This will hopefully yield results that will be of more interest to us.

7. Conclusions

The general conclusion is that the single skin, externally reinforced, brick tank is a viable alternative to more costly tank types available at present. The experiments carried out so far have shown that the construction technique adopted is sound, but further work is still required to achieve a full analysis of the ideas under discussion which will lead to a final design and set of construction guidelines for this type of tank. The work that still needs to be carried out is outlined in the following Chapter

8. Further work to be undertaken

The following have been identifies as areas needing further work:

From section number:	Description of work
1.2	Research into plastic linings for tanks
2.1	Carry out full computer analysis of stresses in cylindrical tanks
2.3	Analysis of stresses in foundations of tanks Foundation design
2.4	Analysis of stresses due to other forces (e.g. wind, earthquakes)
5.1	Research the alternatives to steel strap e.g. methods of adequately tensioning steel or barbed wire
6.2	Further tests on lime mortar specimens - strap application and loading tests
6.3	Further tests to characterise the behaviour of renders – cracking, shrinkage and adhesion with a variety of admixtures and curing regimes
6.6	Tests of free-floating brick cylinder specimens using both cement and lime mortars
Other	Preparation of design and construction guidelines for this style of tank. Construction of full size tank to look at the following: ▪ tank construction techniques ▪ stress analysis in full size tank – including cyclic loading and temperature effects ▪ shrinkage and cracking due to water pressure loading ▪ leakage

February 1999

Introduction
The thin-shell ferrocement tank cover is designed in such a way that it can be manufactured without the use of a mould or shuttering. It can also be manufactured remote from the tank to which it is to be fitted and moved into place once complete. The aim is to reduce the cost of the tank (cover) by eliminating costly shuttering or moulds and by reducing the quantity of material used to manufacture the cover. It also means that the cover can be removed at a later date for maintenance, refurbishment or cleaning. The cover can be manufactured by two persons (one skilled and one unskilled) in a single day (with some time required after that for curing) using tools required for the construction of a simple cylindrical ferrocement tank.

The design is based on a frame known as a reciprocal frame, that has spokes that, when loaded, put little radial loading onto the structure on which it sits. The frame is covered with a wire mesh that is then rendered with a sand cement mix.

Details of the construction process are given here for a 2.0m diameter cover that has an inspection chamber opening of 0.5m. The cover pitch is 25^{o}. Strength tests have proved acceptable up to this diameter. No guarantee is given for greater diameters. The spoke angles have to be recalculated for different diameters – this is one disadvantage of the cover design.

Benefits of the thin-shell ferrocement tank

- low cost – reduced use of materials
- no shuttering or mould required
- strong and lightweight – the tank cover is designed to be strong (through good quality control) and light at the same time
- good quality control can be achieved through easy working environment
- can be manufactured by two people in a single day (one skilled and one unskilled)
- no clambering on top of tanks required during construction
- can be cured easily – in the shade and at ground level
- can be batch produced at one site

Reciprocal frame construction guidelines – for 2m diameter cover

Materials and tools

Materials	Tools
♦ 8mm reinforcing bar – 40m	♦ hacksaw
♦ tie wire – 0.5kg	♦ pliers
♦ chicken mesh (0.9m wide; 10m long; ½” mesh)	♦ tin snips
♦ sand	♦ vice (handy if available)
♦ cement	♦ masons trowel (small)
♦ mortar plasticiser	♦ masons trowel (large)
♦ water	♦ plasterers float
♦ plastic sheeting (reusable)	♦ shovel
	♦ buckets (2)
	♦ wheel barrow (optional)

Stage 1 – making the frame

- Choose a location with plenty of space to work. The procedure requires bending long lengths of reinforcing steel and so a clear working area is essential. Also a ground space of 2m diameter will be needed where no other activity will be carried out for a week (while the cover is cured).
- The first step is to set up a jig for bending the reinforcing bar. The jig is made up of two pegs 5cms long, set about 5cm apart. The steel is placed in the jig and bent as shown in Figure 1. The jig needs to be fixed so that it cannot move when the steel is bent. A workbench is ideal where the pegs can be put into the vice. Alternatively the pegs can be driven into a heavy piece of timber and this arrangement can be used effectively. Steel re-bar (8mm) can be used to form the pegs, but slightly heavier steel is better.

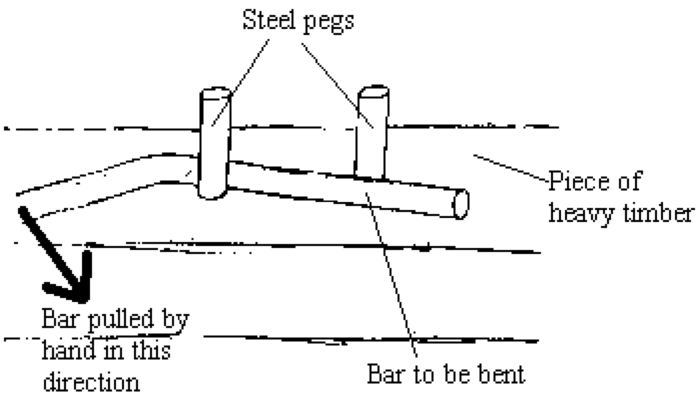

Figure 1 – Jig for bending steel reinforcing bar

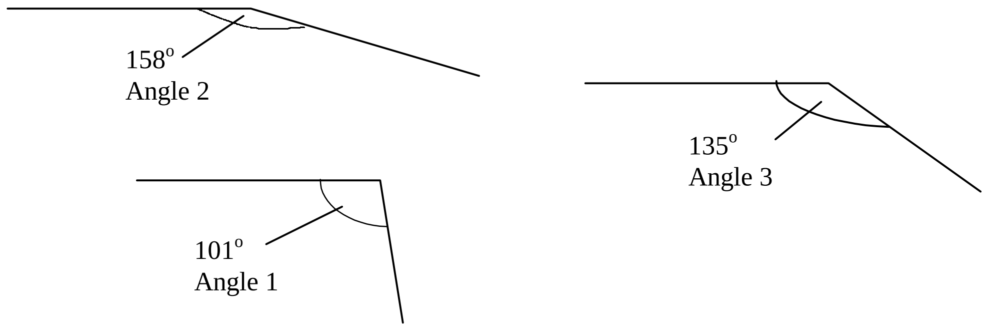
> Tip:
> When bending the re-bar it does not bend exactly where it makes contact with the jig peg. The bending takes place a cm or two on the pulling side. This has to be allowed for when bending. The bending radius can be quite large because of the thickness of the steel. This doesn't present any real problems here.

- The next step is to bend the 8mm reinforcing steel into hoops. Four hoops, diameter 0.55m, 1.0m, 1.5m and 2.0m are required. To make the procedure easy, a peg can be knocked into the ground and used as a centre around which the four circles can be drawn using string and a marker (also mark the positions of the 8 spokes at 45^o intervals for later use). The steel can then be bent gently in the jig to match the circles. The hoops ends are tied with two or three pieces of tie wire. For this the steel is cut slightly oversize to allow for tying. The cutting lengths are given in Table 1. Where the cover is to be fitted to an existing tank the outer hoop should be bent to fit the mean radius of the top of the tank wall and any irregularities in the shape should be taken into consideration.

Diameter	Steel cutting length (add 0.2m for overlap for tying in all cases)
0.55m	1.72m (1.92m)
1.0m	3.14m (3.34m)

1.5m	4.71m (4.91m)	
2.0m	6.28m (2.48m)	

- At this point all but the outer (largest) hoop can be put aside until later.
- The next step is to bend the spokes. There are eight in number and are bent in the jig to the dimensions shown in Figure 2. The cutting length is 1.33m. To aid the bending, the angles can be marked out on the ground (or on a bench) beforehand and then the bent steel can be matched against this. The angles to mark are:



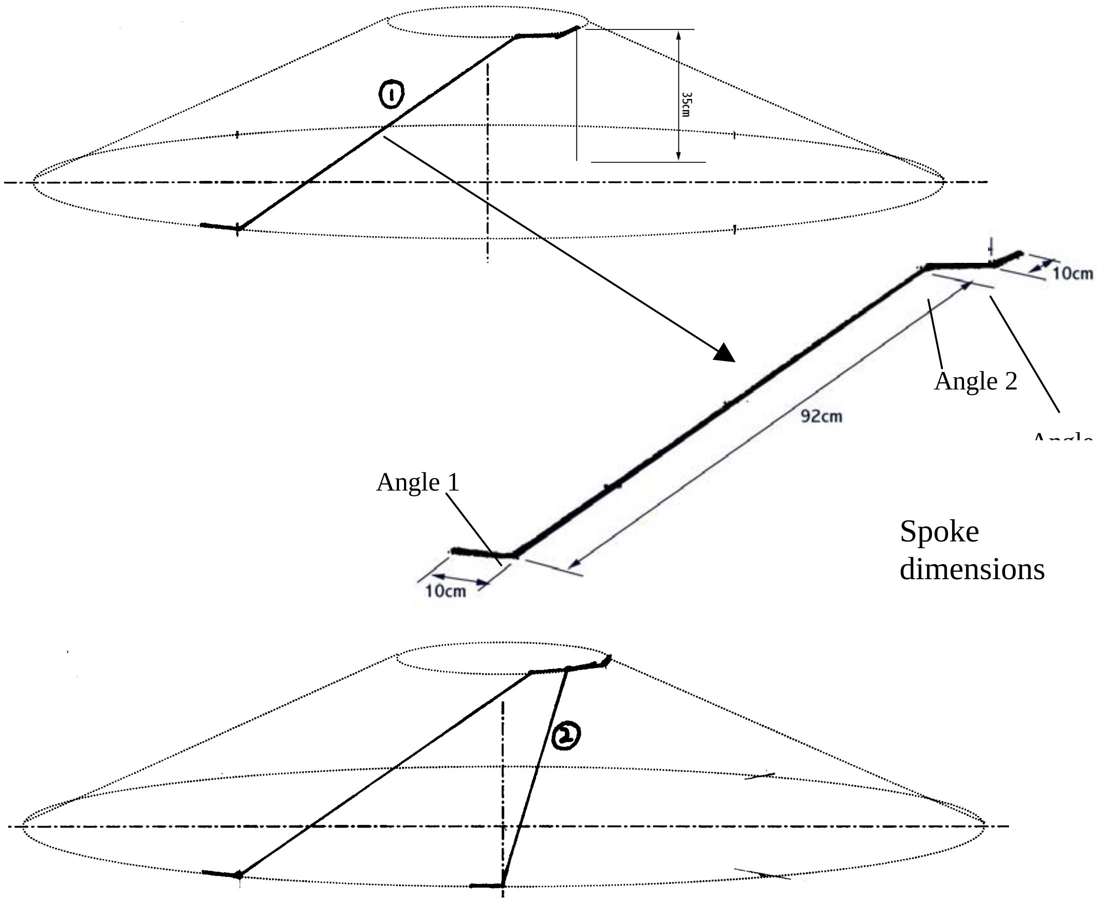


Figure 2. Dimensions and locations of frame spokes

- It is recommended that Angles 1 and 3 are bent first. These are bent in the same plane. The spoke is then turned through 90^{o} and Angle 2 is bent.
- Eight secondary spokes are also cut to a length of 75cm. These are wired to the frame as shown in Figure 3 and support the mesh to reduce the 'panel' size.

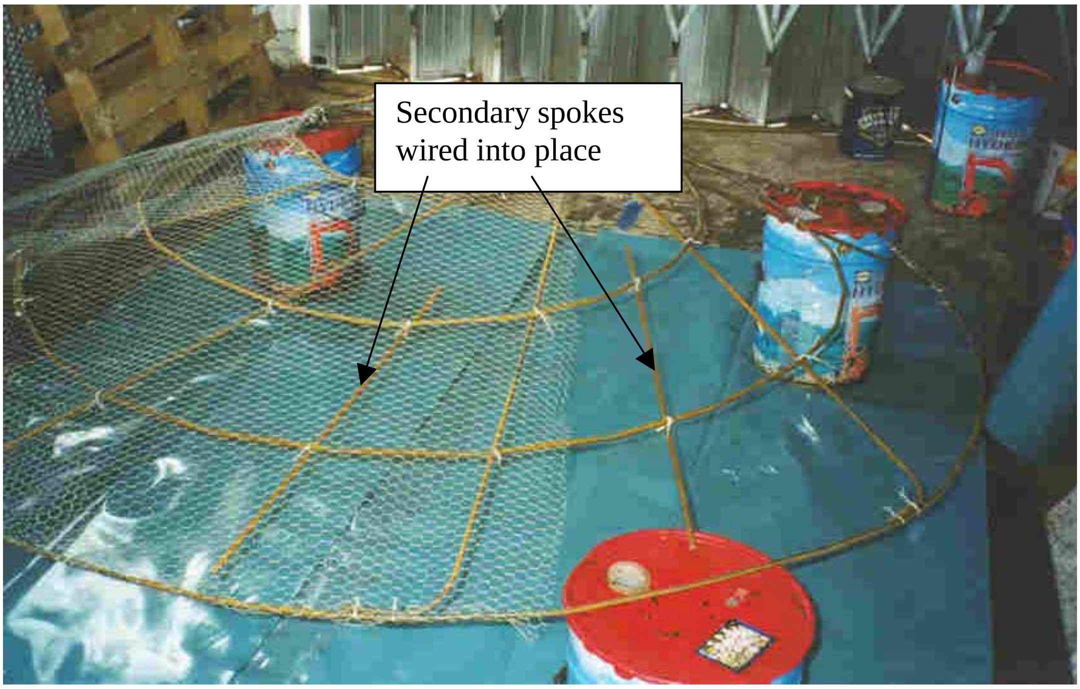

Figure 3. Secondary spokes in place

- Now the spokes are placed one by one inside the outer hoop (as shown in fig 2.) to slowly form the cover frame. It is convenient to have the outer hoop sitting on the ring marked out earlier with the position for the 8 spokes marked also. THERE IS NO INNER RING. This is made up as the separate spokes are joined together. (See Figure 4). Spoke one is placed on a support (a box or piece of wood) which is 35cm high. This is the height of the frame from the ground to the plane of the circular cover opening.

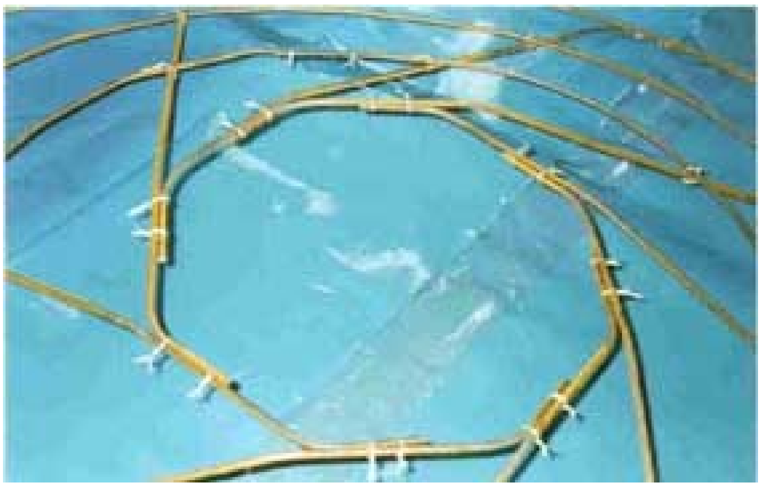

Figure 4. Showing the formation of the inner ring from individual spokes

- Tie the first spoke to the inner side of the outer hoop as shown in Figure 5.**(no 11).**

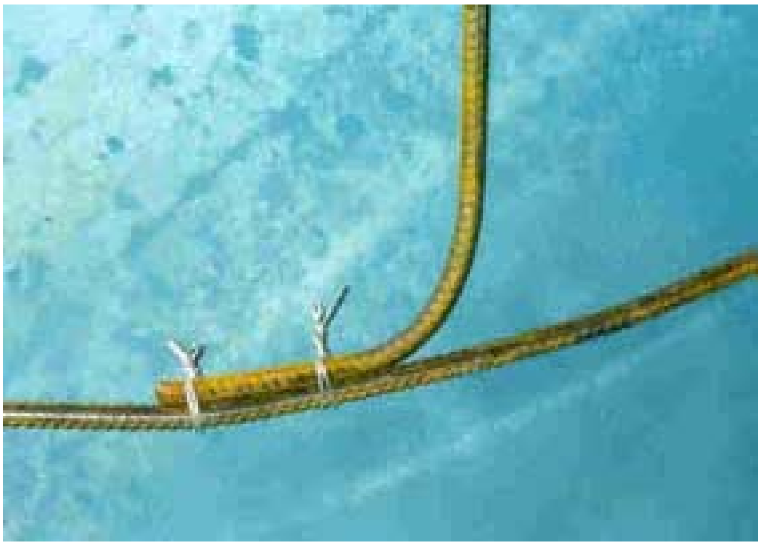

Figure 5. Showing arrangement for tying spoke to outer hoop.

- Place the next spoke 45^{o} around the perimeter hoop (these spacings were marked earlier) and tie it to the first spoke as shown in Figure 6. Continue in this way until the final spoke is tied to the first spoke and all eight spokes are in place.

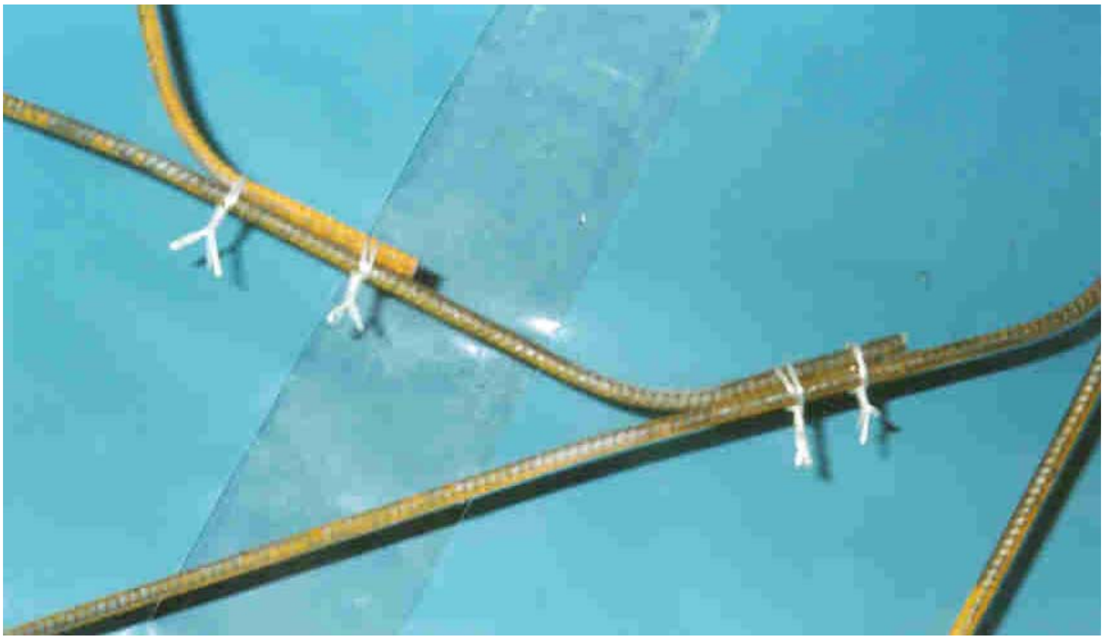

Figure 6. Arrangment for tying spokes to each other.

- Put the two inner hoops in position and tie them in place (Figure 7). The small inner hoop that was formed earlier will be used when the access hatch lip is made later.
- The frame in now ready to have the chicken mesh attached.

Figure 7. The frame with hoops in place.

- Use chicken wire of 0.9m roll width with a mesh size of ½ inch. Ten metres length is required. Two layers of chicken netting are applied.
- Eight pieces of chicken wire are cut to the dimensions shown in Figure 8. Two pieces can be cut from a 2.4m length of netting if cut as shown. A template can be drawn on the ground to aid cutting.

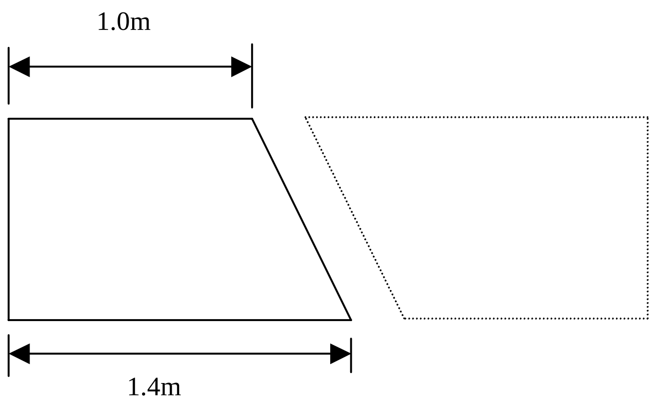

Figure 8. Cutting size for chicken mesh

- The pieces of netting are placed on the frame as shown in Figure 9 and Figure 10 and the overlapping edges are folded over and tied in place, pulling the wire as tight as is possible without distorting the mesh. Use the rough edges of the netting to tie the folded edges into place. Use as little tie wire as possible at this point, as the netting will tied securely when the second layer is in place.

Tip: a screwdriver can be used to pull the loose wires or end loops through holes in the mesh to tie the mesh in place.

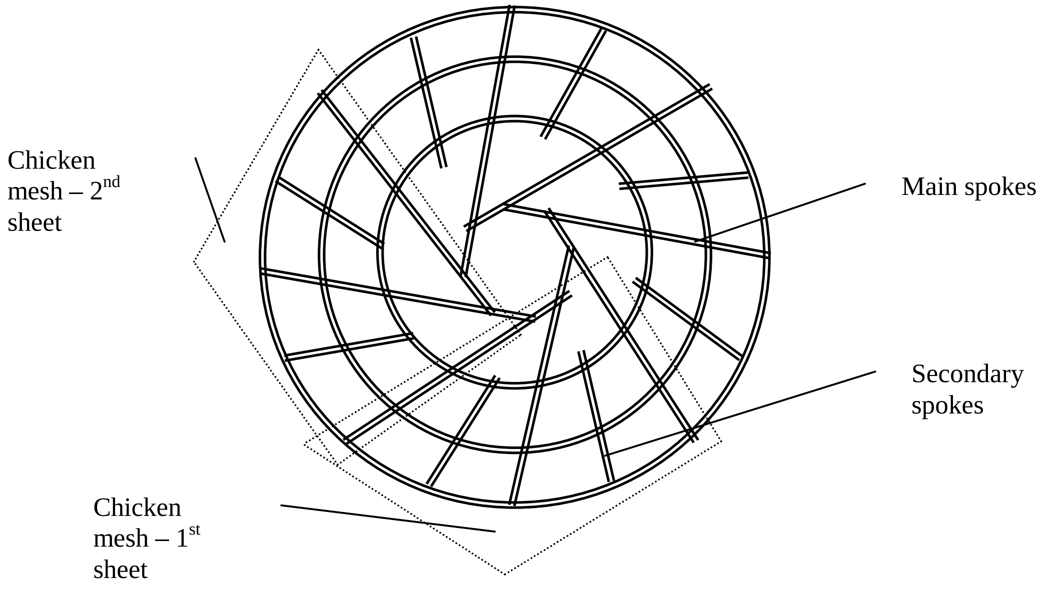

Figure 9. Pattern for application of chicken mesh

Figure 10. Applying the chicken mesh.

- When the first layer is complete start the second layer one spoke out of phase with the first and complete in the same manner.
- Carefully check that the mesh is folded as flat as possible and that both layers are close together. Tie the netting at regular intervals using the tie wire so that the netting is close to the rebar. Bend all tie wires into the plane of the cover. Remember that we are trying to keep the cover as thin as possible.
- The cover is now ready for the rendering (Figure 11).

Figure 11. Cover ready for rendering

Stage 2 - Rendering the cover

Materials

Sharp sand – 150kg
OPC – 30kg
Mortar plasticiser – 0.5 litres (soap powder can be used as a substitute)
Water - 20 litres (approximately)

Procedure

- It is important to use good quality materials and to maintain good standards of workmanship throughout the rendering process. The aim is to apply a layer of mortar to the chicken mesh that is as thin as possible. This, in practice, will vary between about 15mm and 25mm with an average thickness of about 20mm. The first coat is applied from the top and second coat applied from below.
- Put a plastic sheet on the ground so that render mix which falls through during rendering can be reused.
- Elevate the frame so that work can be carried out from above or below. Waist height is most suitable. The frame should be raised on 4 posts or boxes so that it is stable and can withstand the forces applied during rendering. A support should also be placed in the centre to prevent the centre sagging under the weight of the render (see figure 11 above).
- Render preparation: a mix of 3:1 (sand:cement by *volume*) is used. A sharp sand should be used i.e. not a fine sand but sand with a moderately large grain size. There should be no silt or other contaminant in the sand. (**See guidelines for checking sand quality)**. Ordinary Portland Cement (OPC) is used. The quantities should be carefully measured using a container – a bucket for example (do not measure using a shovel as this can be very inaccurate).
- The consistency of the render is very important. It should be dry enough not to fall through the netting while being plastic enough to be workable with a trowel. A mortar plasticiser is required to improve the workability of the render. This means that the water:cement ratio can be kept low while still keeping the render plastic. This ratio should be kept to approximately 0.4 by weight (i.e. 10 parts cement to 4 parts water by *weight*). Low water content not only gives a render which is easily applied to the mesh, but also gives improvements in strength and permeability of

the cured render. In practice it is difficult to control the water:cement ratio because there is usually an unknown quantity of water in damp sand and plasticity is often achieved before the minimum measured ratio is met. The practical method involves experimentation to achieve the desired plasticity with minimum water content. The plasticiser should be used according to the manufacturers instructions.

Tip: use soap powder instead of mortar plasticiser. Experiment to find a suitable quantity.

- Keep mixes small because the render 'goes off' quickly. It may be wise to mix enough render for the whole job and then add water to small amounts as required.
- Applying the render: this is fairly simple to do. Use a plasterers float and a small trowel. Put the float behind the mesh and work the mortar through the mesh onto the float as shown in Figure 12. Wipe the float away so that the mortar is slightly smoothed on the underside. Work small areas – take one 'panel' at a time and complete it. Some of the mortar will fall through onto the plastic sheet – this can be picked up immediately for reuse. Remember that the aim is to apply a very thin layer of mortar. The technique can be easily learned with a little practice.

Figure 12. Applying render to the chicken mesh.

- Where the cover stands on the supports, leave a small section of the outer hoop un-rendered. Wires can be threaded through these gaps later for lifting the cover into place and any securing to the tank body can be done here.
- The outer edge of the tank should be rendered roughly as this will blended into the tank wall when it is put into place.
- Once the first layer of mortar has been applied the cover should be left for a day to allow the render to gain strength.
- The area within 10cms of the inspection opening should be roughened for keying in the lip. A strip 20cms wide from the outer edge to the inner edge should also be roughened to take the access strip (see Figure 13). Tie wires should also be poked through from the underside to tie the access strip reinforcing in place when the render has gained strength.

Figure 13. Showing finished access strip and old tyre used as former for access hatch lip.

When the rendered cover has been sitting for one day the following work can be done:

- Three lengths of steel should be cut and placed radially where the access strip is to be located. They are tied in place. The access strip is then laid using 3:1 mix render to a depth of 2cms. This is then scored to give grip when climbing to the access hatch.
- The lip of the inspection chamber is built up with mortar to a total thickness of 4cms. The 0.55m steel hoop of is placed on top of the existing render and the lip built up to the desired shape. A former can be manufactured to aid in this process or an old car tyre can be cut to give the correct diameter and supported in place (see figure 133 above). A greater lip thickness gives a greater feeling of security to people working on or in the tank.
- The cover is then cured for 7 days. The tank should be wetted twice daily and covered with plastic sheeting to prevent evaporation of the curing water. It is essential that curing is carried out properly.
- A coat of ‘nil’ (pure cement water slurry) is applied to top and bottom after two days of curing.

Putting the cover in place on the tank

- When the cylindrical tank body is being constructed some thought should be given to the method of fixing the cover to the tank. If the cover is to be fitted to a thin walled ferrocement tank four (or more) tie wires should be left protruding from the tank wall and these are tied to the cover when it is in place. For brick, block or masonry walls, the cover can be laid on a bed of stiff mortar and then blended with the tank as shown in Figure 14 below.
- The cover can be lifted into place by four strong people. Strong wire can be placed around the outer hoop where the cover was left un-rendered. Two strong timber poles can be placed through these wires. These poles are then lifted by four (or eight) people Alternatively two poles can be placed under the rim of the cover, but this makes it more difficult to set the cover down.
- Special care should be taken not twist the cover or put any undue stress on it as this could cause it to crack.
- If the tank wall is quite high then a raised platform should be constructed (from earth or timber) to stand on.

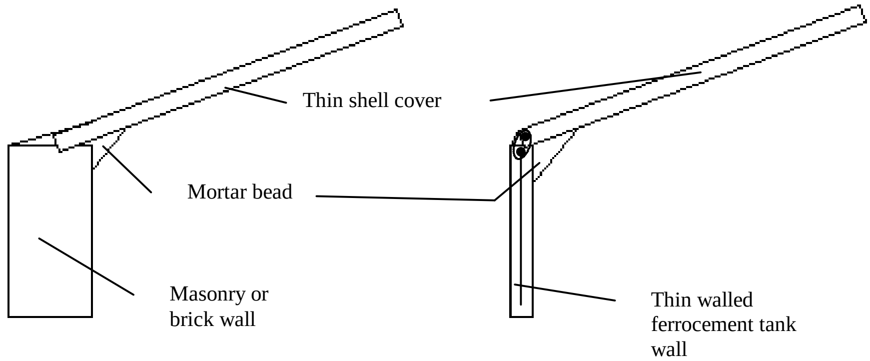

Figure 14. Blending the cover with the tank wall.

- A suitably sized ferrocement disc can be cast as the access hatch cover or another option used if so desired. This should be well fitting to prevent insects and contaminants entering the tank.

Tests for thin-shell, ferrocement tank cover

1. Point loading

The following load was applied with no adverse effect to the cover:

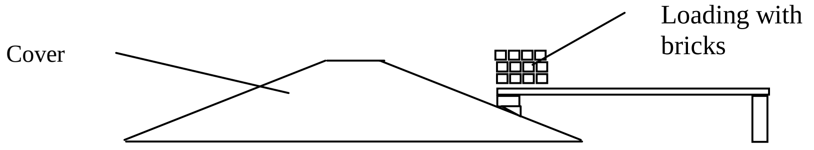

Figure 1 – Loading for point load test

Area of point load = 200 x 100mm = 20,000mm^2

Load applied 160 kg

i.e. 8kg / mm^2

2. Uniform loading

The cover was tested in two modes: constrained at the periphery to prevent slipping and unconstrained. In both cases the cover was loaded to approximately one thousand kg using house bricks (see Figure 4 below) and the deflection at the centre was less than 2mm in both cases, measured with a dial micrometer (Figure 3).

Figure 2 below shows the deflection against load for the constrained and unconstrained uniform loading.

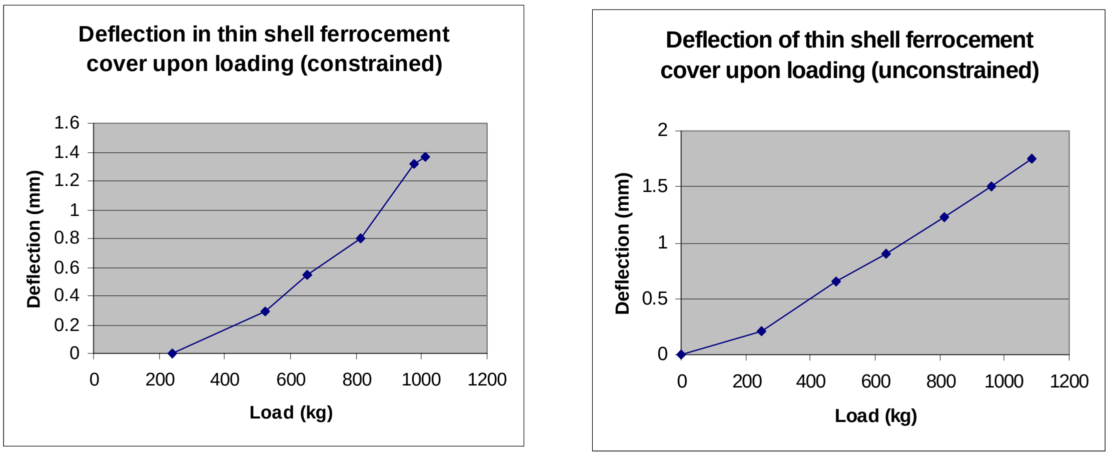

Figure 2 – Deflection of thin-shell ferrocement cover under load a/ constrained at edge b/ unconstrained

Figure 3 – dial gauge in place to test deflection of cover under load

Figure 4 – Thin-shell cover under a load of 1000kg of bricks – an evenly distributed load

The mortar dome cover – guidelines for construction

(Taken form a DTU working by Terry Thomas, Ben McGeever and members of URDT, Uganda)

1. Introduction

The mortar dome cover was developed as part of a collaborative project between the Development Technology Unit and the Uganda Rural Development and Training Programme (URDT), Kampala, Uganda. The cover is being reported here as an example of very low-cost technology for Roofwater Harvesting. The cover was part of a design of tank for underground storage of rainwater. The cover is also suitable for use on above ground tanks.

The Cover is a dome of mortar (containing almost no reinforcement) connected to a reinforced ‘ring beam’ set into the ground. The mortar dome and the ring are made at the same time over a carefully shaped mound of earth. Set into the mound are a bucket and a large plastic bowl. The bucket is to create a way for the rainwater to enter. The bowl is to create a hole to hold the plug in which the pump is set. It has to be large enough (e.g. 0.45 meter diameter) for a man to enter through. The 5 steps in making the dome will now be explained in turn.

2. Construction steps

Step 1 - Making the ‘template’ for shaping the dome

The shape of the mortar dome comes from the shape of the mound of earth it is built on. We therefore need a template to accurately form that mound of earth. Before building the first tank it is necessary to cut this wooden template. Once made, the template becomes a tool that can be used for many more tanks. The template must be the right shape and also strong enough to carry around and use without getting broken. It therefore consists of a piece of plywood, or thin planks, cut to that shape and stiffened by strips of thicker wood.

The right shape for the dome is approximately a upwards ‘catenary’. A downwards catenary is the shape taken by a chain hanging between two nails on a wall, so we mark the template out using such a chain (e.g. 1 or 2 lengths of bicycle chain) and then turn it upside down.

First cut the plywood so that it measures 125 cm by 100 cm and has square corners. Figure 3a shows 2 nails spaced 2.2 meters apart on a horizontal line drawn across a flat wall using a spirit level. Draw a vertical line down the wall from midway between these two nails and mark a short line (the ‘mark’) across it 80 cm below the horizontal line. Hang a light chain between the two outside nails and adjust its length until it just reaches down to this mark. (If you do not have enough chain to do this, see the alternative below.) Slide the thin plywood behind the chain without touching it, so that the long top of the plywood touches the left-hand nail and the right side of the plywood lies along the vertical line. With a pen, copy the shape of the hanging chain onto the plywood, remove the plywood from the wall and saw along the line you have just marked. (Using planks instead of plywood, first nail them rigidly to their stiffening bar so that they can be placed behind the hanging chain; then continue as for plywood).

Although it is easiest to make the catenary with two bicycle chains joined end to end, it can also be done with only one. This has to be hung so that it forms just over half the full U-shaped catenary: one end of the chain is attached to the left-hand nail, the other end is held low and pulled until the lowest point of the chain falls exactly over the ‘mark’. You can now drive in another nail (‘alternative nail position’ in Figure 1) to attach the chain to, while you are copying the chain’s shape onto the plywood.

It is necessary that the chain has no twists and that it hangs freely, otherwise it might take up the wrong shape. The right shape ensures that the mortar dome is strong (by being everywhere ‘in compression’). Rope is not usually suitable instead of chain, because most ropes twist and are not heavy enough to hang properly.

To finish the template, stiffen it with good wooden strips. Now turn the template over so that the long straight side is on top and write the word ‘TOP’ next to it. Smooth the sharp corners to make it safer to carry.

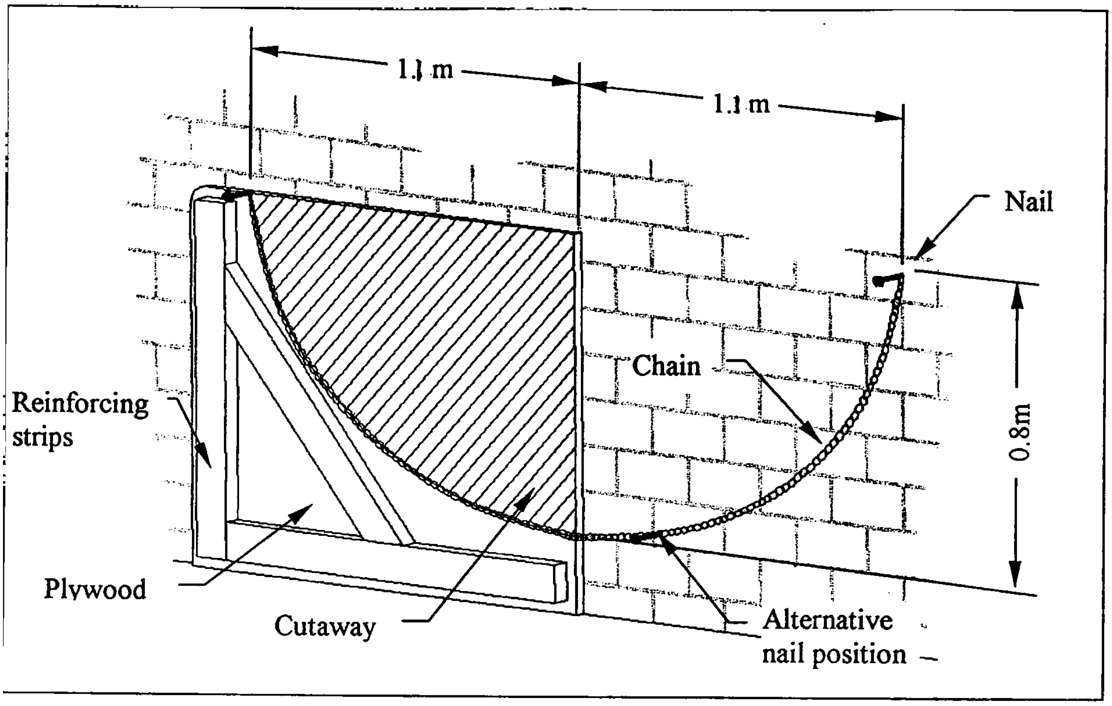

Figure 1 Making the template

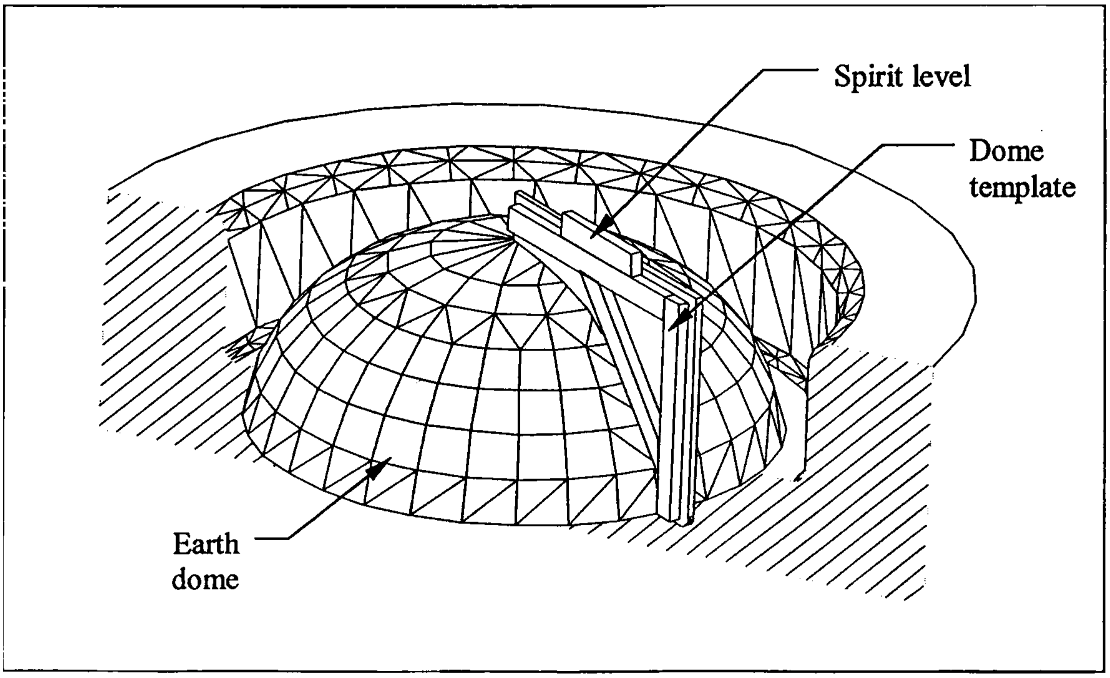

Figure 2 Forming the earth mound

Step 2 Marking out and making the trench and earth mound

The centre of the cover should be marked by a firm and vertical (use a spirit level) thin stake. Make a clear ink mark or cut a ring round the stake about 30 cm above the ground. Using a string 110 cm long looped once round the stake, mark out a circle of diameter 220 cm on the ground. This circle marks the inside edge of the trench in which the ring beam will be cast.

Dig a narrow trench (one hoe's width) outside this circle and throw some of the soil into the centre round the pole. The idea is to dig down 50 cm leaving a mound of firm soil inside the ring rising up to the ring round the stake. The shape can constantly be checked using the template - now with 'TOP' at the top - placed against the stake and rotated like a scraper. The template should be kept level by means of a spirit level and at the right height with its lower corner touching the ring marked on the stake. This is shown in Figure 2.

If the mound is rough or loose or fissured by drying, it can be plastered with more mud and wooden 'floated' to make it smooth and firm.

Chicken mesh can be fixed in the trench so that later on it can be used to improve the joint between the mortar lining the tank wall and the mortar of the ring beam. Make a single strip of mesh by cutting a 1.5 meter length into 5 strips each about 18 cm wide and twist joining them end to end - the final strip should be adjusted to fit round the inside face of the trench like a ring. This ring should now be folded longwise into the vee-shape shown in Figure 3 and the inside half buried in the earth of the dome. To do this you will have to cut out some earth from the inside of the trench, place the chicken mesh then plaster back the earth again.

The trench is now too wide for the ring beam, so fill back a step 10 cm high round its outside so that its bottom becomes only as wide as your foot - about 10 cm. (You will need to walk round this slot when you are plastering the dome). This too is shown in Figure 3. The bottom of the earth dome that faces into the trench should be grooved with a trowel or stick: these grooves will be ‘copied’ onto the inner edge of the ring beam and will later help ‘key’ the plaster joint to be formed there.

Finally place the bucket and the basin on the dome as shown in Figure 4. The bucket (the inlet) should be on the side nearest the house, with its edge touching the stake. The large basin (for the excavation access and later the pump hole) should be on the other side of the stake and with its edge 25 cm from the stake. Weight down the bucket and basin with stones and push them into the soil mound so that they do not rock; local excavation will allow the bucket to be sunk a desirable 20 cm into the soil. Put a small fillet of mud round each bowl as shown.

Pull out the stake without disturbing the mound.

Step 3 Preparing the reinforcing bars

Use 6 mm bar; it does not matter whether it is round or knobbly. Make a ring whose diameter is 230 cm, folding over and linking the ends and hammered the link tight so that there is no play in the joint. This ring will take about 8 meters of bar. Test that the ring will sit in the middle of trench without getting close to either its inner or outer edge.

Make two further such rings but much smaller, one each for the bucket and the bowl. Each ring should have a diameter bigger than its bucket/bowl so as to leave a clearance of 3 cm all round it where it enters the soil dome.

Step 4 Casting the ring beam and the pierced dome

The dome and the ring beam that forms its bottom edge are made of strong mortar in the manner shown in Figure 5. The mix is 1:3 (cement : sand) and 2 bags of cement should be ample. Concrete, mixed 1:4:2 (cement : sand : small sharp aggregate), is an alternative where such aggregate is available or can be made; a concrete dome needs only 1.5 bags of cement. (Concrete is more difficult to place as a plaster than is mortar and the surface finish achievable is not so good.) The ring beam is about 10 cm x 10 cm, while the rest of the dome is covered with 2 cm of mortar. However round the bucket and bowl this depth is increased locally to about 8 cm to make a good lip to hold the bucket/bowl and to cover the reinforcing rings there. As usual all three rings of reinforcing bar must be in the middle of the mortar with several centimetres of cover on all sides. So they must be placed as the mortaring progresses. The big ring, in the ring beam, is therefore placed only after 5 cm of mortar is already in the trench.

It is important to check the mortar thickness nowhere gets less than 2 cm as you work up the dome. There should be no joints in the mortar: the whole dome and ring beam should be made (plastered) in a single session with a mix that is dry enough not to slump. As the soil dome may suck water out of the mortar or concrete applied on top of it, it should be thoroughly wetted before plastering the dome starts. Moreover in a hot climate it is wise to do this plastering early in the day so that the new dome can be covered with wet straw before the sun gets very hot.

Step 5 Curing the dome

As soon as the mortar is firm, gently remove the bucket and basin from the top of the dome.

Once the dome is cast it needs to cure under moist conditions for 14 days to develop a high strength. The simplest way to ensure it is kept moist is to cover it with plenty of grass and douse this with a jerrycan of water every morning and afternoon.

Milestone A3

'Completion of one externally reinforced brick tank, two brick test cylinders, one partially below ground tanks and five thin-shell ferrocement tank covers'.

(Originally titled 'Completion of 6 underground tanks with instrumentation')*

University of Warwick

September 1999

Contents..........1

*Early in the programme, after the initial desk study had identified the areas where further research is required, it was decided to broaden the original scope of the water storage (technology) component of the programme to include above ground, free-standing water storage tanks as well as underground tanks. The focus of this work, as reported in Milestone A2, has been primarily the research into externally reinforced, single-skin brick tanks. It was also decided that we would put some resources into developing a simple, cheap, lightweight, tank cover, as this was seen as an area where little work has been done and where there was much scope for improvement for relatively little input. The title of this Milestone has therefore been altered to reflect the practical research work that has actually been carried out under the programme.

1. Externally reinforced brick tanks

The early work on this topic was reported in Milestone A2 and covered the early tests that were carried out on brick cylinder specimens that were constructed at the University's civil engineering laboratory.

The aim of the tests were to determine the suitability of single-skin, burnt-brick, externally-reinforced (with packaging strap in this case) cylindrical tanks for water storage. The specimens were subjected to pressure forces in order to determine the hoop stresses induced in the strapping and the behaviour of the brick-strapping combination under load and at failure. The test results were then compared with a spreadsheet model that had been generated earlier.

The early results proved promising but were inconclusive due to some uncertainties in the experimental procedure. Further tests are currently underway at the University to more fully model the behaviour of the tank under load.

Figure 1 below shows one of the specimens under test, showing the internal expansion ring used to apply pressure. Figure 2 shows the steel strapping with a strain gauge that was used to measure the hoop stress generated. For fuller details of the tests, please refer to the Milestone A2 report.

Further work has since been carried out on the construction of a full-sized tank for rainwater storage at a field site in Herefordshire. The tank has a capacity of approximately six cubic metres, with a diameter of 2m and a height of 2m. The tank is at present complete, but without instrumentation as yet. The aim of the experimental tank (shown under construction in Figure 3 below), is to further investigate the behaviour of the tank with particular regard to induced stresses under real conditions and also to investigate the feasibility of a number of peripherals designs.

The tank has been built at the site of a Herefordshire based educational charity who run regular residential courses. The tank will store water captured from the roof of a large shower and toilet complex and the water is then pumped to a header tank from where it is piped to the toilets for flushing. The tank will experience regular cycling (emptying and filling) and hence will allow regular analysis of the stresses and achieve a simulation of accelerated ageing. The cost of the system was shared between the University of Warwick and the charity. The schematic diagrams for the system are shown in appendix 1.

The site will also give us a valuable UK based field testing station at which we can pre-test any idea or component before passing them on to partners or field contractors for further testing and development. The site has already been used to test plastic tank liners which are being developed at the University, as well as being fitted with a novel overflow/ washout system. The system is fitted with WISY filters, which will be tested for efficiency at a later stage.

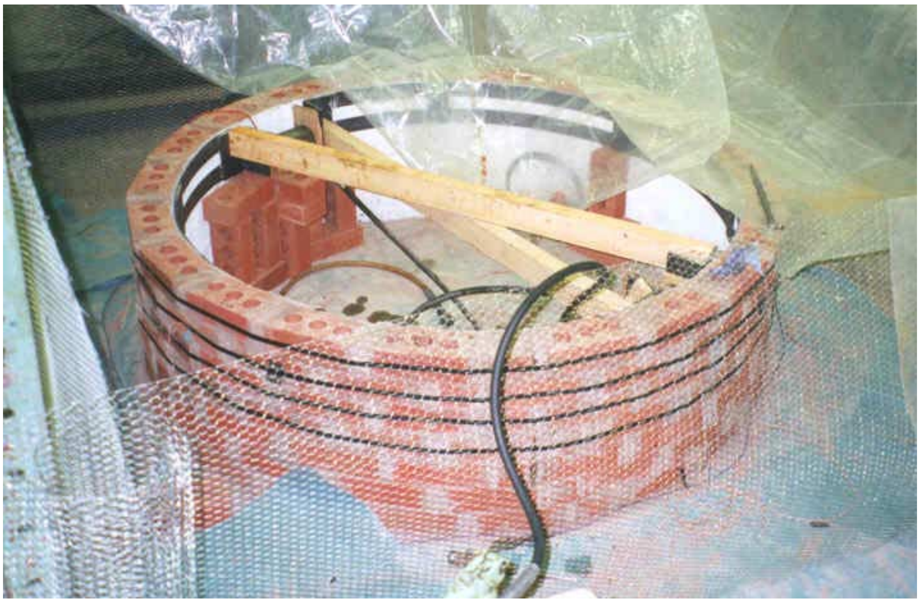

Figure 1 – Tests arrangement for externally reinforced brick cylinders

Figure 2 – Strain gauge used to measure hoop stress generated in steel strap during testing.

Future work in this area will include research into the use of cement stabilised soil blocks in place of brick, used in conjunction with a plastic tank liner, with the aim of reducing costs further.

Figure 3 – Full-size experimental tank under construction at field site.

Figure 4 – Strapping applied to experimental tank.

Results of the tests carried out at the University and at the field site will be reported in Milestone A5.

2. Partially below ground tanks

The work on partially below ground tanks is still in the very early stages and, to date, has been primarily field based. The work builds on previous DTU work in Uganda with fully below-ground tanks. Modifications were made to the original (fully below-ground) design to eliminate some of the problems commonly encountered with this type of tank, while still taking advantage of the beneficial aspects. These problems are:

- ingress of water from above ground causing contamination
- danger to children (and adults) if cover is left off the tank
- danger of collapse if driven over with a vehicle
- difficulties in excavation due to the construction process (see DTU Working Paper number 'Underground Storage of Rainwater for Domestic Use' at http://www.eng.warwick.ac.uk/DTU/workingpapers/wp49/index.html)
- no suitable overflow when tank overfills

The previous tank design is shown below in Figure 5. Approximately 15 of these tanks, which range from 8 to 10 cubic metres, have been built in western Uganda over the past 3 years with good results.

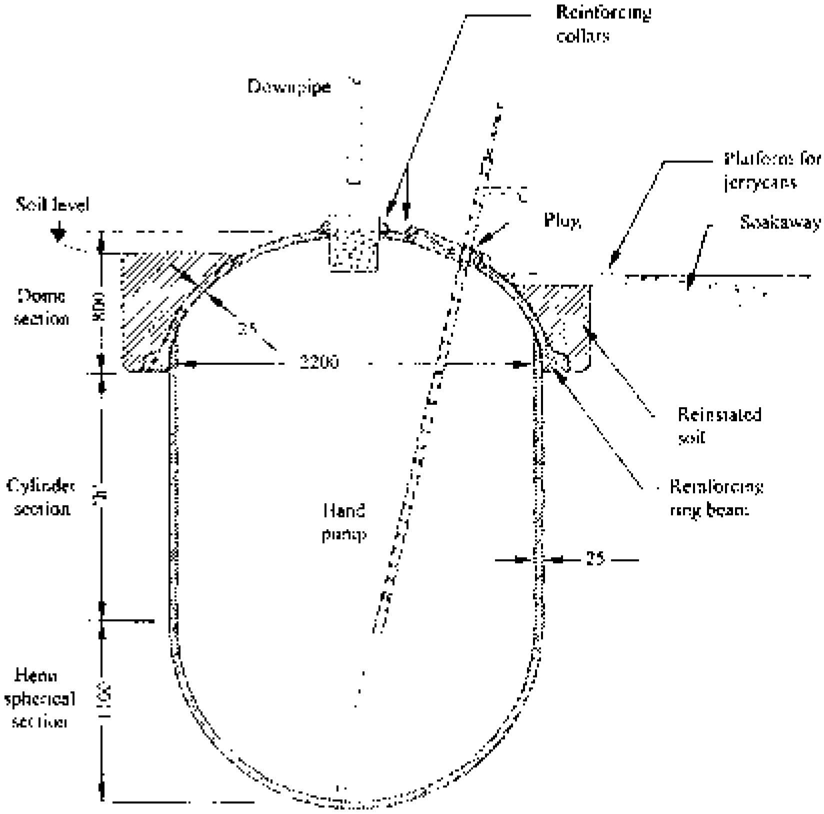

Figure 5 – DTU fully below-ground tank design

The tank is suitable only under certain soil conditions, namely where the soil is sufficiently stable to not cause any concern regarding subsidence. This is the case in many parts of Eastern Africa where the soil is lateritic.

The partially below ground tank (see Figure 6) is raised slightly above ground level in order to eliminate the problems listed above. The parapet wall sits atop a concrete ring beam through which the tank is excavated. The tank is lined with cement render and will, when the technology is sufficiently developed, be fitted with a continuous plastic lining. Water enters the tank through a pipe which directs it to the base of the tank which promotes rapid settling of sediment. The tank is fitted with an improved handpump and floating off-take. The floating off-take takes water always from slightly below the surface level of the water. These two innovations help maximise residence time in the tank, allowing full sedimentation to take place even when water is drawn off as fresh water is entering (except under conditions where the tank is almost empty).

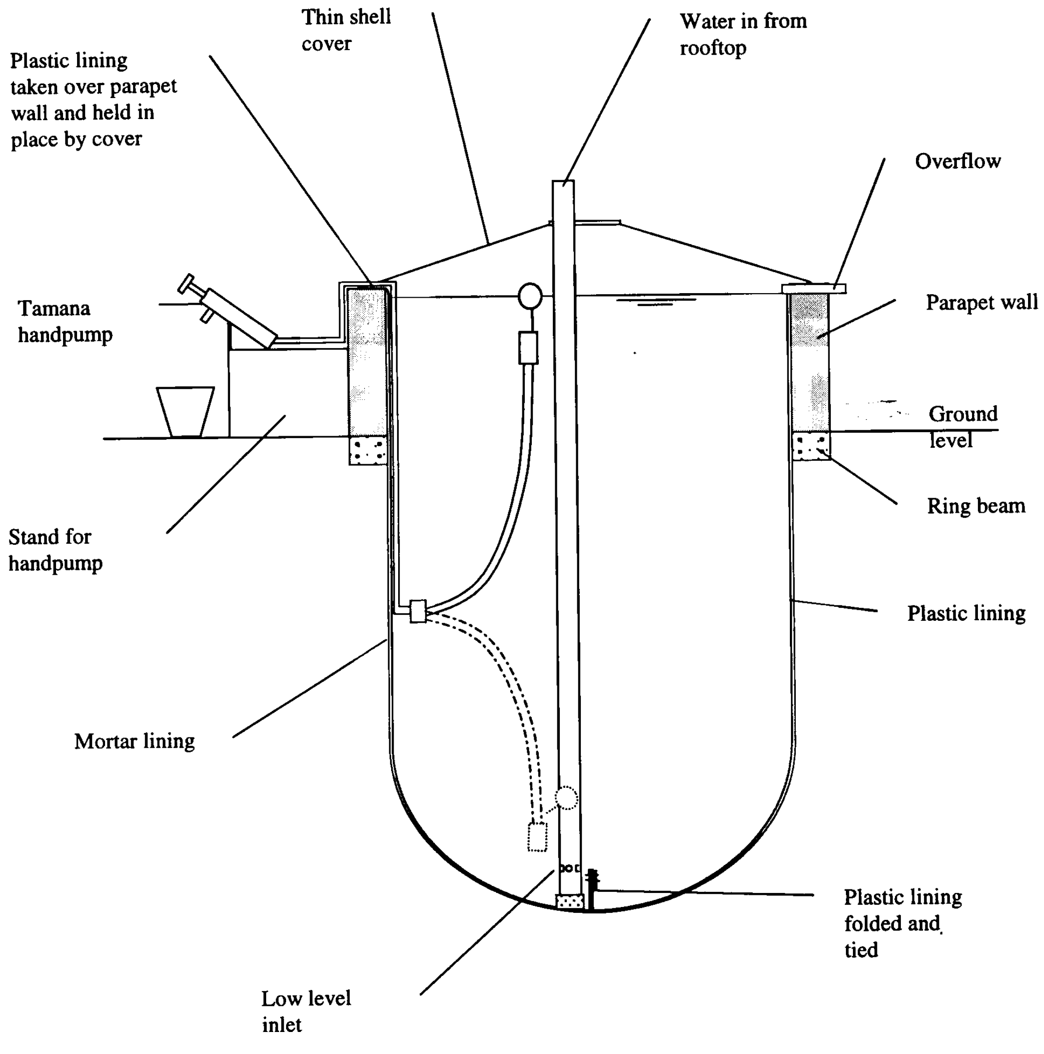

Figure 6 – Schematic representation of the cylindrical, partially below-ground tank

One partially below ground tank has been built in western Uganda. It was hoped that a number of tests would have been carried out by the time of writing this report, but due to logistical problems (funds transfer to Uganda which took 3 months), the tank has not yet been tested.

Figures 7, and 8 below, show the partially below ground tank under construction, while Figure 9 shows the thin shell ferrocement cover being manufactured.

Figure 7 – Bird's eye view of the partially below-ground tank under construction.

Figure 8 – Partially below ground tank under construction in western Uganda, showing parapet wall.

Figure 9 – Thin-shell ferrocement cover being manufacture for partially below-ground tank in western Uganda

Further information and test results form this work will be included in Milestone A5 report.

3. Thin-shell ferrocement tank covers

Milestone A2 report included documentation regarding the instructions for manufacturing a thin-shell ferrocement cover (TSF cover).

The thin-shell ferrocement tank cover is designed in such a way that it can be manufactured without the use of a mould or shuttering. It can also be manufactured remote from the tank to which it is to be fitted and moved into place once complete. The aim is to reduce the cost of the tank (cover) by eliminating costly shuttering or moulds and by reducing the quantity of material used to manufacture the cover. It also means that the cover can be removed at a later date for maintenance, refurbishment or cleaning. The cover can be manufactured by two persons (one skilled and one unskilled) in a single day (with some time required after that for curing) using tools required for the construction of a simple cylindrical ferrocement tank.

The design is based on a frame known as a reciprocal frame, that has spokes that, when loaded, put little radial loading onto the structure on which it sits. The frame is covered with a wire mesh that is then rendered with a sand cement mix.

Details of the construction process are given in Milestone A2 for a 2.0m diameter cover that has an inspection chamber opening of 0.5m.

Benefits of the thin-shell ferrocement tank

- low cost – reduced use of materials
- no shuttering or mould required
- strong and lightweight – the tank cover is designed to be strong (through good quality control) and light at the same time
- good quality control can be achieved through easy working environment
- can be manufactured by two people in a single day (one skilled and one unskilled)
- no clambering on top of tanks required during construction
- can be cured easily – in the shade and at ground level
- can be batch produced at one site

Five of these covers have been produced to date, 3 for testing purposes and two that have been fitted to tanks. One has been made in Uganda by local masons (see Figure 9 above and Figures 10 and 11 below) with no complications.

Figure 10 – 6mm steel framework being formed by local masons in western Uganda for the TSF tank cover.

Figure 11 – TSF cover being completed by local mason in western Uganda. This cover was fitted to a partially below-ground tank.

Tests have been carried out on the cover to determine its strength and the results are shown in appendix 2.

Milestone A4

Completion of three partially below ground tanks, 2 rammed earth tanks, eight cement jars and two stabilised soil block tanks.

(Originally titled 'Completion of 3 sets of 4 tanks and associated instrumentation')*

Development Technology Unit (DTU)

University of Warwick

April 2000

Milestone A4 - Table of Contents

Funded by the European Commission

*Please see the introductory section for an explanation of the change in the title of this report.

1. Introduction

As mentioned in the Milestone A3 Report, early in the programme, after the initial desk study had identified the areas where further research is required, it was decided to broaden the original scope of the water storage (technology) component of the programme to include above ground, free-standing water storage tanks as well as underground tanks. The focus of the work was, initially, broadened to look at tank covers and reinforced brick tanks. We have since moved forward with more radical cost reduction ideas and have been experimenting with two very low cost water storage ideas: the partially below ground tank and the rammed earth tank. We also carried out some water quality experiments in Uganda to test the acceptance of water from cement lined storage vessels. For these experiments we constructed eight 400litre cement jars. Finally, through our connections with Uganda we were asked to carry out some collaborative research with Mr Moses Musaazi of Makerere University into the use of cement stabilised soil blocks for the construction of above-ground water storage tanks.

The title of this Milestone has therefore been altered to reflect the practical research work that has actually been carried out under the programme.

A brief overview of the work that has been completed for this Milestone is given in this report. A fuller report of the work that has been carried out, including the experiments carried out and results obtained for each of the pieces of work mentioned above, will be presented in Milestone A5 (Report A3 '*Performance of Tanks for DRWH'*). This report will be submitted in the near future.

2. Construction of three partially below ground tanks

As reported in Milestone A3, work was started on the design of the Partially Below Ground (PBG) tank in Uganda last year. The work has still, to date, been primarily field based and three tanks have been built until now, in the vicinity of Kyenjojo, Kabarole District in Western Uganda. The tanks have been built by our partner organisation, ARUCED. ARUCED has also received orders for a number of these tanks to be built privately and to date eight tanks in all have been built.

The aim of the design of the PBG is to minimise the amount of material used by partially submerging the tank below ground – the major benefit of sub-surface tanks. The fact that approximately 1metre of the tank protrudes above the ground helps overcome some of the drawbacks normally associated with below ground tanks (see Table 1 below). The ground conditions in this part of SW Uganda are ideally suited to this kind of tank, being lateritic and highly stable.

	Above ground tank	Below ground tank
Pros	• Above ground structure allows for easy inspection for cracks or leakage • Many existing designs to choose from • Can be easily purchased ‘off-the-shelf’ in most market centres • Can be manufactured from a wide variety of materials • Easy to construct for traditional materials • Water extraction can be by gravity in many cases • Can be raised above ground level to increase water pressure	• Generally cheaper due to lower material requirements • More difficult to empty by leaving tap on • Require little or no space above ground • Unobtrusive • Surrounding ground gives support allowing lower wall thickness and thus lower costs
Cons	• Require space • Generally more expensive • More easily damaged • Prone to attack from weather • Failure can be dangerous	• Water extraction is more problematic – often requiring a pump • Leaks or failures are more difficult to detect • Contamination of the tank from groundwater is more common • Tree roots can damage the structure • There is danger to children and small animals if tank is left uncovered • Flotation of the cistern may occur if groundwater level is high and cistern is empty heavy vehicles driving over a cistern can cause damage

Table 1. Pros and Cons of Tanks and Cisterns

The design also tries to minimise the amount of cement used by employing a plastic liner to form the water proof lining for the tank. Until now the plastic liner has not, however, been fitted and the water proofing has been achieved by means of cement render. Further work in Uganda in the coming months will include the manufacture of plastic liners and these will be fitted to subsequent tanks.

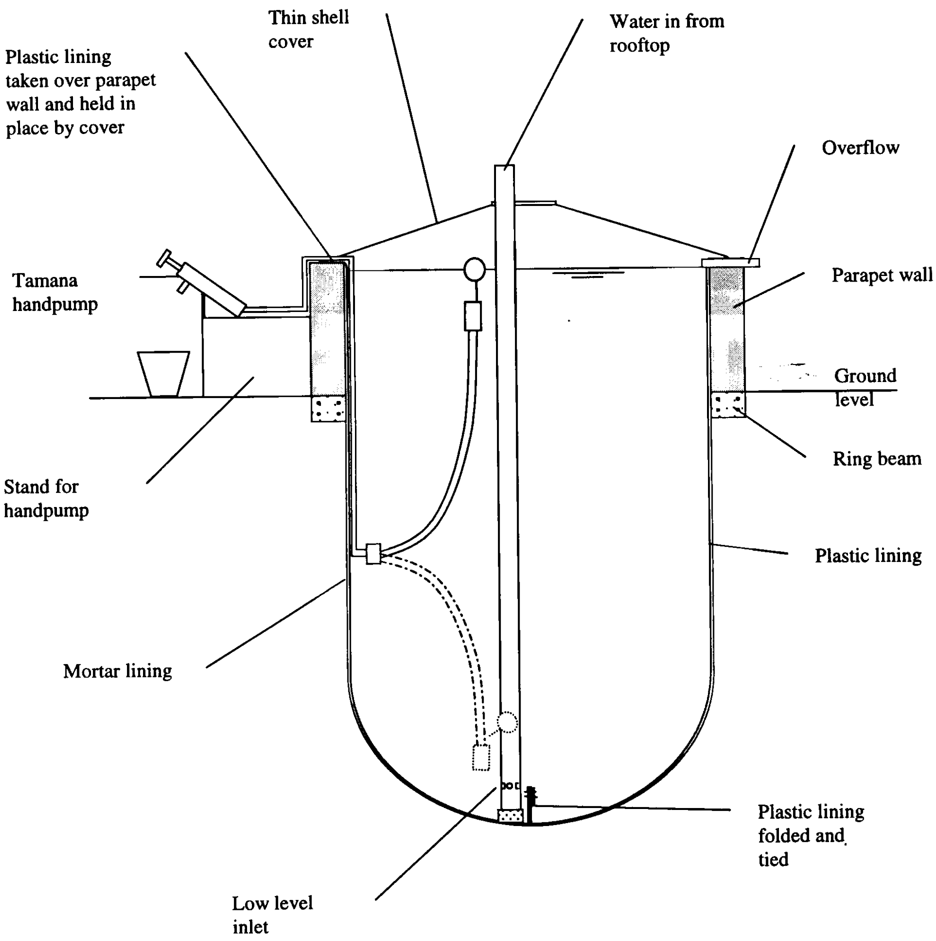

Figure 1 – Schematic drawing of the Partially Below Ground Tank

A costing exercise has been carried out to estimate the benefits of using the PBG tank against the traditional ferrocement tank (assumed to be amongst the cheapest options) and the rammed earth tank (described below). A brief summary is given Table 2.

	Ferro-cement tank	***Rammed earth tank***	***Partially below ground tank***
Material	394	179	107
Labour	81	98	90
Total cost	475	277	197

Table 2 - Comparison of costs between a ferrocement, rammed earth and PBG tank – all 11 cubic metres

Each of the PBG tanks was fitted with a thin shell ferrocement cover, described in a previous report and developed under this programme.

Figure 2 – A thin shell ferrocement cover near completion and ready for fitting to a PBG tank

Figure 3 - A completed PBG tank showing inlet pipe and handpump for extracting water

Initial leakage tests were carried out on a number of tanks using a device developed at Warwick (see Figure 4). These tests are continuing at present and will be reported later.

Figure 4 – Leakage test apparatus being tested in the field on a PBG tank

3. Construction of two rammed earth tanks

The direction of the experimental work at the University has shifted from reinforced brick tanks (reported in Milestone A3) to a more radical design of tank – the rammed earth tank. The aim is to adopt a low-cost technique commonly used for house building in areas of the world such as North Africa, North and South America and the Middle East. The technique uses a mixture of sand and clay, sometimes with a small amount of stabiliser such as cement, which is rammed, either manually or pneumatically, between wooden shutters. To use rammed earth as the structural material in a water storage vessel a waterproof liner is required. This can be provided by employing one of a number of possible options, such as cement render or a plastic sheet liner (as mentioned earlier, this latter is being developed for this application at the University). It is a technique that is relatively simple in essence and requires little in the way of imported material.

Figure 5 – A section of wall rammed between the wooden shuttering shown after removal of the shuttering

So far, the work that has been done on rammed earth tanks has been experimental, and mainly focused on adapting the basic technique (generally used for construction of straight walls in the building sector), to the construction of circular walls for water storage tanks. A 0.7m inner radius quadrant shuttering (see Figure 5) was manufactured and a number of test sections were rammed using a locally excavated soil (local to the University). The soil had to be modified somewhat to make it suitable in terms of cohesion. Wall thickness was increased gradually from a starting minimum of 60mm. We eventually opted for a 100mm wall thickness although even this is unsuitable for manufacture in the field. It is ideal, however, for testing purposes.

A tank, of radius 0.7m and depth 0.7m, has been constructed in a test pit at the University, and fitted with a plastic liner. The tank has been fitted with steel straps to give added hoop strength, but these will be removed after initial tests. The straps will be fitted with strain gauges and will be linked to computer data logging equipment. Measurements of strain, water depth, and temperature will be taken during tests. It is hoped that full-scale testing will take place within the coming month (May 2000). The aim is to seal the top of the tank with a large wooden disc, which will be pierced with a header pipe. The water pressure head will be gradually increased to a maximum of 5m while logging the variation in strain and water depth. The tank has been designed to fail at about 4m, so the test should be destructive, giving valuable information on the strength of rammed earth as a possible alternative to conventional building materials.

Figure 6 – Bird's eye view of the rammed earth tank under construction in the test pit at the University

Figure 7 – Revised shuttering arrangement shown during construction of the experimental tank

4. Construction of eight cement jars for water quality experiments.

There has been much discussion about the acceptability of water that is stored in vessels lined with cement mortar. Many users complain about the taste of the water, especially in the early days when the cement is still leaching calcium. An experiment was set up in Uganda, and carried out by the DTU's partner organisation, ARUCED. Eight small jars of 400 litres each were build and cured using different methods. The aim these experiments was to try to quantify the acceptability of water from cement lined vessels that were cured in a number of different ways. The experiment was designed to determine the efficacy of 8 different curing regimes in the search to find a regime that would minimise the taste problem. The experiment was also used to look at some technical aspects of small cement jars, as well as the user aspects of small rainwater jars and their benefits to users.

The outcome of the taste experiment has been unsatisfactory. There were a number of problems with the experiment, many of which were outside the control of the people involved, but some due to poor experimental procedure. They included:

- Key staff leaving the organisation during the experiments
- Failure of equipment that had been taken to Uganda from the UK
- Curing water being taken from an unknown source
- Poor siting of tanks which meant that sampling was difficult on a daily basis

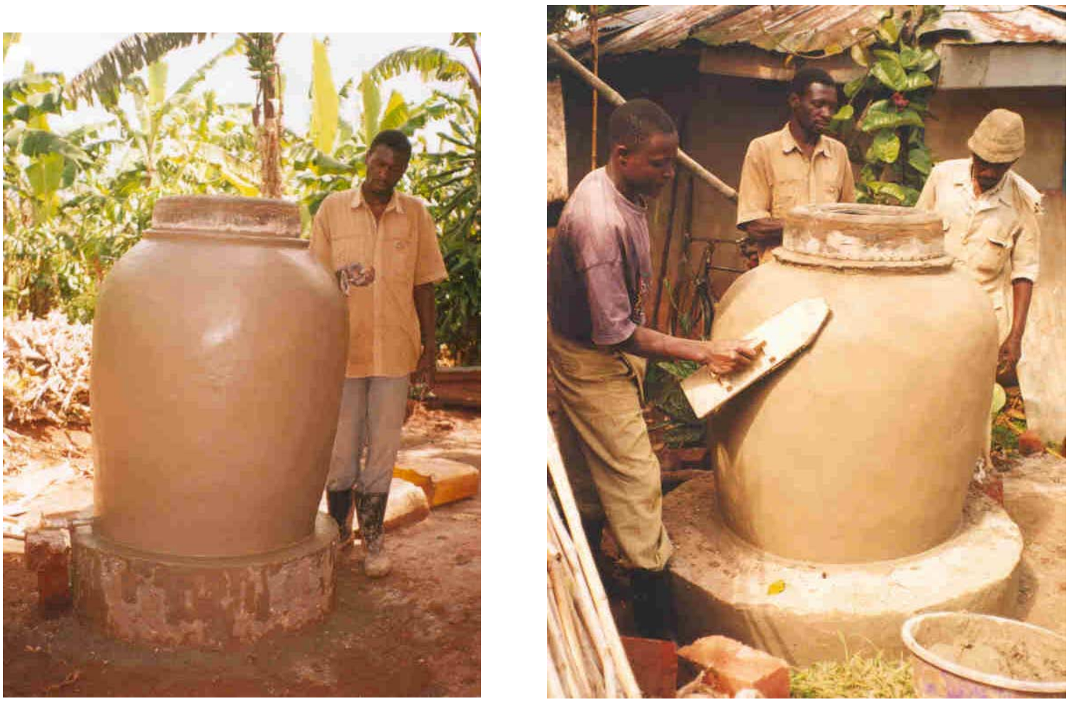

Figure 9 - 400 litre water storage jars being constructed as part of the water quality testing experiments in Uganda

A full report on the taste experiments will be presented later. The user studies are still underway. On a technical level, a number of findings have been made:

- Significant training is required to teach local masons the art of jar construction using this technique (the technique was taken directly from a classic ferrocement construction manual by S. B . Watt titled ‘Ferrocement Water Tanks’ [It Publications 1978]).
- Often the jars failed because the walls were of insufficient thickness – some method is needed of

5. Construction of two stabilised soil block tanks in Kampala, Uganda

In March 2000, two experimental cylindrical water tanks were built at Kawempwe, Kampala in collaboration with Dr Muses Musaazi, a lecturer at Makerere University. Both were built above ground of curved stabilised-soil blocks with end interlocking, 280mm x 140mm x 110mm high, made with an Approtec (Kenyan) manual block press. The soil used was a red somewhat pozzolanic local soil previously known to make strong blocks. The tanks were built on concrete plinths, lined with ‘waterproofed’ mortar (3 parts sand, 1 part cement and .02 parts ‘Leak Seal’ waterproofing compound). There was no metal reinforcing.

Figure 10 – Showing one of the stabilised soil block tanks under construction

Tank 1 is 2050mm high, has internal diameter 1300mm, wall thickness 140mm (+ 15mm render) and used 15 x 15 = 225 blocks incorporating 6% cement (100 blocks per 50kg bag). It has been filled with water and therefore has withstood a maximum head of 2.05m at the wall bottom. Volume = 2720 litres, max hoop stress = 0.19 MPa

Tank 2 is 1880mm high, has internal diameter 1000mm and the same wall thickness, but used 12 x 14 = 168 blocks with only 3% cement (180 blocks per 50 kg bag). It has been filled with water and therefore withstood a head of 1.88m at the wall bottom. Construction is continuing to extend its height up to 4m, testing its ability to resist pressure forces at both 3m and 4m head. Volume = 1476 litres, maximum hoop stress (so far) = 0.13 MPa.

Materials use included 1 packet (50kg costing $\$_{US}11$) of cement for the render, 1 packet for a conical (reinforced) lid, 1 packet for mortar between the blocks and ½ packet in the foundation. Thus only $^1/_5$ to ¼ of the cement is in the blocks themselves. Experiments to achieve curved blocks with *vertical* interlocking, if successful, will significantly reduce the quantity of mortar needed for block-laying. The lid may well be made more cheaply, as that employed was designed to carry certain testing devices.

Figure 11 – Showing the interlocking blocks used for the tanks

Report A3

Stabilised Soil Tanks for Rainwater Storage

Development Technology Unit

University of Warwick

Prepared by Mr. D.G. Rees

September 2000

This report is submitted as Milestone A5 under EU Contract ERB IC18 CT98 0276 : "Domestic Roofwater Harvesting in the Humid Tropics". That Milestone, under Task A – Technology, was originally to have been a report on the performance of underground tanks. Due to a re-sequencing of the research programme this Report A3 "Stabilised Soil Tanks for Rainwater Storage" has been substituted as the Milestone.

Contents

1. Introduction

The present cost of roofwater storage tanks is too high for many potential users. Warwick University, under an EU contract with three other partners, is investigating ways of reducing it within the specific context of the contract title above.

One cost-reduction strategy is to employ cheaper materials than hitherto. Soil ‘as dug’ is certainly cheaper than the metal, mortar or plastic commonly used for tank building. Stabilised soil *may* be cheaper provided not much stabilising additive is used. Although soil-based walling is widely used in housing, water tank walls pose special problems. They require of their materials two extra attributes, namely waterproofness and *tensile* strength that are only of minor importance in housing. Since soil is not impermeable and wet soil has no tensile strength, a process of material adaptation is required before soil can be recommended for tank construction.

Sections 2 to 4 of this paper review the various techniques of soil selection, stabilisation and construction. Section 4 addresses tank design using this material. Two promising technologies are identified, namely construction using stabilised soil blocks (SSB) and construction using stabilised or even unstabilised rammed earth (RE). Section 6 describes the theory, design, prototype manufacture and Ugandan field testing of SSB rainwater tanks. Section 7 covers the same sequence for RE tanks, but also includes the results of laboratory trials.

The paper finishes with conclusions and the identification of further work required to confirm the initial promise of SSB and RE construction. Four appendices cover cost comparisons, test data and detailed construction guidelines. (The guidelines are in the form of a free-standing Technical Release designed for use in mason training.)

Note on units: Both imperial (foot=0.3 m and inch=25 mm) and metric units are used in this report, reflecting the predominance of the former amongst builders in Equatorial countries and the greater ease of the latter for calculations.

2. Soil/earth building technology

Almost a third of the world's population lives in unbaked earth housing. The technology used varies from country to country and region to region, and sometimes even from house to house. A wide variety of earth construction technologies are known to exist and a few are listed below.

- Adobe – sun-baked earth bricks
- Wattle and daub – a wooden lattice with daubed earth in-fill
- Compressed earth blocks – using a ram (of which there are many designs)
- Direct shaping – hand shaped earth
- Cob – coarse fibre reinforced balls of earth stacked and compacted lightly
- Dug-out – dwellings excavated from earth
- Rammed earth – earth compacted between shutters with a tamper

Of these seven variants, only two appear at all suitable for constructing (above-ground) tanks, namely stabilised soil blocks and rammed earth.

Figure 2.1 Buildings (a clinic and a latrine under construction) made from stabilised soil blocks in Tanzania

All the technologies mentioned above are ancient techniques that have been passed on from generation to generation. Many have only lost favour within the last century with the advent of modern building materials, particularly brick, cement and steel. They are still used widely in many developing countries where cement is prohibitively expensive for the poorer sections of society (see the map in Figure 2.2). In some cases cement is used in small quantities to 'stabilise' the earth, giving extra strength and impermeability. Earth building technology is seeing something of a revival in the West amongst groups keen to maintain traditional techniques and those who appreciate the superior properties of earth as a building material e.g. its thermal, aesthetic, environmental and cost advantages. Improved techniques have been developed by architects and engineers over the years.

Stabilised soil block (SSB) technology that has received a great deal of attention over the last few decades and is now seen as a mature technology with a good future in the building industry world-wide. It is a technology particularly suited to drier climates, although it is practised in many humid areas. Suitable earth is mixed with a small percentage (typically 5 – 10%) of cement and is compacted using a manual or hydraulically assisted ram or press (Figure 2.3). The compaction process can be static (slow squeezing) or dynamic (impactive), but the static process is more common.

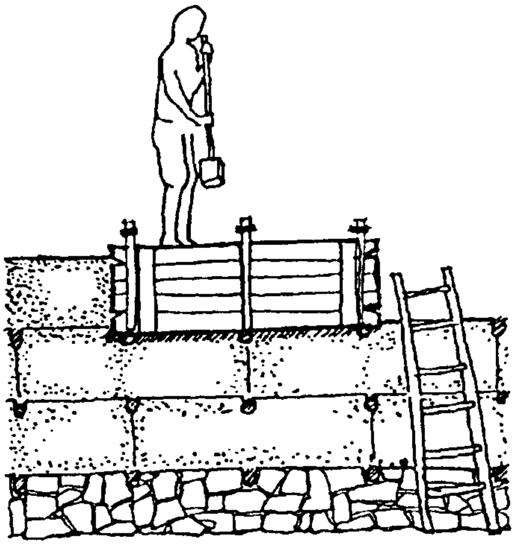
Static compaction pressure ranges from 2 MPa in manual lever machines up to 10MPa or more in machines with hydraulic assistance.

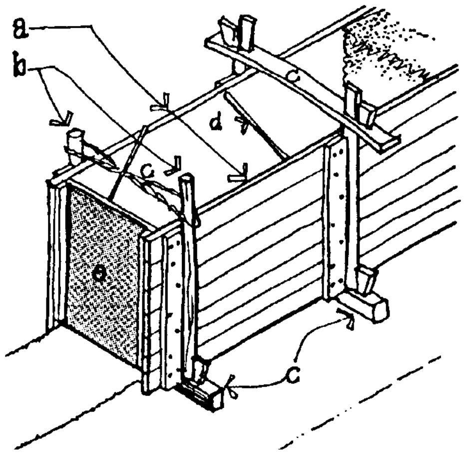
Figure 2.2 Map of the world showing areas where earth construction technologies are, or have been, widely used

Figure 2.3 A CinvaRam press being used to produce stabilised soil blocks in Africa

Rammed earth (RE) is a technique whereby earth is rammed, using a rammer or tamp, between two shutters. The shuttering is removed to reveal the wall, usually constructed in sections of a few feet long by a foot or two deep. The shuttering is then moved along and the next section of wall is rammed to form a continuous wall. The shuttering is then raised and placed on top of the first 'lift' to construct the subsequent 'lifts' (see Figure 2.4). Unlike SSB production, the RE wall is built in situ. Wall thickness for a typical two-storey house is in the region of 12 to 24 inches. Curved walls of rammed earth are not common, but are found occasionally where the technique is more developed. The curved sections are usually for decorative purposes.

Typically rammed earth has been used for the construction of housing. The technique has been used to successfully construct buildings of several stories that have lasted for centuries.





a = shuttering
b = retaining stakes

Figure 2.4 (i) rammed earth as practised in Morocco and (ii) basic elements of formwork or shuttering (from Norton[1997])

3. Soils - identification, classification and testing (field and laboratory methods)

3.1. Characteristics of soils

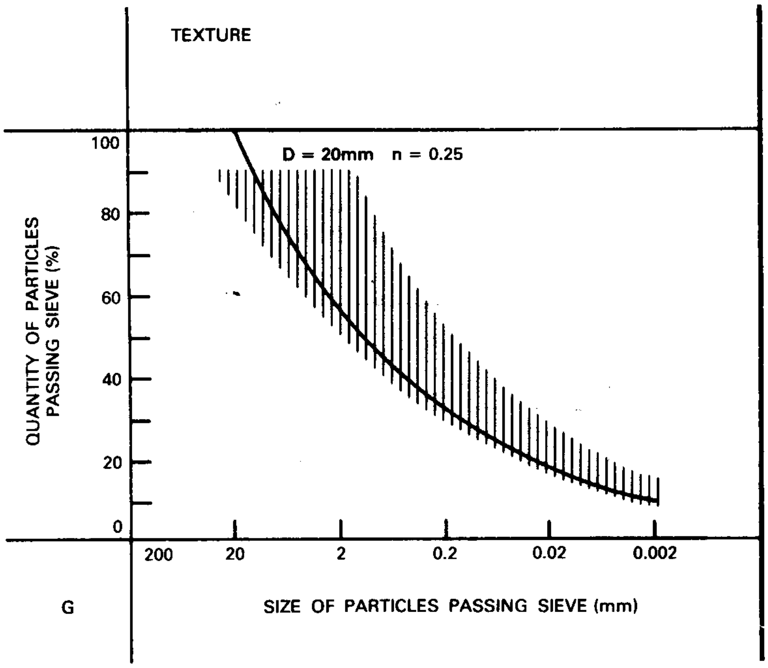
Not all soils are suitable for construction and methods have been developed for identifying those that are. For rammed earth (RE) construction a soil should be a mix of fine gravel, sand and silt with a small clay content. There should be no organic material present. Soil for stabilised soil block (SSB) construction needs to be of a higher fines content. However the actual soil used for either technique varies widely. Norton [1997] suggests the figures shown in Table 1 as suitable for rammed earth construction. The clay content should be sufficient to allow the soil to bind without causing excessive shrinkage. Soil varies widely in quality and content and so experimentation is required to find a suitable soil.

Table 3.1 – showing suitable values for soil particle distribution for rammed earth structures (Norton[1997])

Sand / fine gravel	45 – 75%
Fine sand / silt	15 – 30%
Clay	10 – 25%

Soil is generally characterised by 4 fundamental properties: texture, plasticity, compactibility and cohesion. These properties are described briefly below.

Determining the soil texture involves passing the material through a series of standard sieves and observing the fraction retained by each sieve, thus determining the grain size distribution. Further analysis is usually required to determine the fines content i.e. the make-up of the silt and clay passing through the finest practical (0.063 mm) sieve. Graph 3.1 shows the acceptable range for soil that is to be used for rammed earth structures. The ASTM-AFNOR standards and the decimal system standard for grain size distribution can be found on page 32 of Houben [1989].



Graph 3.1 Showing the acceptable particle distribution for a soil used for Rammed Earth construction (Houben [1989])

The Plasticity Index (PI) is an indicator of the plasticity of the soil. The PI is a function of the Liquid Limit (LL) and the Plastic Limit (PL) of the soil (together known as the Atterburg limits) and is a measure of the likelihood of the material to deform. LL is the % of water in a soil when it is changing from being ‘plastic’ to being ‘liquid’. PL is the water % at the boundary between solid and plastic behaviour. Numerically PI = LL – PL. There are agreed definitions of these transition points. Figure 3.1 shows on an Atterburg limits chart the type of stabiliser to be used with any particular soil.

The **compactability** of a soil defines its ability to be compacted to a maximum for a given compaction energy and degree of humidity {Houben 1994}. The compactability of a soil is measured by the Proctor compaction test (see Section 3.3).

Cohesion is a measure of the ability of a rammed soil to remain together when under tensile load. Cohesion is a function of the moisture content and the clay content (or other cementitious material) of the soil. Cohesion is higher when the moisture content is less than the PL. Cohesion increases with clay content, but so unfortunately does shrinkage.

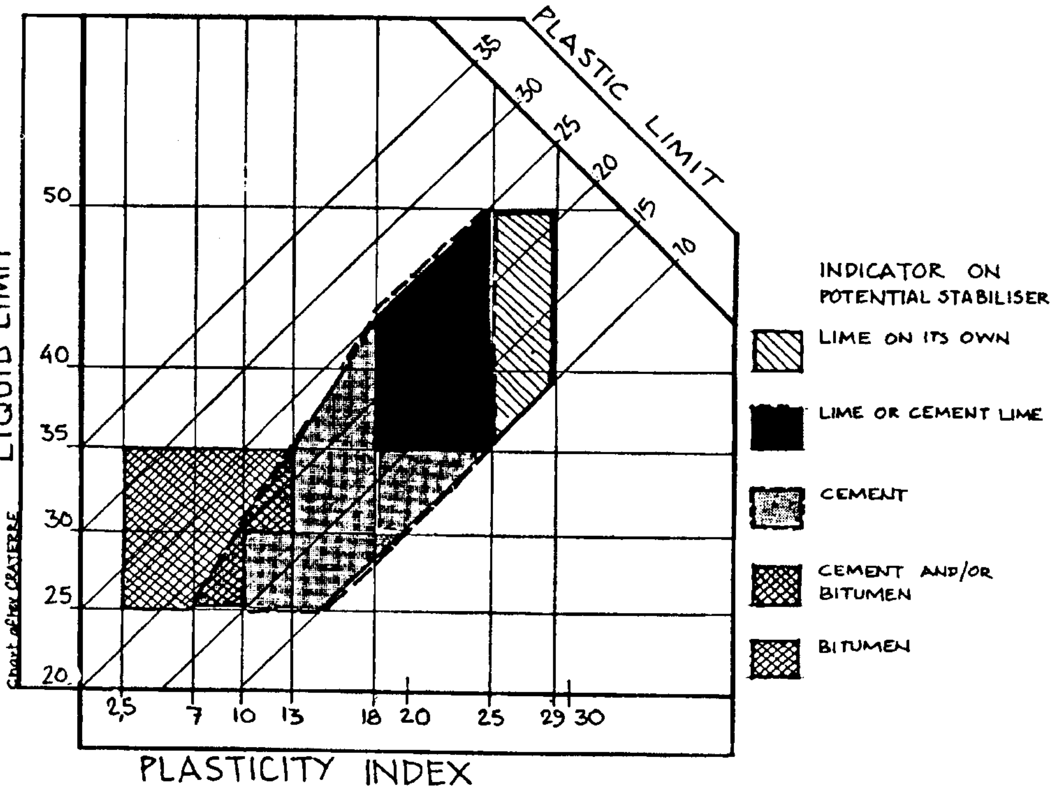


Figure 3.1 – The Atterburg limits chart (Norton[1997])

3.2. Soil suitable for rammed earth structures

A sieve analysis should indicate the ranges shown in Table 3.1 if a soil is to be used for earth construction.

Soil for use with rammed earth structures should be humid, i.e. not too dry and not too plastic, say in the region of 4% to 15% moisture content. The optimum moisture content (OMC) is defined later in this document and a method shown for determination of OMC.

3.3. Soil identification and classification

The suitability of a soil for building with is often established via three sorts of test – field tests, laboratory tests and construction trials.

Field tests

These are cheapest and come first. There are numerous initial sensory observations that can be made to help classify the soil in the field. These include:

- visual and tactile observation to analyse particle distribution
- sedimentation test to give more detailed particle distribution
- there are a number of tests to gauge (very roughly) clay content, including a simple test whereby a roll of clay is pushed over the edge of a table until it breaks - the length of the broken part gives an indication of the clay content
- drop test to determine optimum water content
- the smell of soil can sometimes give an indication of the presence of organic matter

More detail on these tests can be found in the relevant literature, especially Keable[1996], (Rammed Earth Structures – A Code of Practice).

Laboratory tests.
British Standard BS 1377 and corresponding standards in other countries cover the tests suitable for soils used in construction work. The tests are used to determine the main characteristics and suitability of the soil in question, as well as to give an initial idea of the performance of the material. The main tests that are used are described very briefly below:

A *'classification test'* is performed to determine the particle distribution of the soil. The test is carried out by passing the soil through a set of standard sieves (Figure 3.2). Material passing through the smallest sieve in the set is deemed to be a mix of clay and silt: these two components cannot be separated by further sieving.

Figure 3.2 – Wet sieving is the standard soil classification method

To determine the *'clay to silt ratio'*, the fraction of the soil passing through the last (0.063 mm) sieve is analysed using a hydrometer. The specific gravity of the liquid with its suspended particles, indicates its clay content. An alternative simpler test takes advantage of their different sedimentation rates to distinguish between clay and silt.

The compaction of a soil is dependent upon its moisture content. A *'compaction test'* is used to determine the maximum density of the material and the moisture content at which it occurs – called the optimum moisture content OMC. At maximum density the compressive strength of the soil will be greatest. To find the OMC a test is carried out using a simple compaction apparatus (see Proctor compaction test in Box 3.1) to compact a number of samples with different moisture contents. The samples are weighed and measured. The dry weight is then found after drying the compacted sample in an oven and the OMC is that moisture content which has produced the sample of greatest density.

Box 3.1 BS Ordinary Test (or the Proctor test) for compaction

This test uses a 2.5kg metal rammer with a 50mm diameter face that falls into a cylindrical mould of 105mm diameter. The drop height is kept at a constant 300mm to ensure consistent energy transfer between blows. The blows follow a pattern over the face of the sample to ensure repeatability and consistent compaction of the entire sample. Each sample made up of three layers of soil that has passed through a 20mm sieve and each layer is given 27 blows of the rammer. After compaction the sample is trimmed off to a set height that gives a constant volume of 1000cm³. This is then weighed and the density can be calculated.

In the previous section we touched briefly on the consequences of shrinkage. The *'shrinkage box test'* measures this property and is simple to carry out. It involves measuring the shrinkage of a sample that is allowed to dry naturally over a period of 14 days. In practice, if the walls of a tank are constrained, say at the base, then cracking will take place if shrinkage is significant. Conversely, where a tank's cylindrical wall is free to shrink without constraint no cracking will take place. If shrinkage is found to be too great, due to an excess of clay, the soil will have to be either modified or rejected.

'Liquid and plastic limit tests' can be carried out either in the field, although it is preferably to perform them in a laboratory. Some equipment is needed. See section 3.1 for more detail.
A *'normal moisture content test'* is used to determine the normal moisture content of the material to be used. An oven and accurate scales is required.
To measure the rate at which water passes through a material requires a *'permeability test'*. Sophisticated equipment is required.
For many applications of rammed earth walls (i.e. housing and larger buildings), it is the compressive strength that should be maximised, so *'compressive strength tests'* are commonly applied to the material. *Wet* compressive strength, which is invariably less than *dry* compressive strength, is most commonly measured. Unfortunately little consideration is given to the *tensile* strength of the material which concerns us more in water tank design. Confusingly we have four possible strength measures: *dry compressive*, *wet compressive*, *dry tensile* and *wet tensile*.

Although Houben and Guillaud [1989] indicate reasonably good values for dry tensile strength of rammed earth (0.5 –1 MPa), little work has been directed at further increasing its value. For the application being considered here, the tensile strength of the material is of paramount importance. The OMC considered earlier is the moisture content that will optimise dry density (we could call this the DOMC , after Montgomery [1999]), and hence compressive strength. It is unclear to the author if this DOMC can be used to optimise dry tensile strength. Further investigation is required to find the water content to maximise dry tensile strength, which we could call the Tensile OMC (or TOMC). We then need to consider the wet tensile strength of the materials as this has great implications on the design of tanks to hold water.

Performance tests.
Even where we have applied field and laboratory tests to the raw material (soil) or to specimens prepared from it, it is still desirable to test samples of the walling during construction. In this way we can pick up not only soil variations but also imperfections in the construction process (such a deviations from intended proportions or procedures). These performance tests are usually applied either to samples drawn from batches in the construction process (e.g. every 50th block made) or to specimens sawn out of larger components.

Some of the tests that may be applied are:

- Wet and dry compressive strength
- Wet and dry tensile strength (modulus of rupture)
- Wet and dry bending strength
- Permeability
- Adhesion of render to walls

More details is available in the literature – see Houben

3.4. Calculating the quantity of soil required for a tank

The quantity of soil required for tank construction is calculated below. The quantity of soil required for tank construction is based on tank size, wall thickness and the density of the compacted material.

Weight of soil required $W = \pi (r_o^2 - r_i^2) H \times \rho_c$ (equation 2.1)

where
r_o = external radius of tank
r_I = internal radius of tank
H = height of tank
ρ_c = density of compacted material

For laboratory and development tests approximately 150 kg of soil is required.

4. Stabilisation of soils – methods for improving soil characteristics

Frequently one finds that the most readily available soil is not suitable for construction purposes. In such cases the main options are to

- bring in a suitable soil from elsewhere
- blend together different local soils
- add some sort of stabiliser.

Which option is chosen will usually depend upon their relative costs. However if wet strength is required, no natural soil is adequate and stabilisation (e.g. addition of cement) is essential. The physical characteristics of soil can be improved in a number of ways. Usually, the main reason to improve soil is either to obtain a suitable physical grading for a poor soil or to improve some other physical characteristic such as the strength, stability or water resistance of the soil.

Soil suitable for soil construction should be well graded with a suitable content of fines and larger particles (see Table 3.1). For raw soil, this is often not the case and soils have to be modified such that their grading is suitable for use. This will involve adding a material that is lacking in the raw material, removing unwanted particles by sieving or mixing a number of soils to obtain a suitable blend.

4.1. Additives and composite materials

A large number of additives and composites are available for adding to rammed earth. Their purpose is improve the properties of the material in one of a number of ways: *Chemical stabilisers* are added to the soil to bind or alter the grain distribution characteristics of the soil and hence improve its cohesion and stability. Common stabilisers include cement and lime, which are added in small quantities, say up to 10%, and can improve material strength and stability several fold. There is a wide range of synthetic additives available from specialist suppliers in some countries (Texas, USA is a good example, where earth building is a commonly practised building technique). They are not, however, generally available in developing countries and so we will not consider them in this work.

Waterproofing agents are available that reduce the permeability of soil structures. A commonly used water repellent is bitumen, which is mixed with the soil in an emulsion form. The emulsion is made using a solvent such as gasoline or kerosene diluted sufficiently to be mixed with the soil (Norton[1997]). Many synthetic waterproofing additives are available. Most earth walls, bearing in mind that such walls are used for buildings, are given a waterproof render, or a sacrificial coating. Renders and linings will be discussed later in the document.

Fibres can be added to increase the tensile strength of the material and help prevent cracking during the curing process. Straw is a common fibre additive and it also helps to reduce the weight of the material. Unfortunately it is only durable in permanently dry conditions.

Reinforcement is widely used to create a composite in which the matrix (e.g. soil) provides some properties and the reinforcement (e.g. steel wire or polypropylene or hessian rope) provides much of the tensile strength.

Box 4.1 Discussion of the effects of soil shrinkage on tank design, and design implications.

Upon drying a rammed earth wall will shrink as the moisture is drawn out of the structure and the clay, which is expansive (different clays having differing degrees of expansivity), shrinks. If the structure is constrained in any way, say for example, at the base of the tank, then this could result in cracking. For an unreinforced tank such cracking would seriously reduce tensile strength and could cause sudden and catastrophic failure of the structure. This needs to be considered when determining the OMC (or TOMC) and the author suggests that this area of rammed earth tank design needs further work at present. It is for this reason that some form of reinforcing could be used to give additional tensile (hoop) strength to the structure. Possible forms of reinforcement include:

- Externally applied steel packaging strap (as demonstrated by the author {Rees, 1999} on single skin brick tanks)
- Hoop wire rammed into the structure – ideally barbed wire would be used as it is cheap, strong and the barbs offer resistance to 'pull-through'.
- Fibre such as straw or short lengths of polypropylene rope can offer localised strengthening

Box 4.2 Stabilisation of soils (Montgomery[1999])

Stabilisation techniques can be broken down into three categories, Houben (1994): Mechanical, Physical and Chemical. Mechanical stabilisation compacts the soil, changing its density, mechanical strength, compressibility, permeability and porosity. Physical stabilisation changes the properties of the soil by acting on its texture, this can be done by: controlling the mixture of different grain fractions, heat treatment, drying or freezing and electrical treatment. Chemical stabilisation changes the properties of the soil by adding other materials or chemicals. This happens either by a physico-chemical reaction between the grains and the materials or added product, or by creating a matrix which binds or coats the grains.

Stabilisation fulfils a number of objectives that are necessary to achieve a lasting structure from locally available soil. Some of these are: better mechanical characteristics (leading to better wet and dry compressive strength), better cohesion between particles (reducing porosity which reduces changes in volume due to moisture fluctuations), and improved resistance to wind and rain erosion. Using one or more of the stabilisation techniques listed above, many of these objectives may be fulfilled. Optimum methods depend greatly on the type of soil, and a careful study of the local soil is necessary to suggest an effective method of stabilisation. In the case of mechanical stabilisation, the soil is compacted to a greater density, and there will always be an improvement in its mechanical properties with virtually any soil type. This is not true however with other forms of stabilisation, where different soil mixtures can lead to better or worse properties using the same technique. In the majority of cases mechanical stabilisation is used in conjunction with a common chemical stabiliser, such as cement. If the stabiliser and the soil are mixed together thoroughly and there is a suitable clay fraction in the soil, the compaction process reduces the quantity of chemical stabiliser required in the block. The increased density also increases the effectiveness of the cement matrix, given that the cement is left in a moist environment (the hydration period to let the cement cure) for at least 7-14 days. For details on selection of soils for cement stabilisation see Gooding (1993 - B).More details on the process of cement stabilisation can be found in Houben & Guillaud (1994) and Spence (1983).

5. Tank design using stabilised soils

It is certainly inconvenient, and it can be dangerous, for a water tank to fail (because at some point in it the local stresses exceed that which the tank material can bear). We therefore need to be able to calculate the size and location of the peak stresses. Unlike other areas of structural design, stretching does not need to worry us much unless it is severe enough to cause the cracking of a superficial waterproof coat.

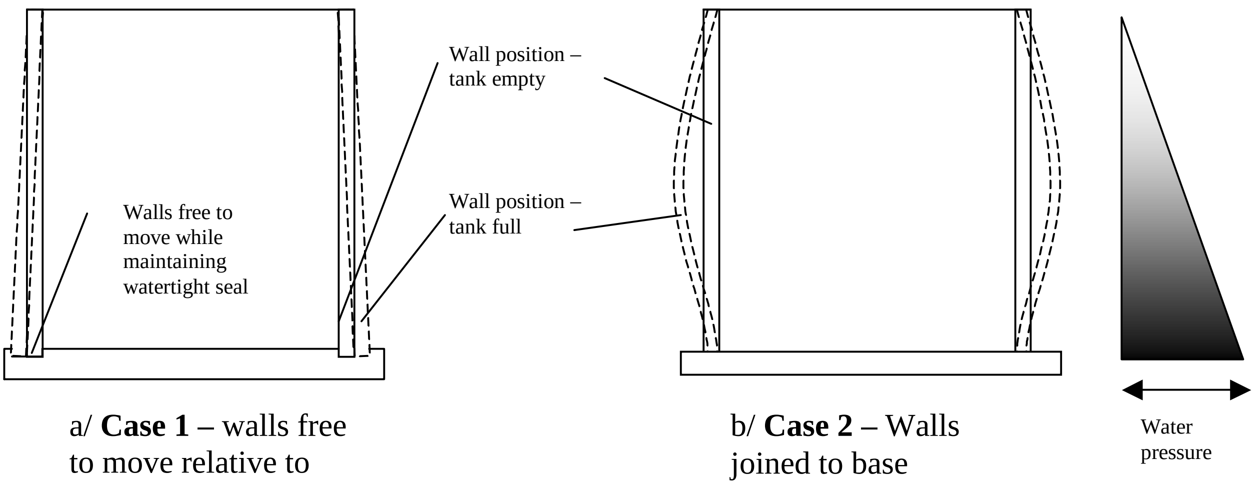
Our general design objective is to produce a safe watertight tank. This we can do either by using a single walling material that is both strong (in tension) and waterproof or by combining a strong material with a waterproof one. A wall of unstabilised soil is not waterproof and (when wet) doesn't have any tensile strength either. We therefore have either to stabilise it or to keep it dry by applying a waterproof skin to its inside face. In the latter case we must allow for the possibility that the skin will be punctured during the life of the tank – including some sort of reinforcing that may not save the tank but will prevent it bursting suddenly and dangerously.

5.1. The theory of stresses in cylindrical tanks

Tall cylindrical tank walls experience a horizontal tensile 'hoop stress' which is proportional to the diameter *D* of the tank, the local pressure *p* on the walls of the tank and the thickness of the tank wall *t* (Equation 5.1). As *p* increases towards the bottom of the walls, so too does the hoop stress.

$$\sigma_t = \frac{pD}{2t} \qquad \text{(Equation 5.1)}$$

However the stress in a cylindrical tank wall near to its base is also be affected by the type of joint between the tank base and tank wall. There are two obvious cases to consider as illustrated in Figure 5.1 below. In Case 1, the tank wall is made so that is free to move slightly at its base and yet still maintain a watertight seal. The water pressure against the wall will cause the diameter of the tank to increase until the hoop stress is wholly taken up by tensile stretching of the wall. (In the figure the increase in diameter is exaggerated here for clarity: in practice it might be less than 1 mm). The maximum hoop stress will be experienced at the base of the wall and will decrease linearly with height to zero at the top of the wall.



a/ **Case 1** – walls free to move relative to base

b/ **Case 2** – Walls joined to base

Figure 5.1 – The two cases for wall-to-base union in cylindrical tanks

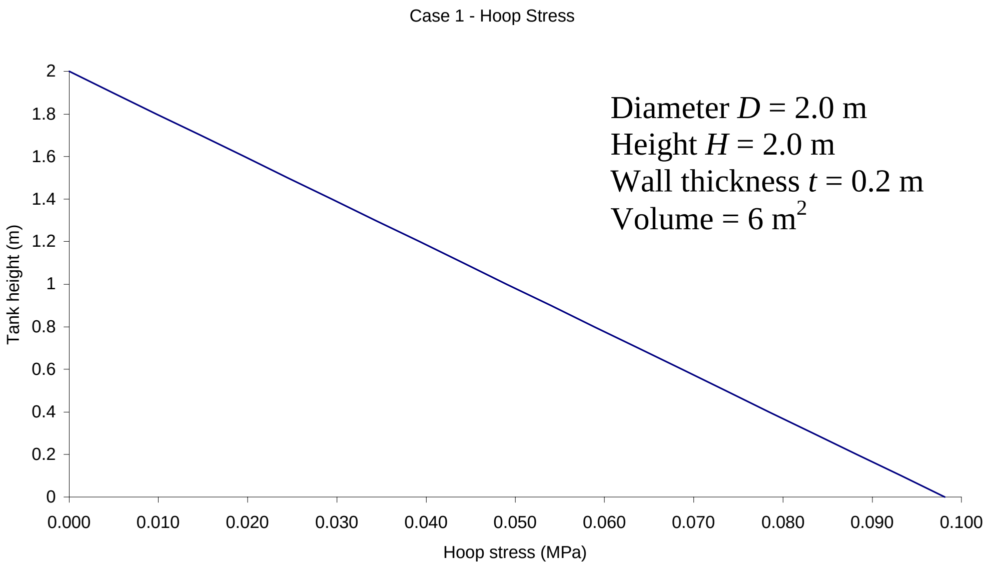


Figure 5.2 – Hoop stress in the tank wall for Case 1 (i.e. wall and base separate)

In Case 2, where the wall and base are monolithic i.e. the wall and base are continuous (and the base is assumed to be rigid), the situation becomes more complex. Bending and shear stresses are set up in the wall as a result of the restraining effect of the base slab. There now exists a combination of bending, shear and hoop stresses. The lower part of the wall is now constrained and is not free to move as in Case 1. The result is that a bending moment is generated in the wall that is a maximum at the joint of the wall and the base. This bending moment sets up vertical tensile stresses on the inner face of the wall of the tank that can be more than twice the magnitude of the horizontal hoop forces. Shear forces are also generated although these can generally be neglected as they are small in comparison the other induced forces. This is illustrated graphically in Figure 5.2

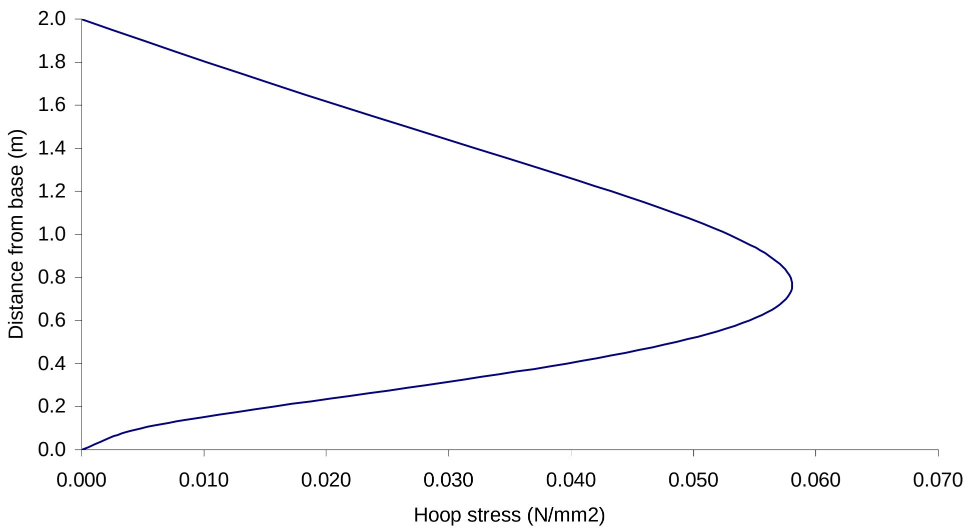

Figure 5.3 – Hoop stress for Case 2 (i.e. wall and base monolithic)
(*D*, *H* and *t* as in Figure 5.2)

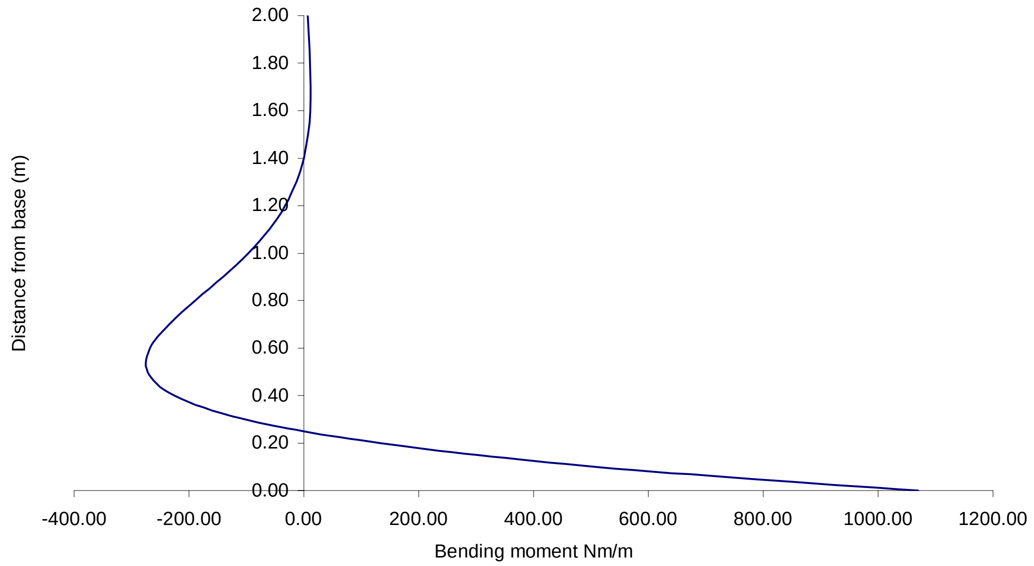

Figure 5.4 – Bending moment induced in tank wall for Case 2 (*D*, *H* and *t* as in Figure 5.2)

In Figure 5.2 we see that for Case 1 the hoop stress increases linearly from zero at the top of the tank wall to a maximum of 0.098 MPa at the base/ wall joint

In Figure 5.3 we see that for that Case 2 the hoop stress is a maximum of 0.058 MPa – less than in Case 1 – and occurs at 0.8m from the base (i.e. 0.4*H*). The hoop stress then drops off to zero at the base where the strain is zero. In Figure 5.4 we see the effect of the rigid constraint on the bending moment that is now induced in the wall. The maximum vertical tensile stress in the bottom of the inner face of the tank wall in Case 2 is 0.16 MPa, considerably more than the maximum hoop stress in either Case 1 or Case 2. So the tank is now vulnerable to cracking at the wall-base joint.

5.2. Conclusions from Section 5.1 and implied design considerations when using soil as a building material

Note:
Case 1 - wall is free to move at base (flexible joint)
Case 2 - wall and base are continuous (monolithic joint)
(assuming rigid base in both cases)

Table 5.1 Summary of conclusions from Section 5.1 and resulting design implications

Conclusions from Section 5.1	Design Implication
In Case 2 a bending moment is set up in the wall due to the constraint at the base of the tank. This is a maximum at the joint of the wall and the base and causes vertical stresses whose size is more than twice the maximum hoop stress. No bending moment is induced in Case 1.	Sliding base / wall joint are preferable to avoid complex stress regimes in the tank walls (see Box 4.1 below). These are difficult to achieve in practice.

The vertical stress cause by bending is very sensitive to changes in wall thickness as it is proportional to $1/t^{2}$; thus halving wall thickness will multiply stress by four. The hoop stress is only proportional to $1/t$.

Where a monolithic base / wall joint is used it is wise to use a good safety factor when considering wall thickness or to thicken the wall near the joint.

The maximum hoop stress for Case 2 is always less than that of Case 1 (for an identical tank profile) and is experienced at some point above the joint of the base and wall, typically 0.3H to 0.6H, but lower for very thin walled tanks.

Do not design the wall thickness to decrease with height in the case of monolithic tanks.

For a tank of identical profile, the maximum bending moment set up in Case 2 will be of greater magnitude than the hoop stress set up in Case 1 or Case 2 (see Figure 5.5).

A greater wall thickness is required for Case 2 than for Case 1. This implies more material usage and hence higher cost. On this point, it is worth bearing in mind that many materials will have a greater tensile strength than bending strength and so the problem will be compounded.

Deflection is greater for Case 1, as there is no constraint at the base to restrict movement of the wall.

Strengthening at the base can help reduce deflection for Case 1. This is important where renders are used to help prevent cracking due to excessive strain.

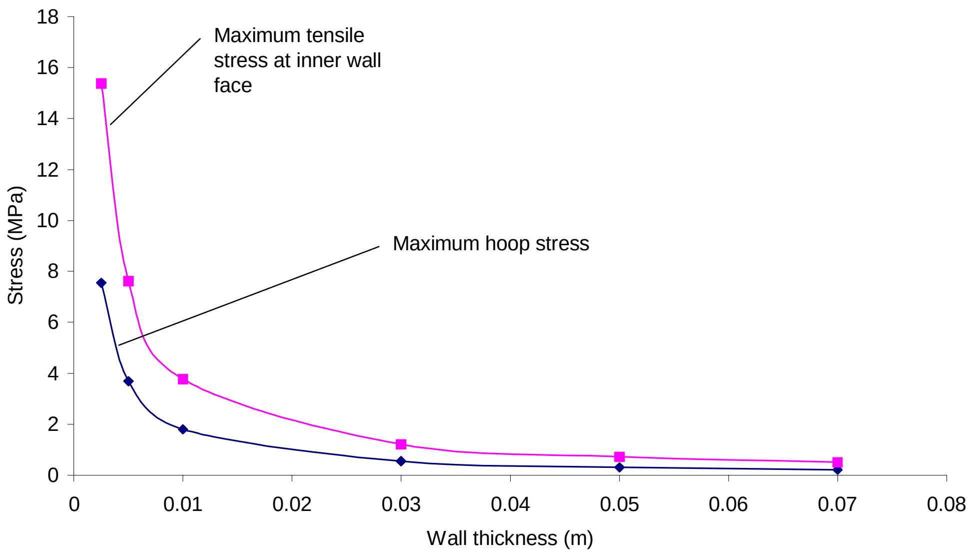

Figure 5.5 – The graph shows the relationship between hoop stress, maximum tensile stress due to bending and wall thickness. (*H* and *D* as for Figure 5.2) Note the significantly higher values for bending-induced tensile stress.

Box 5.1 Sliding / flexible base wall joints

Sliding of flexible joints between the wall and the base of a tank are common for large concrete storage. The reduction in stresses by using such a joint is well documented and the subsequent savings in materials well recognised. Such joints, in concrete structures, are usually effected using a bitumen layer between the base and the wall. The degree of movement in the wall is very small and the flexibility of the bitumen allows sufficient movement while maintaining impermeability.
The technique developed at the University of Warwick for work with soil tanks has been to lay two layers of polythene sheet beneath the wall of the tank. The sheets can have a smear of grease to help them slide across on another. The effect is to produce a 'sliding' joint that allows the wall and the base to act independently which, as pointed out in earlier, reduces stresses, simplifies tank design and leads to lower costs.

5.3. Spreadsheet design for rammed earth tanks

A spreadsheet has been developed at Warwick (Turner 1999) for aiding the design of cylindrical tanks. The spreadsheet allows the main variables to be entered and gives output in terms of design parameters. The main variables are tank diameter, tank height, material properties (or relative volumes in the case of composites), required safety factor and wall thickness. The outputs are given for both a tank with monolithic base and wall, and for a tank with separate base and wall. The outputs include maximum hoop stress, maximum bending moment, maximum deflection, maximum tensile stress on inside face of tank wall, maximum shear stress, tank volume and overall tank diameter. The spreadsheet allows the designer to play with the parameters until a satisfactory design solution is reached. Table 5.2 shows the general layout of the spreadsheet. The spreadsheet was used to design both the laboratory experimental tank and the field experimental tanks described and discussed in Section 7.

Table 5.2 Showing the input and output cells of the spreadsheet developed at Warwick to aid design of cylindrical tanks.

Data input section - click on boxes for data input instructions			
Parameter		**Value**	**Unit**
E (matrix)	e.g. soil	700	MPa
E (fibre)	e.g. steel	2.1E+5	MPa
po(matrix)		0.5	Poisson's ratio
po(fibre)		0.1	Poisson's ratio
thickness		0.20	m
tank rad		1	m
height		2	m
Vol. Fraction of fibre		0	0 – 1
po(total)		0.5	
E(total)		700	MPa
Volume		6.283	cubic metres

Output cells –for a Rammed Earth tank The output here is for a tank monolithic with base		
Tensile strength (of soil)	0.50	MPa
Safety factor required	4.00	
So design stress is	0.1250	MPa
Maximum hoop stress generated	0.0579	MPa
Position of max hoop force		m from base
Maximum bending moment	1069	Nm (always at base)
Maximum deflection	0.0033	mm
Position of maximum deflection		m from base
Maximum tensile stress on inner face of wall	0.16037	MPa (always at base)
Maximum shear stress	0.00021	MPa
Overall tank diameter	2.4	m

Output here is for tank wall unconstrained at base		
Tensile strength	0.50	MPa
Safety factor required	4.00	
Design stress	0.1250	MPa
Maximum hoop stress generated	0.098	MPa
Maximum deflection	0.1401	mm
No bending moment generated		

5.4. Construction principles when building with earth

There are several basic rules to follow when building with earth:

- The wall should be well protected from damp or wetness. Wet earth has less strength than dry and unstabilised earth will quickly become a mess of mud should it become saturated.
- Good foundations are used to protect the base of the wall from rising damp and often the first foot or two of wall above the foundation will be from stone or other impermeable material.
- Where a roof is fitted, the wall can be protected by using large overhanging eaves to prevent rain from hitting the wall directly.
- Renders or other coatings help to protect the wall from rain also. Practitioners colloquially use the phrase “good hat and boots” to describe the protection required – an overcoat doesn’t go amiss either!

The benefits of using earth as the construction material are numerous:

- low material cost (see cost comparison with ferrocement in Section 8)
- suitable material readily accessible locally in many parts of the world
- a well-known and widely-used technology in many parts of the world
- a simple technology that is easily taught to semi-skilled people

The drawbacks of using earth for tank construction are:

- not suitable for below-ground tanks or cisterns
- in the case of leaks serious problems can develop, especially if unstabilised earth is used
- high labour input – a problem where labour costs are higher

6. Stabilised soil block (SSB) tanks

6.1. Introduction

The work carried out on Stabilised Soil Block (SSB) tanks has been done in conjunction with Dr Moses Musaazi, a lecturer at Makerere University, Kampala and private entrepreneur working in the construction industry. Dr Musaazi also directs the Gatsby Trust in Uganda whose aim is to promote small-scale private enterprise through training. He has been working with SSB's for some time, both for low-cost housing and also for the construction of small too medium sized domestic rainwater storage tanks. Warwick University approached Mr Musaazi with the aim of working together to test the strength of the SSB tanks through practical experimentation.

A full report of the work that has been completed by Dr Musaazi is found in Appendix II.

6.2. The basic principles of SSB manufacture and construction

Stabilised, compacted, soil block technology is mature and widely used throughout the world. It involves compacting a suitable soil, which is often mixed with a small percentage (typically 5 – 10%) of cement, using a manual or hydraulically assisted ram or press. The compaction process can be static or dynamic, but the static process is most common. Static compaction pressure ranges from 2MPa (manual) up to 10MPa or more (hydraulic). This compaction reduces the voids in the material and hence it susceptibility to attack from water. Figure 2.3 shows a CinvaRam press being used on a building programme in Tanzania. Figure 6.1 shows some common press types.

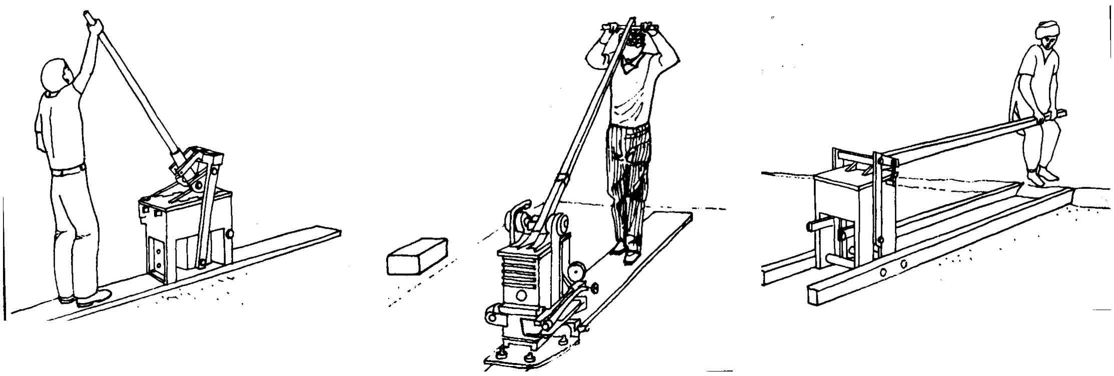

Figure 6.1 – A small selection of the many press types available for purchase (Houben[1994])

Special moulds can be manufactured to produce blocks required for special purposes. In the case of the cylindrical tanks manufactured in Uganda, curved blocks were produced using the mould shown in Figure 6.2.

(**Figure 6.2** – Mould for producing curved blocks)

(**Figure 6.3** – Curved blocks after curing)

For information about tank linings and water extraction for SSB tanks see Section 7.2. These principles are the same for RE and SSB tanks.

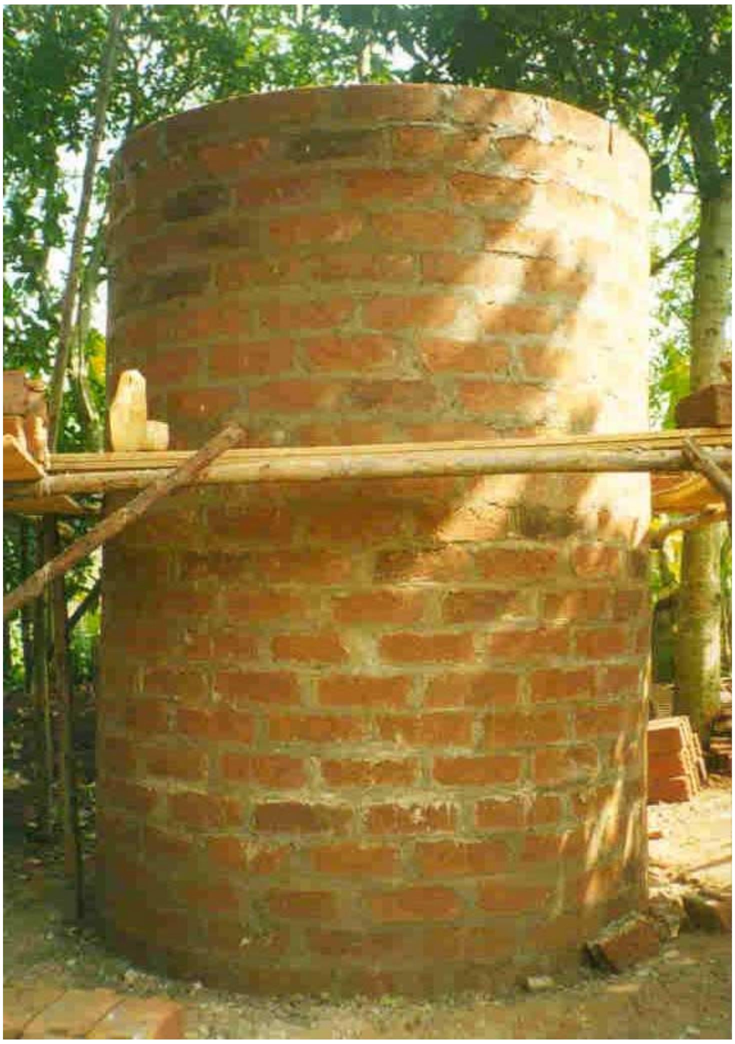
6.3. Field testing of SSB tanks in Uganda

Tests on SSB tanks started in March 2000 in Kampala. A small cylindrical tank (1.0m internal diameter, 2.1m height) was built and an attempt made to fit sealed covers to it. The tank was to have been pressurised by means of a header pipe fitted to the cover, however this proved impractical so it was simply subjected to the pressure (21 kPa) derived from its own height. The materials used are specified in the report in Appendix II. The soil used was stabilised with 5.25% OPC.

The experimental method was changed for subsequent tests and two tanks were built of the same curved end-interlocked SSBs. No reinforcing was included, but the tanks were rendered inside with a waterproof mortar. Details are:

Tank diameter (internal) in m	Tank Height in m	Code	% cement
1.67	3.8	SST1	5.25
1.00	5.2	SST2	3.27

SST1 was tested in July 2000 and failed dramatically when only part full. SST2 is still under test.



(**Figure 6.4** – A SSB tank of 1.67m diameter)

SST1, according to theory and using the *dry* tensile strength for the blocks from the literature, should have been able to withstand about 5 times the stress induced by the water pressure at which it burst (at 2.5m water pressure). There were, however, some irregularities:

- Some of the blocks analysed after the experiment seemed to have no wet strength and disintegrated completely in water.
- The tank was filled from a large water tanker. The waterproofing agent that was used in the cement render lining takes time to act and so water would have been passing through the tank lining and into the soil matrix. This would have reduced the strength to somewhere below the dry strength quoted in the literature.

SST2 by contrast was filled slowly by rainwater from a gutter and has sustained a pressure, 53 kPa corresponding to its full height, for many weeks despite being built with considerably less cement in the blocks than SST1. The peak stress in SST2 is 50% greater than that at which SST1 failed.

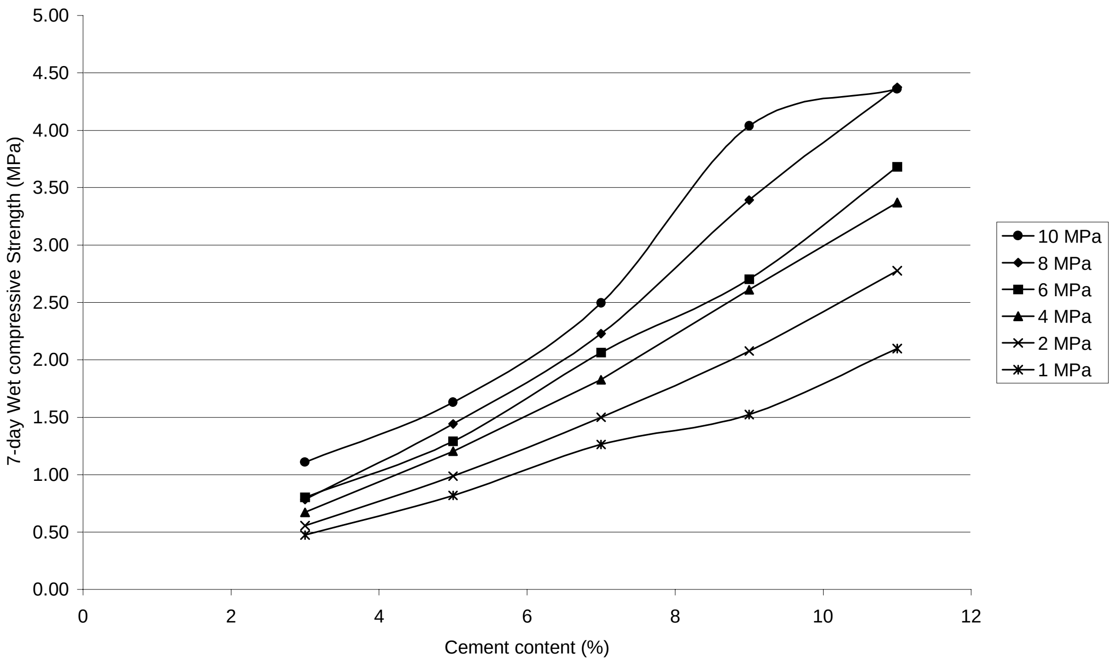
A further complication in the analysis of any tank made of blocks or bricks is uncertainty about how tensile forces travel from one block to the next. One route is via the mortar that separates blocks of the same course. Mortar does not have very high adhesion to blocks, although in this case the loose interlock between block ends would have provided some shear connection. The other route is via shear forces into, and then back out of, the overlapping blocks in the courses above and below the course of interest.

Three further but smaller SSB tanks have been built and sold.

6.4. Conclusions concerning SSB tanks

It is unclear exactly what was the failure mode of SST1. It appears that the lining was not sufficiently waterproof to prevent water passing to the stabilised soil matrix, causing the soil to rely solely on its wet strength. The maximum stress induced in the wall of the tank at 2.5m water pressure is 0.234 MPa. This is the maximum resultant tensile stress on the inner face of the tank wall due to both bending and hoop stresses (as calculated using spreadsheet by Turner [1999]).

If we look at Graph 6.1 we see that the 7-day wet compressive strength for the material (which has a 5.25% cement content and was compacted at about 2MPa, is about 1MPa. Similar figures are found in Houben for 28 day wet compressive strength – see Table 6.1. The usual rule of thumb for dry to wet strength ratio for soil is 5:1. So we see that the wet strength of the soil blocks would be in the region of 0.2 MPa, which is lower than the induced stress prior to failure. It could therefore be said that the tank performed better than might be expected.



Graph 6.1 Graph showing variation of 7-day wet compressive strength with cement content for a number of compaction pressures (Gooding [1993]).
Cement content = 5.25% in our case.

So for this diameter tank (1.67m), using the construction method outlined in Appendix V, and with the standard 2.2m height, the dry strength would give a safety factor of approximately 5. However, if the tank lining should fail, or if the tank should become saturated for any other reason, then the tank would be on the border of failure as the wet strength (~0.2MPa) is approximately equal to the induced stress (0.2026MPa).

Table 6.1 Compressive and tensile strengths for SSB's. All the above assume 2MPa compaction pressure an assume tensile strength to 0.2 x compressive strength

Source	Compressive strength	Estimated tensile strength
Gooding (see Graph 6.1)	1MPa (7 day wet)	0.2MPa
Houben	1 – 2MPa (28 day wet)	0.2 – 0.4MPa (estimated by author)
Houben	5 – 12 MPa (28 day dry)	1.0 – 2.4MPa (estimated by author)

The analysis above would hold if the subsequent tests on the SSB's from the tank debris had not shown that some of the blocks had NO wet strength. The only explanation for this is that these blocks failed before their minimum strength was reached.

6.5. Further work with SSB tanks

Further suggested work on this area of work includes the following:
full laboratory analysis of the soil (the soil used in Kampala was somewhat pozzolanic and was assumed to be superior to standard lateritic soil there)

- development tests to determine the soil / block performance (however there is some suspicion that the blocks in SST1 had been starved of their proper cement allocation)
- further full-scale tank tests with some modifications to improve tank performance
- investigate methods for improving tensile strength e.g. reinforcing with barbed wire
- further work to investigate the relationship between wet and dry tensile strength of stabilised soils

7. Rammed earth (RE) tanks

7.1. Introduction to RE tank development

The general aims of the work carried out on rammed earth tanks (RE) are listed below:

- to set out the theory of RE tank design and to investigate the options available for RE construction
- to develop the specification for an experimental laboratory tank and two experimental field tanks
- to develop the skills required (within the research team) to analyse soils for building, in both the laboratory and in the field
- to investigate soil modification techniques and methods to develop a soil suitable for tank construction
- to develop the tools and equipment required for RE tank construction

- to develop a technique suitable for rammed earth tank construction
- to develop a technique for tank lining using plastic sheet
- to test a rammed earth tank under laboratory conditions to verify the theory
- to build a number of tanks in the field to test the feasibility of the technology and its suitability to LDC skills
- to test a tank under field conditions, again to verify the theory
- to carry out a cost analysis of a RE tank to allow comparison with other tank types
- to develop guidelines for the manufacture of RE tanks

Three (3) RE tanks have, to date, been designed and constructed:

- A tank of 1.4m diameter and 1m height was built at the University (RE-UK*). The tank was from unstabilised soil. The aim was to test the general principle of construction and to allow for initial tests to be carried out on earth tanks. The tank was completed in May 2000 and simple tests carried out, but full tests are yet be to be carried out on this tank. The simple tests include; fitting experimental linings, applying steel strapping and filling the tank a number of times to test strength. The full tests are to include a pressure test to ascertain the actual strength of the tank and to allow comparison with the theory.
- Two tanks of stabilised soil of 2m diameter and 2m height were constructed at Kyera Farm, Mbarara in June and July 2000. The first (RE1*) was constructed to a high specification (see Section 6.4.2) with concrete base and masonry wall section to 0.35m high. The second (RE2*) was designed to be very low cost using predominantly stabilised earth. Both were stabilised with 4% cement and reinforced with barbed wire hoops at 75mm intervals (see Appendix IV for Rammed Earth Tank Construction Guidelines)

** Note:*
For easy identification of the three tanks, they have been labelled as follows

RE-UK	- UK built tank
RE1	- Uganda high specification tank
RE2	- Uganda low specification tank

7.2. The basic principles of rammed earth construction

The general principles for building with earth are outlined in Section 5.4. and a full account of the rammed earth construction process used for the experimental tanks in Uganda is given in Appendix IV.

Some other points regarding RE construction are listed below:

- Availability of suitable materials is a key factor. If significant work is required in modifying the soil once it has been excavated, then the process can quickly become too costly.
- Wall thickness tends to be high, compared with modern materials. This is due to the relatively low compressive strength of the material and the variability in material quality. Compressive strength can be improved by using a small percentage (say 5% – 8% by weight) of cement mixed with the earth.

- Tensile strength is fairly low – in the region of 0.5 – 2.0 Mpa. The tensile strength can be improved by adding fibre or composite materials as well as by stabilisation with cement.
- The technique is characterised by high labour input and low material costs. This is well suited to many developing countries where labour is cheap and manufactured materials are costly.

The tools required for rammed earth construction can be few and of relatively low cost. In the West, sophisticated tooling has been developed, and sometimes costly pneumatic rams are used with steel shuttering, but in the less developed countries (LDCs) the tools have remained unchanged for centuries. Many designs of wood shuttering have been developed to meet the needs of the builder, but the principle actually varies little world-wide.

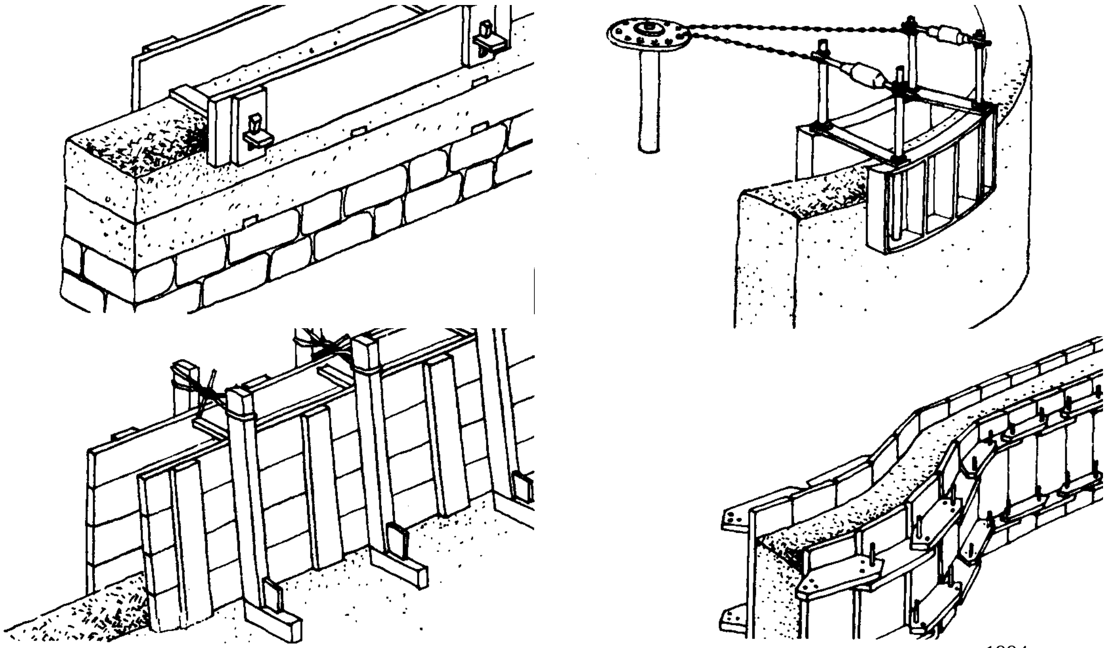


Figure 7.1 – Common types of shuttering used for RE construction (Houben[1994])

7.3. Equipment for making cylindrical RE tanks

Shuttering Most shuttering used for RE construction is designed to be used for the construction of straight walls. There are few examples of shuttering for curved walls, and those shown in the literature seemed to be unsuitable for cylindrical tank construction. The shuttering was, therefore, designed by the author and manufactured at the University workshops (RE-UK) and by local carpenters (RE1 and RE2) - see Figures 7.2 and 7.3. The UK shuttering required some subsequent strengthening to prevent deflection when compaction was taking place. The second set of shuttering was suitably strengthened during manufacture.

- *Shuttering fabrication methods used in UK*

The materials and techniques used for the shuttering construction varied slightly between the UK and Uganda. In the West, plywood is readily available, whereas in Uganda it is not. Plywood is well suited to forming curved surfaces through lamination and so 4mm plywood sheets were used to form the curved faces of the mould – 3 layers glued together. Plywood (12mm – doubled up) was also used to form the main strengthening spines of the shuttering. The tie rods were from 12mm steel rod with T's welded on one end and threaded to sufficient length on the other. The nuts used were fitted with wings to make shuttering assembly easier. The end-stops were made for 12mm ply. The shuttering is shown in Figure 7.3.

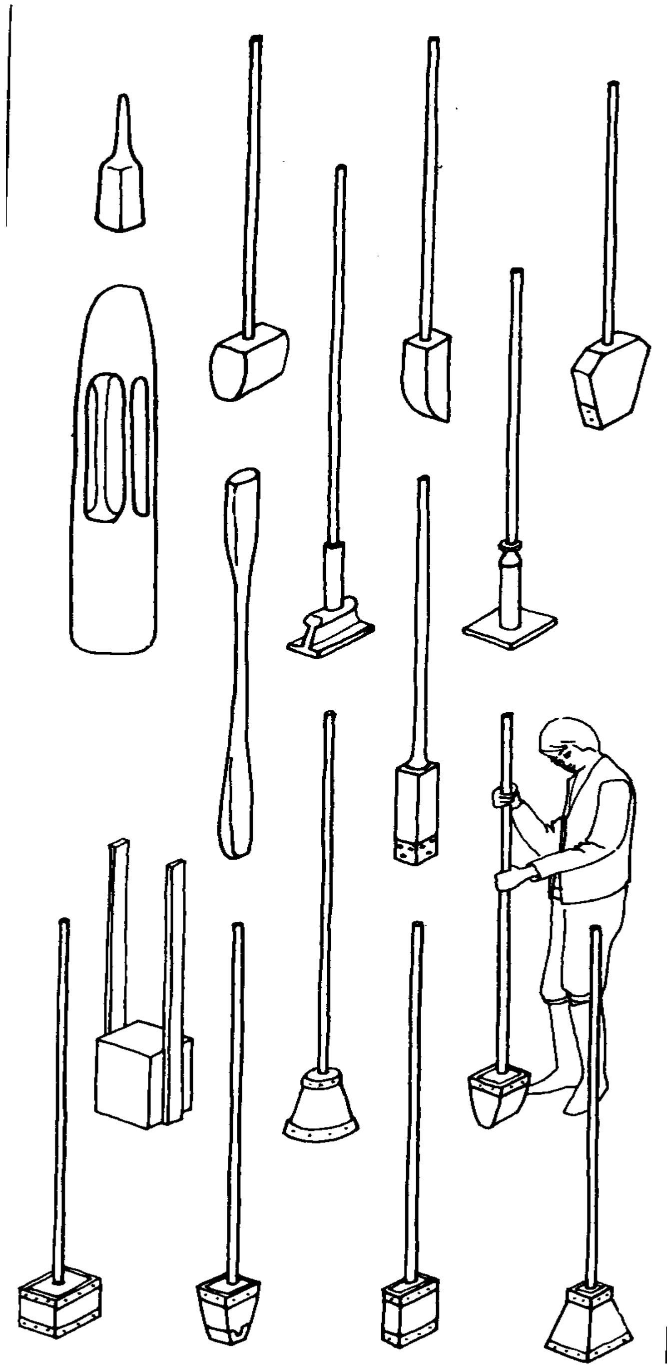

Figure 7.2 – Common types of rammers used for RE construction (Houben[1994])

- *Shuttering fabrication method used in Uganda*

In Uganda sawn hardwood timber is more commonly available and this was used for the construction of the shuttering. The curved faces of the mould were made using 25mm x 25mm strips of timber butted to one another and glued and nailed carefully to each other and to the main spines. The spines and end-stops were from hardwood. The work was carried out at a local workshop and needed constant supervision to ensure that the work was done in accordance with the drawings. The workshop had few power tools and most of the work was done by hand. Again, the tie rods were of 12mm steel rod with T's and threaded section. The shuttering is shown in Figure 7.4. Design drawings for the shuttering are shown in Appendix V.

Figure 7.3 – Shuttering manufactured in the UK

Figure 7.4 Shuttering manufactured in Uganda

- *Test for shuttering strength*

The standard test for strength of shuttering is that the mid point deflection of the shuttering, when loaded with a 150 kg weight (e.g. 3 bags of cement) should less than 3mm. Loading is mid point between the vertical stays.

- *Expected useful life of Shuttering*

Based on the experience in Uganda, where the shuttering was used to make two tanks, it is estimated that well-made shuttering should be good for the construction of between 15 and 20 tanks, with some maintenance required to repair any damage caused during ramming.

Rammers / tampers The tampers were manufactured at the University workshops and at a local workshop in Uganda. Drawings are shown in Appendix V. The handles were of hollow round section steel in order that the weight of the rammer can be adjusted by partially filling the handle with sand. The profiled 'V' rammer, used for creating a joint that helps prevent shear, was made using a piece of 50mm angle iron welded to the flat base of the rammer.

Covers The DTU ferrocement thin-shell cover was used on both RE1 and RE2 and a special sealed (pressure-resistant) cover is to be developed for RE-UK.

Tank linings
Experiments have been carried out with two types of tank lining:

- *Plastic lining*. Work on plastic linings has been underway for some time at the University by an MSc student. A technique has been developed for welding 250 micron construction or damp proof membrane (DPM) plastic sheet to make 'bags' (similar to large bin liners) that fit inside the tank structure to form a waterproof lining. The welding technique has been successfully developed but there are still problems to be overcome in relation to the quality of 'off-the-shelf' plastic sheet and failure of the lining due to abrasion.
- *Cement render lining with waterproofing agent*. This is a more traditional form of waterproofing for water storage tanks and was eventually used for both the field experimental tanks. Further investigation into the nature of render linings, with particular respect to permeability and the effects of waterproofing agents, is underway at the University.

7.4. Laboratory work on RE tanks

Aims of the laboratory experiments Between November 1999 and May 2000 laboratory tests were carried out at the University of Warwick. The work was carried out to allow the author to gain experience with earth building technology and to develop a technique suitable for building tanks from soil. The full aims of the work was as follows:

- to set out the theory of RE tank design and to investigate the options available for rammed earth tank construction
- to develop the skills required (within the research team) to analyse soils for building, in both the laboratory and in the field
- to investigate soil modification techniques and methods to develop a soil suitable for tank construction
- to develop the tools and equipment required for RE tank construction
- to develop a technique suitable for rammed earth tank construction
- to develop a technique for tank lining using plastic sheet
- to test a rammed earth tank under laboratory conditions to verify the theory with regard to:
    - hoop strength (reinforced and un-reinforced)
    - the effect of rain on stabilised soil
    - performance tests for soil:

- wet and dry tensile strength
- wet and dry bending strength
- wet and dry shear strength (all three to be carried out at experimental and applied levels)
- swell and shrinkage
- erosion
- abrasion
- passage of water
- compatibility (adhesion) with renders and mortars

Preparation for the laboratory experiments The test site was established in a disused water turbine testing sump in the university laboratory. The set up for the experiments was time consuming and the preparation of the site took several weeks, mainly fitting lighting and safety equipment to conform with university safety regulations

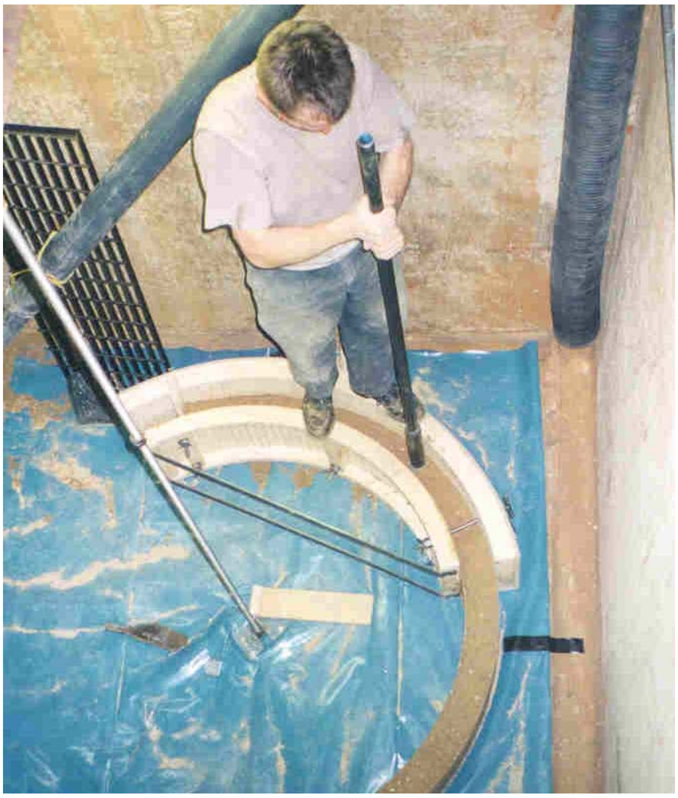

Figure 7.5 Showing tank test area at the university laboratory

Desk work to develop experimental tank specification
Sufficient deskwork was undertaken to formulate a specification for the RE tank. The theory of stresses in tanks is given in Section 4 along with detail of the spreadsheet used to analyse stresses and to develop the specification for the experimental tank. The specification is as given below:

Table 7.1 Specification for laboratory experimental tank

Tank internal diameter	1.40m
Depth	1.0m
Wall thickness	0.1m

Wall / base joint	‘slippery’ joint using plastic sheet
Section bonding	Polypropylene knotted rope to give tensile bond for vertical joints V channel ramming for better horizontal joints
Drying time	2 weeks in dry environment

Work carried out in the laboratory

Soil analysis What was thought to be a suitable soil was purchased from a local quarry and an analysis was carried out. The soil is known locally as ‘Hoggin’The soil was analysed using the standard wet sieving technique and the following results were obtained:

Table 7.2 Soil classification for Hoggin from Husbands Bosworth, UK, December 1999. Sample size 1500g, oven dried for 24hrs, wet sieved

Sieve Size (mm)	Weight retained	% retained	Description
20.000	220.6	14.87	Pebbles
6.300	394.6	26.59	Gravel
2.000	379.8	25.60	Gravel
0.420	222.5	15.00	Coarse sand
0.063	146.3	9.86	Fine sand
<0.063	120.0	8.09	Silt, fine silt and clay

Table 7.3 Results of a sedimentation test carried out on particles passing through 0.063mm sieve (from Table 7.2 above).

Time elapsed since agitation	Settled depth (mm)	% of total settled depth	Description	%age of total soil sample
1min	18	56.25	Sand	18.46
30 min	25	21.875	Silt	7.18
24 hrs	32	21.875	Clay	7.18

The soil was assessed and it was noted that:

a) there were many large stones >30mm
b) there was an excessive amount of material over 6.3mm in size – about 40% of total
c) there was insufficient clay for binding the material (7.18% of total material content)
d) there was insufficient sand in the soil

Soil modification It was decided that the soil should be modified. Several experiments were carried out to formulate a suitable soil and the following procedure was developed to prepare the required soil:

a) all large stones >30mm were removed
b) the soil was sieved to remove all particles above 10mm
c) the soil was then sieved again to isolate all particles between 5mm and 10mm
d) kaolin (china clay) was purchased and used to make up the deficiency in clay content

e) concrete sand was acquired to make up the deficiency in sand in the original soil

The final mix was as follows:

Hoggin <5mm	- 30%
Hoggin 5mm – 10mm	- 20%
Concrete (builders) sand	- 35%
Kaolin	- 15%

No stabilisation was carried out at this point and the material could therefore be recycled during the early tests.

Table 7.4 The sieve analysis for the modified soil (now known as Soil 4)

Sieve Size (mm)	Weight retained	%age retained	Description
6.300	83.80	9.16	Coarse gravel
2.000	232.10	25.37	Gravel
0.420	274.45	30.00	Coarse Sand
0.063	160.70	17.57	Fine sand
<0.063	163.80	17.90	Silt and clay

Soil 4 was used for all subsequent construction work in the laboratory.

Compaction tests and Optimum Moisture Content Compaction tests were carried out (as described in Section 3.3.2) on Soil 4 to determine the Optimum Moisture Content (OMC). The results show a moisture content of 9% to be optimum. However, in practice a figure of 8% was used as soil with 9% moisture content was too 'sticky' and caused the soil to stick to the rammers.

Liquid limit and plastic limit tests – the Atterburg chart Tests to determine the liquid and plastic limits were carried out and the results shown below:

Table 7.5 – LL, PL and PI Figures

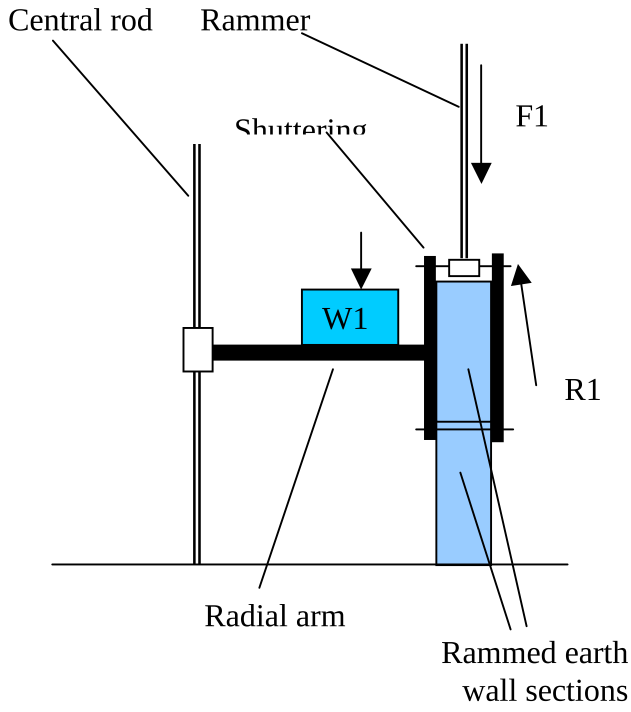
Liquid limit	14.80
Plastic limit	9.59
Plasticity Index	5.21

Figure 7.6 – Early experimentation with ramming wall sections

Initial ramming tests and developing the technique for RE tank construction The shuttering was developed in such a way that 3 sizes of wall thickness could be tried; 60mm, 80mm and 100mm. The reason for this was that it was doubtful if the smaller wall thickness (the lower lifts) would withstand the compaction blows of subsequent lifts.

Early tests showed a number of problems with the ramming technique:
- the shuttering was deflecting and causing the wall section geometry to loose its true curvature
- the 60mm thick wall showed signs of cracking when the shuttering was clamped to it for the subsequent section
- when ramming, a reaction caused the shuttering to bounce or lift slightly (see Figure 7.7)
- the geometry of the shuttering was crucial and problems were encountered due to slight irregularities in the geometry

These problems were overcome by some adjustments to the shuttering:
- strengthening was added to prevent deflection
- the wider setting was used to produce a wall of 100mm thickness
- radial arms were fitted to the shuttering to maintain centrality and to allow weights to be added to prevent 'bouncing' (see Figure 7.7)
- the geometry of the shuttering was corrected slightly as no allowance had been made for the width of the end stops



The ramming force, F1, causes a reaction in the shuttering, R1, which causes the shuttering to lift and hence cause deformation. The weight, W1 (two x 25kg bags of sand were used), counteracts R1 and prevents the deformation.

Figure 7.7 Showing the forces created through ramming and the measures taken to counteract these forces

Manufacture of experimental tank A tank of 1.4m diameter and 0.7m height was built in a disused turbine testing sump (see specification given in Section 6.3.3). The tank was built from Soil 4. The aim was to test the general principle of construction and to allow for initial tests to be carried out on earth tanks. The tank was completed in May 2000 and simple tests carried out, but full tests are yet be to be carried out on this tank The simple tests include fitting experimental linings, applying steel strapping and filling the tank a number of times to test strength. The fuller tests are to include pressure tests to ascertain the actual strength of the tank to allow comparison with the theory.

Figure 7.8 Showing the experimental tank in the sump at the university

Composite materials for added tensile strength Composite materials and reinforcement can be used to improve the strength of compacted soil. For improved tensile strength the added material should have good tensile properties and be malleable so that it can be rammed into the soil matrix. Some ideal materials include barbed wire, polypropylene fibre and straw.

External reinforcement for added tensile strength External reinforcement such as steel packaging strap, barbed wire, or plain fencing wire can be wrapped around the finished tank walls for added tensile strength.

Laboratory tests Due to time constraints and unforeseen problems with developing the technique for RE tanks, other planned laboratory tests have not yet been carried out. Tests are being undertaken at present to verify the theory with regard to:
hoop strength (reinforced and un-reinforced)
the effect of rain on stabilised soil

- performance tests for soil:
- wet and dry tensile strength
- wet and dry bending strength
- wet and dry shear strength (all three to be carried out at experimental and applied levels)
- swell and shrinkage
- erosion
- abrasion

- passage of water
- compatibility (adhesion) with renders and mortars

This work will be reported at a later date.

Conclusions and discussion concerning laboratory work on RE tanks Soil analysis was carried out for a locally sourced soil. The soil was modified to create a suitable soil for RE tank construction. The tools and techniques for RE tank construction have been developed.

Developing the technique for RE tanks proved to be more problematic and time-consuming than was originally thought, with much work needed to overcome geometry problems. The level of accuracy required, both in shutter manufacture and in the construction process, is higher than expected. Early tests show that the RE tank design has good potential.

Soil preparation time is high and so a suitable soil should be sought in the field that requires little preparation.

The problems encountered during the construction process meant that few further tests have yet been carried out.

Further laboratory work
Recommended further work is listed below:

- Manufacture of sealed cover and tank pressurisation equipment
- Pressure testing of the existing experimental tank
- Data logging to allow analysis of the stresses in the tank during pressurisation
- Performance tests to analyse the soils characteristics in use
- Experiments to determine the effects of cement content on stabilisation
- Experiments to determine the effect of cyclic loading on rammed earth tank walls (cracking, joint failure, etc.)
- Waterproof lining (resistance to penetration, fixing methods, liner penetration for off-take, etc)
- Wet strength tests of tanks

7.5. Field work

The principal aims of the field tests were:

- to test the technique developed in the laboratory for rammed earth tank construction
- to test the technique for tank lining using plastic sheet
- to build a number of tanks to test the feasibility of the technology and its suitability to LDC skills
- to test a tank under field conditions to verify the theory
- to carry out a full cost analysis of a RE tank to allow comparison with other tank types

Specification for 2 experimental field tanks

The specification for the two rammed earth tanks is given in the tables below. The specifications were drawn up using the results of the spread sheet analysis and with the specific aim of testing a) a tank using standard building guidelines for rammed earth construction (RE1) and b) a low-cost tank using predominantly stabilised earth and minimising the cement content (RE2).

High Specification RE Tank (RE1)

Tank internal diameter	2.0m
Tank external diameter	2.4m
Tank height	2.0m
Tank capacity	approximately 6 cubic metres
Concrete base thickness	100mm un-reinforced (on 100mm hardcore where ground is soft)
Concrete base diameter	2.8m
Soil wall thickness	0.2m
Soil make-up	10% clay, 15 – 30% silt, 50 – 70% sand, 10 – 20% garvel, 4% cement stabilisation
Reinforcement	barbed wire hoops at 50-60mm spacing in rammed earth sections steel reinforced cement hoops at spacing shown in drawing
Lower wall dimensions	350mm stone masonry, 0.2m thickness
Tank lining	waterproof render approx. 15mm thick (or plastic liner)
Cover	thin shell ferrocement cover
Water extraction	By gravity – washout also by gravity

Low Specification RE Tank (RE2)

Tank internal diameter	2.0m
Tank external diameter	2.4m
Tank height	2.0m
Tank capacity	approximately 6 cubic metres
Base	100mm stone with 50mm compacted stabilised soil, 2.8m diameter
Wall	Stabilised soil, 0.2m thickness
Reinforcement	barbed wire hoops at 50-60mm spacing in rammed earth sections
Soil make-up	10% clay, 15 – 30% silt, 50 – 70% sand, 10 – 20% garvel, 4% cement stabilisation
Tank lining	plastic liner
Cover	thin shell ferrocement cover
Water extraction	by handpump where plastic liner is used

Some of the design features and design considerations that were incorporated are outlined below:

- The wall sections were given a ‘V’ profile to prevent shear. The aim was to encourage better bonding and so reduce the likelihood of shear. The profile was achieved using a special ram with a V attached. See Figure 7.9.

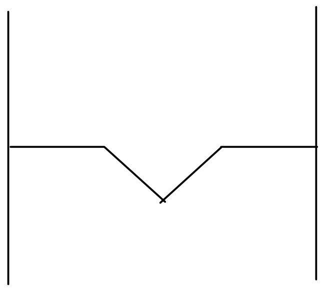


Figure 7.9 – Profile of the joint between 'lifts'

- The principle adopted for house construction of good protection at the base and overhanging eaves for protection from above were adopted, especially in the case of RE1
- The tank size is based on useful capacity and available catchment area
- Minimal cost – the general aim of this task is to reduce the cost of storage for rainwater
- The use of local materials as far as possible
- Durability – a minimum of 10 - 15 years life expectancy
- Easily constructed by local artisans in developing countries
- Foundations – these should be:
    - should be laid in a good sound soil
    - be protected against ingress of moisture
    - be protected against frost (not an issue in the Trpoics0
    - be protected from wind erosion – sand blasting in severe storms
    - be protected against animals, rodents, insects, etc
- Protection from surface water through good drainage (Houben pg 252) – ground to slope away from tank, ground gutters, moisture barriers,
- Foundations in unstable soils need to be considered – ground stabilisation may be needed

Work carried out in the field

The two tanks specified in the previous section were constructed at Kyera Farm. The procedure for their construction is outlined in Appendix IV. Each step of the work was carefully observed and monitored against the aims set out in Section 6.4.1. An initial field soil analysis was carried out to determine a suitable soil. Some modification was needed and then a full laboratory analysis was carried out on the modified soil.

Tests carried out in the field

Soil analysis – field tests

Three soils were analysed crudely in the field. The following tests were performed:

Sensory tests

The soil was analysed by feel, look and smell to test for initial suitability

Sedimentation test. The results are shown below:

Table 7.6 Results of the sedimentation test carried out in the field

Soil source	Soil code	T1	T2	T3	% sand	% silt	% clay
Murram from farm <4mm	S1	40	42.5	42.5	94	6	0
Anthill P <4mm	S2	22	53	53	37.7	62.3	0
RE2 excavation site <4mm	S3	53	59	59	89.8	10.2	0

Notes:
T1 = reading taken in mm, start time plus 1minute
T2 = reading taken in mm, start time plus 30 minutes
T3 = reading taken in mm, start time plus 24 hours
The murram has some organic material; good distinction between layers.
Anthill has little organic matter; poor distinction due to uniform colour.
RE2 excavation site high organic content; good definition.
Clay content is shown as 0% in each of the above. This is because further settling of the sand and silt after initial measurement caused final reading to be low.

A further sedimentation test was carried out to estimate the clay content. Tests were carried out on the murram and the anthill soil. Soil passing through a 0.075mm sieve was sedimented and readings taken at 20mins, 24hrs and 48hrs. From the readings obtained, the clay content was estimated to be:

Table 7.7 Results of tests to determine clay content of soils

Soil	**Clay content**	**Comment**
Murram from farm <0.075mm	4%	Again definition was difficult and the reading was not fully trustworthy
Anthill P <0.075mm	0%	Settling took place rapidly indicating little or no clay content

Soil modification

None of the three soils tested was fully suited to RE construction. However it was found that by mixing the larger particles of the murram (those retained on a 4mm sieve) with the crushed anthill soil, a suitable soil was developed. Stabilisation was provided by adding 4% cement. The cement percentage was kept deliberately low to save on cost. The final mix is shown in Table 6.8.

Table 7.8 Showing mix used for modified soil for RE tank construction

Material	**Quantity**
Crushed anthill soil	80%
Murram >4mm	16%
Cement	4%
Water	Added in sufficient quantity and checked using field test

Soil analysis – laboratory tests

An analysis of the modified soil was carried out at the Central Materials Laboratory, Ministry of Works and Housing, Kampala. The analysis is summarised below.

- *Sieve analysis*
  The full analysis is shown in Appendix III but a summary is given in Table 6.9

Table 6.9 Summary of sieve analysis for RE1 and RE2 tank soil

Classification	
Pebbles	0%
Gravel	21%
Coarse sand	17%
Fine sand	17%
Silts	10%
Fine silts	19%
Clays	16%

- *Other tests*

Table 7.10 Results from laboratory tests for construction soil

Test name	Testing for	Result
Hydrometer analysis	Specific gravity	Gs 2.65 (measured)
Atterburg limits(1)	Liquid limit	34
	Plastic limit	16
	Plasticity index	18
Normal moisture content	Normal moisture content	2%
Compaction and OMC(2)	Material density	1,930Kg/m^3 (Maximum dry density – MDD)
	Optimum moisture content	12%
Linear shrinkage	Linear shrinkage	10%
Permeability	Permeability	4.09 x 10^{-7} m/s
Unconfined compressive strength	Unconfined compressive strength	0.2MPa @ 95% MDD

Notes:
[1] Referring to the Atterburg Limits Chart in Figure 2.1, we can see that the ideal stabiliser for this soil is cement.
[2] A heavy compaction test was carried out to determine density and OMC:
The results are discussed in Section 6.4.7.

Water bearing test on finished tanks

RE2 was filled using a bowser. It was filled quickly using a motorised pump. The tank held water for about 8 hrs but damp patches appeared at the base of the tank. 'Piping*' caused loss of water which became critical after about 12hrs and there was a total loss of water after approximately 14hrs. As the wall became damper, 3 major cracks appeared in the tank wall. The possible reasons for the failure are discussed in Sections 6.4.7 and 6.4.8.

*Piping is a term used in the dam industry and is a mode of failure whereby water finds a path from one side of the dam wall to the other and the subsequent erosion of the wall causes failure.

Figure 7.10 The experimental rammed earth tank under construction at Kyera Farm, Mbarara, Uganda.

As a result of the failure of RE2, RE1 was relined and is awaiting slow filling by rain. RE1 has not yet be tested at full working water pressure.

7.6. Results of field and laboratory tests

Some observations regarding the laboratory tests:

- The results of the sieve analysis shows that the soil is suitable for RE construction.
- Referring to the Atterburg Limits Chart in Figure 2.2, we can see that the ideal stabiliser for this soil is cement.
- Compaction density (MDD) seems rather low – normally we would expect a MDD of at least 2000Kg/m^3.
- OMC seems rather high – this is normally in the range of 8 – 10%
- Permeability is high at 4.09 x 10^{-7}m/s. The norm for stabilised soil is 1 x 10^{-8}m/s.
- Unconfined compressive strength seems very low and this figure is not trusted.
- Linear shrinkage is also high.

The result of the water bearing test described in Section 7.4. was discouraging as far as the overall viability of RE tank technology is concerned. The failure highlighted a number of points:

- Soil tanks should have sufficient wet tensile strength to cope with total saturation in water. This has a strong impact on the design of such tanks and could result in excessive wall thickness.
- A tensile reinforcement should be included within the soil matrix to prevent catastrophic failure in the event of saturation.
- A good tank lining is critical. A poor leakage of the lining will cause rapid degradation of the wall.
- Where a waterproofing agent is used in a render lining it should be given adequate time to take effect. Follow the manufacturers instructions and where they are

lacking, fill the tank slowly, at no more than 200mm per day after 2 weeks of curing in a saturated environment.

7.7. Observations made regarding the RE tank construction technique and field tests

The construction technique developed in the laboratory was further refined in the field. The following observations were made:

- Soil preparation was initially very time consuming, until a groundnut sheller was acquired and modified to mill soil through a 4mm sieve (see Appendix IV). This reduced soil preparation time to about one tenth.
- RE construction is a time consuming process. The cost analysis in Section 6.5 shows how labour intensive the process can be.
- The shuttering used in the field had no radial arms and so the reaction discussed in Section 7.3 was dealt with by standing on the shuttering whilst ramming.
- The level of accuracy attained in the field was lower than in the laboratory. This was not a problem, however, as soil was cut away with a machete if the geometry was not perfect. This was more feasible in the field as the wall thickness of these tanks was higher.
- Some work was carried out to assess the feasibility of plastic liners for use with soil tanks. There were problems in a number of areas: finding good quality plastic sheet; finding plastic sheet of a suitable size; abrasion of liners when in use causing small puncture holes. The technique is not recommended for use at present.

Limitations of the field tests Time constraints were tight due the limited amount of time in-country. It was difficult to set up and execute proper tests during the limited time available, the construction process itself being very time consuming. The tests that were carried out were done so hurriedly and give only an indicative feel for the behaviour of the tank.

7.8. Conclusions, discussion and planned further work concerning RE tanks

Discussion The probable mode of failure of RE2 is outlined in this Section. It appears that water passed through the lining of the tank almost immediately the water was placed in the tank. It seems probable that the waterproofing agent had had insufficient time to act and that water was passing through the render under full water pressure. Alternatively, the lining was of poor quality and water passed through cracks in the lining. The water forced its way through the soil matrix under piping action until it emerged at the outer face of the wall, and the resultant erosion increased the ‘pipe’ area until the water could flow freely from the tank (see Figure 7.11).

The fact that cracks appeared in the tank wall mean that the wet strength of the soil was insufficient to withstand the forces exerted through normal working water pressure, which is not tolerable.

Figure 7.11 Failure of RE2 through 'piping' – this figure shows the leakage at the base of the tank and the crack running through the wall

Further work on RE Tanks A similar water pressure test will be carried out on RE1, as was carried out on RE2. This tank has been relined and will be filled with rain during the coming wet season (starting September 2000). Staff at Kyera Farm have been asked to observe the tank as it slowly fills.

The following is a list of further work that is recommended to clarify uncertainties regarding the technique:

- Performance tests on soil samples taken from field
- Further investigations into suitable levels of soil stabilisation
- Investigation of techniques for improving wet strength of stabilised soil
- Investigation of techniques for decreasing permeability of stabilised soil (e.g. inclusion of bitumen emulsion)
- Further field tests including destructive tank pressurisation tests
- Further work to develop suitable plastic or other flexible linings

8. Cost analysis

A cost analysis for an 11 cubic metre ferrocement tank and an 11 cubic metre rammed earth tank has been carried out

The bill of quantities for the ferrocement tank was taken from Gould and Nissen-Peterson, 1999. The rammed earth tank is an externally rendered tank fitted with a thin-shell ferrocement cover. It is also fitted with a plastic 'sock' lining as described later in this document. Hoop strength is augmented using barbed wire hoops spaced every 0.1m for the entire height of the tank. Cement content is 5% and moisture content of the soil is 8%. We have used material prices based on costs in Uganda as of August 1999. This allows us to make a realistic analysis using costs from a single location and an identical size of tank. We are therefore making a direct cost comparison. The cost comparison and relative benefits may change if the costing is repeated for a different location (with different prices). India, for example, has lower cement prices, which would impact greatly on this comparison. One pound sterling is roughly equivalent to 2440 Ugandan shillings (UGX) as of January 2000. Transportation costs for materials (other than sand) are not included.

The costing figures are shown in the table in APPENDIX I and the table is self-explanatory. Some points to consider are:

- Cement is the major cost in the ferrocement tank. There is little means of reducing the cost without reducing wall thickness. Transportation of cement can be costly if the site is remote.
- The cost, including labour, of the thinner walled rammed earth tank is about 80% that of the ferrocement tank. Material costs are about 72%. This reflects the higher labour input required.
- If suitable soil is available on site then the material costs of the RET can be reduced significantly.
- The RET wall sits on a concrete ring rather than a concrete disc. The base of the tank is of compacted earth. This helps reduce costs as concrete raft bases consume significant quantities of material and are therefore expensive.
- The RET wall is stabilised. The wall would have sufficient strength without stabilisation and the cost could be reduced further. Stabilisation is desired however in case of wetting of the wall.
- If stabilisation and reinforcing is omitted, the cost of the (thinner-walled) RET drops to 697,000 UGX or £278.28, 58.5% that of the ferrocement tank cost (including labour).
- Tooling costs, shuttering and moulds in particular, tend to be higher for the ferrocement tank, although for both tanks the moulds / shuttering can be reused many times.

9. General conclusions, discussion and plans for further work

9.1. Discussion

A number of stabilised soil tanks have been constructed and tested, using two different soil construction techniques. Two tanks have failed under test and the failures have been analysed in the relevant sections of the report. Two further tanks are still under test. Some important lessons have been learned from the initial tests and these lessons will be used to guide further research. The main lessons learned are listed here:

- When designing stabilised soil tanks one should take into consideration wet tensile strength of the material. It is inappropriate to use the dry tensile strength as the design strength value unless it can be guaranteed that water will never reach the soil matrix.
- A composite tensile member is recommended to prevent sudden catastrophic failure of a tank.
- Tank linings should be fully impermeable to prevent water reaching the soil matrix.
- Plastic linings

9.2. Recommended further work

Stabilised soil block tanks

- Full laboratory analysis of the soil
- Performance tests to determine the soil / block characteristics
- Further full scale tank tests with some modifications to improve tank performance
- Investigate methods for improving tensile strength e.g. reinforcing with barbed wire

Rammed earth tanks - Laboratory work

- Manufacture of sealed cover and tank pressurisation equipment
- Pressure testing of the existing experimental tank
- Data logging to allow analysis of the stresses in the tank during pressurisation
- Performance tests to analyse the soils characteristics in use
- Experiments to determine the effects of cement content on stabilisation
- Experiments to determine the effect of cyclic loading on rammed earth tank walls (cracking, joint failure, etc.)
- Waterproof lining (cyclic loading with a variety of ‘sharp’ objects to test resistance to penetration, fixing methods, liner penetration for off-take, etc)
- Wet strength tests of tanks

Rammed Earth Tanks - Field work

- Performance tests on soil samples taken from field
- Further investigations into suitable levels of soil stabilisation
- Investigation of techniques for improving wet strength of stabilised soil
- Investigation of techniques for decreasing permeability of stabilised soil (e.g. inclusion of bitumen emulsion)
- Further field tests including destructive tank pressurisation tests
- Further work to develop suitable plastic or other flexible linings

Other work

- Render linings for tanks – permeability tests and effects of waterproofing agent on render (both in early stages and longer term)
- Methods for reducing permeability of compacted soils (e.g. treatment with bitumen emulsion)
- Further experiments on the relationship between wet and dry strength in tension
- Tank linings from plastics
- Termite attack on soil tanks
- Sliding joint at base of tank

APPENDIX II - REPORT ON WATER TANKS FROM STABILISED SOIL BLOCKS

(by Engineer Dr. M. K. Musaazi PhD DIC, August 2000)

Machinery

Manual Block Press (by ApproTec Kenya): Specially modified by authorized manufacture (Makiga Engineering Services, Kenya) to make curved interlocking blocks. There are two Block Presses designed so that 13 blocks interlock to make a 1.0m internal diameter circle or 17 blocks make a 1.5m internal diameter circle.

Material

Murrum (red) soil or volcanic soil and Ordinary Portland Cement (OPC)

Material Preparation

Sieve soil with a 5mm wire mesh. Mix while dry with OPC in the ratio.
Cement : Soil = 1: 19

i.e. 50kg(l bag) of OPC makes 110 SSB blocks each of about 9kg. A little water is added to make the mixer just damp.

Block Making

Prepared material compressed by 40% to make one block at a time.
Two men make 330 blocks/day.

Curing and Drying of Blocks

Blocks are cured under a black Polythene sheeting for five days if made from murrum and for 2 days if from volcanic soil. Dried for 5 days under direct sunshine, after curing, before used to make tanks.

Tank Building

A 150 mm concrete base is made and blocks laid the following day. Blocks interlock to form a circle desired internal diameter.

Experience has shown that the internal diameter can be increased from design by as much as 0.5m without any noticeable distortion of the circle.

The blocks are laid using a 1:4 cement to sand ratio. One bag (50kg) of OPC lays about 200 blocks. The inside of the tank is plastered with fine sand, OPC and water proof cement (I kg added to 50kg of OPC).

Block Size:

Length = 280 mm
Width = 140 mm
Height = 110mm

Hence the tank wall is 140 mm thick plus 10 mm of plaster.

Tank Sizes

The size of course depends on the internal diameter and height. The tanks that have NOT failed number five as tabled below:

TANK NO.	DIMENSIONS	CAPACITY (Litres)	WHEN MADE MONTH, 2000	REMARKS
1	Int diam – 1.0m Height - 5.2m Block layers – 13 Total blocks – 507	5,800	March	Full up to 3.5m as of 1st August 2000
2	Int diam – 1.24m Height - 2.12m Block layers – 15 Total blocks – 240	2,500	March	Full to capacity as of 1st August 2000
3	Int diam – 1.20m Height - 2.12m Block layers – 14 Total blocks – 210	2,400	April	Full to capacity as of 1st August 2000
4	Int diam – 1.20m Height - 2.12m Block layers – 14 Total blocks – 210	2,400	April	Full to capacity as of 1st August 2000
5	Int diam – 1.20m Height - 2.12m Block layers – 14 Total blocks – 210	2,400	May	Full to capacity as of 1st August 2000

One tank that ruptured when trying to fill it with water had the following dimensions:

Int. Dia = 1.67 m
Height = 3.80 m
Blocks/layer = 19
No. of layers = 28
Capacity = 8.324 litres

Tank ruptured when about 2.5m full.

Possible causes of tank failure:

(i) Diameter too large, hence insufficient hoop strength
(ii) Filled too quickly with a tanker – this does not give the waterproofing agent time to work properly

(iii) Blocks from volcanic soil seem not to have been stabilised – broken blocks disintegrated completely when soaked in water. This could be due to poor workmanship, although the building team are known and trusted.

(Figure AII.1 – Tank built for experimental tests in Uganda)

(Figure AII.2 – failure of the SSB tank was catastrophic – the debris remaining after failure is shown here)

RECOMMENDATIONS FOR DESIGNING RAINWATER HARVESTING SYSTEM TANKS

O-DEV Contract No. ERB IC18 CT98 027
Milestone A6: Report A4

January 2001

THE UNIVERSITY OF WARWICK

Development Technology Unit

School of Engineering, University of Warwick

CONTENTS

1. INTRODUCTION

The water store (the 'tank') accounts for a large fraction of the cost of any roofwater harvesting system. Most poor households cannot afford to buy as large a tank as their roof catchment area might justify. There is therefore a strong incentive to seek cheaper yet adequate forms of tank.

The cost of a tank depends upon its size, the type and quantity of materials used in its construction, the labour needed to build it and in some areas the 'hire' of special equipment. The tank itself might be regarded as having two main parts; a water store and a set of ancillaries to lead water into and out of it (taps, an overflow, a filter, a level indicator etc.). In this paper, we restrict ourselves to considering just the water store.

Rainwater collection is in no way a new technology and is described in many publications (Gould & Nissen-Petersen, 1999; Lee & Visscher, 1992; Pacey & Cullis, 1996)In the last decade, there have been many attempts to identify better tank designs. Therefore this report starts with an analysis of needs and constraints and follows with an analysis of good existing designs. Lastly comes a description of our own work towards making tanks cheaper.

2 TANK REQUIREMENTS & CONSTRAINTS

2.1 Needs and specification

Tanks need to be watertight although some leakage (such as <5% of daily abstraction) might be tolerable if it does not weaken the structure or cause puddles. They also need to hold the required volume and to be adequately durable (say 25 years before they become unserviceable). Beyond these basic requirements we can list many further specific requirements. Tanks should:

- have a means of being charged with water without unduly disturbing tank-bottom sediments and if possible maintaining stratified flow (the bacterial quality of outlet water is maximised if the flow through the tank resembles 'pipe flow', namely 'last in is last out'
- be able to handle excess input by overflowing in a convenient and safe manner - preferably without leading water unnecessarily via the tank (such water may drop unwanted sediment in the tank)
- have a means by which the water can be extracted which is convenient for the user and which does not pollute the water left behind (as dipped buckets may)
- exclude vermin and as far as possible mosquitoes
- exclude light (so that algae do not grow and larval growth is inhibited)
- have some form of ventilation, especially if there is not an efficient filter to prevent organic material from entering the tank and decaying there
- be easy to access for cleaning (where cleaning is needed) and be unlikely to be damaged during cleaning
- have a sufficient structural safety factor to withstand wear and tear, some impacts and occasional large natural forces caused by winds and (in places) earthquakes

- not present hazards to passers-by or small children and (in some societies) offer some protection against deliberate poisoning
- not give the water a bad taste

2.2 Local constraints

There are often also local constraints upon the construction process, such as:

- absence or excessive expense of particular materials (e.g. cement, sharp clean sand)
- constraints upon the plan-area space, height or depth of a tank
- tank location; some designs are easier to locate than others

3 ROUTES TO CHEAPER TANKS

3.1 Changing To cheaper materials

Surface tanks for roofwater storage are commonly made of brick, ferrocement, concrete blocks, plastics and galvanised iron. Some of these materials are themselves variable in make-up (the cement or steel fraction within ferrocement can be varied) and all can be varied in thickness, as is discussed in the next section. Requiring a material to be both strong and waterproof considerably constrains its choice, Once however one accepts that waterproofing and structural strength can be separated and accommodated by different materials – a number of new materials options appear.

Bricks

Burned bricks are often made locally and are available much more cheaply than materials which have to be imported into an area such as plastics or cement. Tanks made from bricks can therefore be cheaper than those of "imported" materials and will also keep more of the money spent on the tank within the community. The challenge when building such tanks is to absorb the tensile stresses typical of water tank with a structure best suited to compressive forces. The Rainwater Harvesting Research Group has experimented with a number of alternatives such as external reinforcing and shaped bricks. This work is detailed in Section 7.

Stabilised soil

Another "earth technology" is to use a small amount of cement to hold together (stabilise) an otherwise soil based block. This technique can dramatically reduce the quantity of cement needed to make a tank of equivalent strength. The wet strength of stabilised soil is considerably lower than cement so the designer must either balance the cement content to ensure the wet strength is sufficient or employ some waterproof barrier to prevent water soaking into the blocks.

Rammed earth

Ramming earth between to walls ("shutters") compacting it, gives the wall a stiffness that simple soil building does not have. The technique uses only local materials and can be achieved without particularly specialised labour, it does however require some specialised tooling such as the shutters and a tamper to ram the earth into place but these can be made locally and used to make several tanks spreading their cost. The tank wall, however, is not waterproof with this technique so a means of waterproofing the inside surface must be employed.

Wattle and daub

A traditional technique for house building in many marts of the world, wattle and daub used mud to fill in a structure made from collected roundwood. The technique is well known and practised at a village level and requires no specialised tooling or knowledge to implement. All materials are available locally and usually need only be collected, thus the only capital requirement is labour making it extremely suitable for “self help” projects.

Like all “raw” earth technologies, the technique, results in a structure that is not waterproof and so a method of holding the water must be employed. One excellent example of this is the Rwandan “tarpaulin tank” which utilises an UNHCR tarpaulin in an excavation to hold the water with a wattle and daub enclosure. This tank is further described in Section 6.

Plastics sheeting

Plastic sheeting is becoming available in many parts of the world and can be used for lining otherwise permeable tanks to render them waterproof. At a basic level this could be simple polythene sheet but this tends to have a short lifespan. There are also several fibre reinforced plastic sheets such as those used for tarpaulins becoming available in centres and also in areas of specialised demand. At present it is unlikely that these materials will shortly become widely available due to a lack of demand but appropriate promotion/dissemination could change this situation.

Waterproof coatings

Waterproof paints are quite common in the developed world where they are used to seal ponds, swimming pools etc. these paints are available in some LDC centres and local variants may be developed. Quality control will become a major issue for these to be used as any uncoated sections could result in dangerous catastrophic failure of the tank.

3.2 Minimising the volume of materials used

A second method of cost reduction is by reducing material quantities. In general we can save materials by four approaches, namely:

- removing material where it is not needed
- reducing overall material use by reducing safety factors if they are unnecessarily high
- making use of some existing structure (e.g. the wall of a house or the ground itself)
- adopting a more efficient shape whereby overall tank wall thickness can be reduced

Removing material

The first of these approaches is sometimes prevented by practicalities. Wall thickness is often dictated not by strength but by buildability. For example the upper part of the walls of a cylindrical tank are subject to lower pressure than the bottom and so theoretically could be thinner. Unfortunately it is impractical to taper bricks or even ferrocement as one builds up the wall. the. It is, however possible to go some way toward this ideal.

- If coiled wire reinforcing is used, the spacing can be varied from close-spaced at the bottom of a wall to wide-spaced near the top.
- Materials can be concentrated so that extra strength is provided only where actually needed; for example cement content of ferrocement or stabilised soil blocks can be varied with height above the base (using least at the top).
- Material thickness can sometimes be reduced step-wise by, for example using a double run of bricks at the bottom and reducing to a single run further up the tank.

Material savings should be balanced against the extra complexity of manufacture. All of these techniques have quality control implications and should be used only when workers are familiar with the techniques or are well supervised.

Reducing safety factors

The stresses in water tanks can be calculated and then the expected stress compared to measurable properties such as maximum tensile strength, compressive strength, change of shape under load, etc. So long as the expected stress is lower than the chosen maximum material stress (usually the tensile yield stress in the case of tanks), then the structure will not fail. In practical problems, the expected stress is multiplied by a safety factor (F_S) for a number of reasons.

- The local load may be larger than we realised (indeed our method of calculation may itself contain serious inaccuracies)
- The material may be weaker than it should have been or some of the original strength may have been lost through wear and tear
- The material will almost certainly not be homogeneous, that is it will be stronger in some places than others (this is especially true of building materials)

A safety factor of 5 is typical for a water tank made of building materials. If the safety factor is very large (say $F_S = 15$) then material is being wasted and savings can be made.

Few practitioners of DRWH in developing countries include a well-considered safety factor in tank design calculations. The safety factor is usually applied to tanks in one of two ways:

- by arbitrary application during design, usually leading to excessive wall thickness as the engineer errs on the side of caution
- by trial and error leading to many trials and many errors

Arbitrary application can be expensive in terms of materials, while trial and error is expensive in terms of broken tanks (and even downright dangerous if field trials use consumer tanks).

Defining a sensible safety factor can be difficult given the extreme variations in quality of materials and workmanship in developing countries. The normal engineering approach to safety factor application is to use standard engineering materials (of more or less known strength) and to look up the appropriate safety factor in an engineering data book or approved ‘code of practice’. The nature of tank construction in LDC’s is however such that ‘standard’ (well-quantified) civil engineering materials are rarely available. Sand and aggregates as found in the local village and cement itself is often of dubious quality. Reinforcement may be of poor quality and the strength of bricks fired in a clamp kiln will vary from one to another. Safety factors will therefore vary depending on the type and variability of the material used and the level of skill available to build the tank.. Some suggested Factors of Safety are in Table 1

Table 1: Factors of Safety

Material	Skill level	Factor of safety
Ferrocement	High	2-3
	Medium	4-5
	Low	7-8
Burned Brick	High	3-5
	Medium	6-8
	Low	9-12
Galvanised Iron	High	1.2-1.4
	Medium	1.5-1.8
	Low	1.9-2.3

Architectural integration

The third approach, of saving costs by integrating a rainwater tank with a house structure, has been discussed from time to time but rarely found to yield decisive economies. For space or aesthetic reasons, tanks have often been located within a house's structure (especially where the house is multi-storey) but it is hard to show that any significant material saving has been so obtained. A shallow tank with a large area may substitute for part of a roof, however the requirement that the tank's top be *lower* than the bulk of the roof from which it is supplied restricts this substitution to say veranda roofing or between stories of a multi-story dwelling. The volume of the tank is also limited by the structural integrity of the roof supports as $1m^2$ of water weighs in at one tonne!

Conversely a very tall tank might substitute for walling. This has been proposed by ??? for Australian houses (ref?) but the architectural detail of moving from normal to tank walling and back again is complex and the long, flat wall will be subject to large bending stresses. Moreover a deep, thin tank has a poor ratio of volume to wall area and may also be difficult to clean. A tank could be made as a core round which a house could be built, in the same way as some traditional village houses in India were built around grain stores. All in-house tanks, however have the problem of ensuring that tank overflow will never inundate the house – as often happens with roofs having 'internal' gullies. Any leakage from these tanks will also enter the house.

Finally tanks can be built into the basements of houses saving space and integrating the tank and house foundations. Laurie Baker has used this technique extensively in his design of The Centre for Development Studies in Karalla India albeit for non-drinking water purposes. If this strategy is to be used, account must be taken of the fact that even ground floor floors will have to be suspended and water will need to be pumped from the storage.

Optimal tank shape

Since the shape of a tank affects both the volume-to-surface ratio and the distribution of forces, it is worth examining the effect of tank shape upon material requirement. As always these material savings must be balanced against the additional complexity in manufacture, straight sides are much easier to form than curves and can be produced with a larger selection of materials. Table 2 shows a summary of tank shape from the viewpoint of induced stress, material use and construction. Three common tank shapes are considered: the cuboid, the cylinder and the doubly curved 'Thai' water jar shape.

Table 2: Relative merits of some common tank shapes

Tank shape or type		Stresses	Material usage	Construction
Cuboid		Stresses are unevenly distributed around the structure. Bending stresses are especially high near the edges.	The ratio between material usage and storage capacity is higher than for a cylindrical or doubly curved tank.	Construction is quite simple using most materials
Cylindrical		Stresses are more evenly distributed with bending stresses only near the bottom	There is an improvement in the material use to storage capacity ratio (a saving of 7.5% over a similarly proportioned cuboid)	Construction becomes more difficult with some materials e.g. bricks, but the shape is well suited to construction with materials that can be bent e.g. ferrocement and GI sheeting or built in sections
Doubly curved tanks (e.g. Thai Jar)		Stresses are well distributed. The base of the tank is of smaller diameter, reducing both hoop stresses and bending stresses there.	Material usage to capacity ratio is very good (savings of up to 20% over a cuboid)	Construction can be difficult, often relying on specialised moulds. Materials must be pliable and able to curve in two directions e.g. ferrocement and clay

The table shows that the cuboid shape fares relatively badly in terms of material use versus storage capacity and it is also associated with high peak stresses. The cylindrical shape deals quite well with stresses in comparison, and it has a lower (better) ratio of walling material to storage volume. It is still easy to manufacture, a technique well suited to circular or irregular forms. The ‘Thai’ style tank has the ideal shape to cope with the main induced stresses but requires greater skill and tooling to make.

Underground tanks

Significant material savings can be made if the tank is built underground. If the soil is suitable it can take the weight of the water and the walls can be made considerably thinner as they will simply be used as a waterproof layer stopping the water seeping into the soil. The geometry can also be very efficient (hemispherical) as the ground will act as a former for construction and the tank needn’t stand up on its base like an above ground tank. This material advantage should be balanced against the additional cost of digging a hole (which can be significant if the ground is particularly hard) and the possibility of the tank becoming contaminated by leaks or a rising water table floating the tank out of the ground.

3.3 Minimising labour and equipment costs

Generally labour costs rise as equipment costs are reduced and *vice versa*, so one should seek to get the best balance. What that balance is clearly depends upon location. In rural Africa digging deep pits by hand is cheapest, in urban Asia it would often be possible and cheaper to hire a back-hoe for the job. Similarly the transport of 'centrally' produced tanks or jars by motor vehicle might incur only modest costs in an urban area but quite excessive ones in a hilly rural area with few roads.

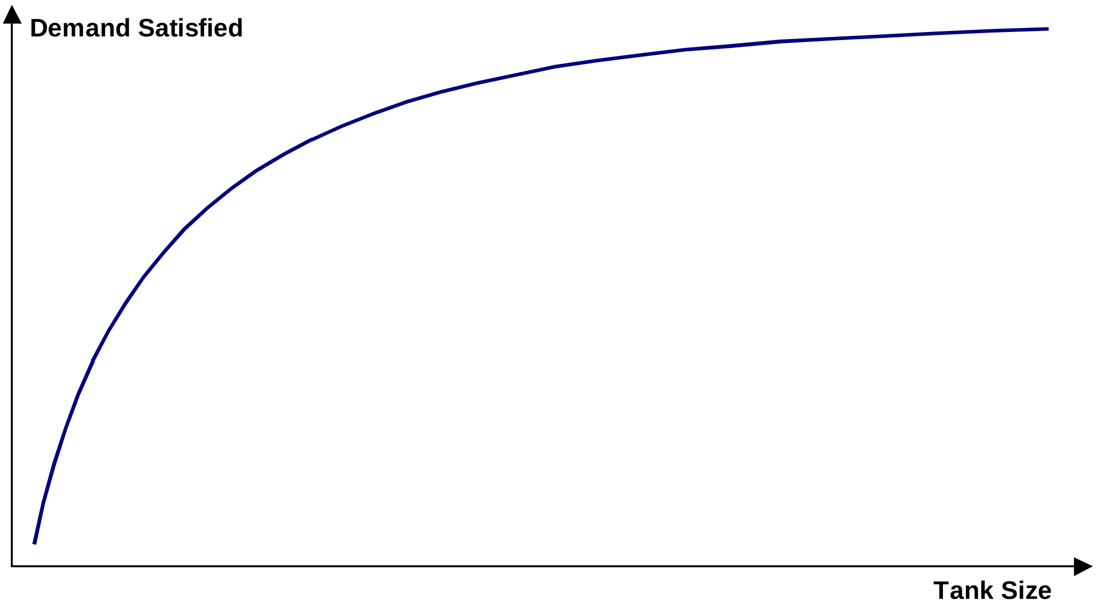
Employing moulds to build tanks improves their accuracy (and thereby may save materials) and also saves labour by reducing 'setting out' times. Moulds themselves become cheaper (per tank) if they are durable and can be used many times. Recycling moulds however requires suitable organisation – such as their attachment to a multi-system programme or availability for hire – and easy transportability.

In many cases, organisations assisting the construction of RWH systems have as their major objective the creation of income-earning opportunities in a specific locality. In consequence they seek to minimise the capital requirement associated with use of complex or motorised equipment, and to maximise the labour fraction of total costs. This approach may or may not minimise overall RWH tank costs.

3.4 Appropriate sizing

One of the simplest ways to make a tank cheaper is simply to make it smaller. Figure 1 shows the water demand satisfied by a tank compared to its size. As can be seen economics of tanks are such that the benefit of a tank is not strictly proportional to its size. The reason for this is that a smaller tank will be filled and emptied (cycled) often whereas a larger tank will only be cycled rarely. A fuller discussion of this is found in section 5

Figure 1: Benefits of tank sizing



Thus, while a large tank may be beyond the affordability of a household, a smaller tank will usually provide significant time-savings, particularly during the rainy season when footing can be wet and slippery. Another tank may also be added later and the total system capacity grown this way. This modular approach has can be seen in many parts of Southeast Asia.

3.5 Mass production

Tanks (particularly smaller tanks) benefit from the economies of scale that come with mass-production. In Thailand, a country that has undergone a massive rainwater harvesting promotion programme, 400 litre jars are produced for less than $US5. Another possibility is the mass production of some parts portion of a tank such a the lining and this way reducing the overall complexity of tank construction and allowing local materials and skills to fill in the balance.

4 STRUCTURAL STRENGTH & STRUCTURAL FAILURE OF TANKS

In a famous case over 150 years ago, the engineer Stephenson (who had no means of analysing structures) designed an early railway bridge by a careful series of experiments on a scale model. He built the model rather weak then loaded it until it collapsed. He then strengthened the part that broke first and repeated the procedure several times. By the end of the process the bridge had increased in weight by 50% but was 6 times stronger. We might use this technique to develop more materials-efficient tanks. Unfortunately the process would be long, expensive and perhaps unreliable (since testing long-term durability is harder for tanks than for steel bridges). Moreover today we have a much better (although incomplete) understanding of theory behind the structure of a tank.

4.1 Failure modes

There are number of possible modes of structural failure for a water jar or cistern, of which the most common are:

- Cracking and leaking (which may be temporarily repairable but often later progresses to failure)
- Leaning over, due to inadequate foundations
- Bursting (which can be dangerous, with fragments flying some distance)

It is a normal pattern that when a product like a RWH tank is first introduced to a new location a very ‘conservative’ design is used. It is in consequence expensive and may need subsidy. It should be the aim of any such programme to use the period of subsidy to simplify or cheapen the product by some degree of trial and error. Unfortunately failures resulting from a practical search for the design limits are embarrassing and can lead to mistrust of the product. For this reason it is prudent to perform such experiments in private (‘behind a hedge’) at least until the probability of failure appears low. Moreover the design should be chosen to exhibit functional failure such as leaking before any dangerous failure such as bursting.

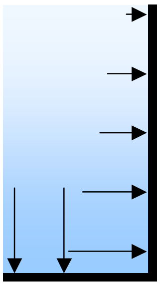
4.2 Stresses due to the stored water

Pressure forces

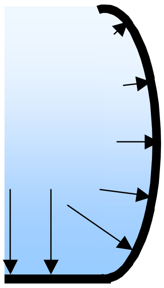
Water exerts a pressure proportional to its depth equivalent to 10 kPa. Per meter. The pressure always applies a force perpendicular to the inside surface of the tank, so at the bottom it acts downwards, over most of the walls it acts outwards and near the top of a doubly curved tank it can even act upwards (see Figure 2)

Figure 2: Action of pressure in a water tank

a. Straight sided



b. Doubly curved



Generally this pressure puts the tank walls into tension (stretch). This is unfortunate because many materials traditionally used for building and transferred to tank construction are only 10% or 20% as strong in tension as they are in compression.

Stresses in cylindrical tanks

In the case of a simple cylinder, the tensile stress acts around the cylinder and is called “hoop stress”. This stress can be found using the equation:

$$\sigma_h = \frac{p\,r}{t} \qquad (1)$$

Where:

σ_h is the hoop stress

p is the water pressure

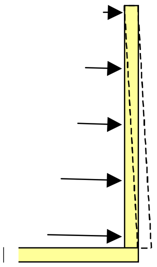
r is the tank radius

t is the wall thickness

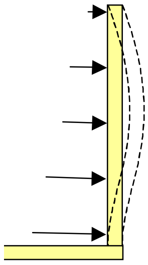
This simple result however is only true when the walls of the tank are free to move as shown in Figure 3a. The movement is only very small and can be achieved by using a flexible material between floor and wall such as bitumen or by allowing the wall to slide along the floor. Where the walls are fixed, such as at the base of a tank, they will tend to bow out as shown in Figure 3b

Figure 3: Movement of tank walls due to pressure

a. Unconstrained



a. Constrained



This will change the hoop stress and also cause two other stresses acting in different directions as are shown in Figure 4.

Figure 4: Stresses caused by constrained walls

a. Shear Stress

b. Bending stress

The wall will be stressed in shear at its edge where the water pressure forces it outwards but the base opposes this: the shear stress acts through the wall in a horizontal plane (Figure 4a). Another stress is due to bending of the tank walls as they bow outwards. This is especially high near the joint and will cause vertical compression of its outside face and tension on the inside face of a tank (Figure 4b) both acting vertically up the wall which can cause cracking of the inside face leading to failure.

Quantifying this situation is rather more complex and uses the technique of shell theory where the tank walls are idealised as being very thin (like egg shells). The theory also breaks the problem down into two parts. The first part considers the wall to be very flexible and therefore incapable of being stressed in bending or shear. The second part looks at the bending only and is confined to the boundaries between the wall and the floor where these forces are most prevalent. Furthermore the tank is considered to be made of a material whose properties are constant throughout and which will deform in direct proportion to the forces acting on it (Hooke's law). The relevant equations (Flugge, 1967) are:

$$N_\theta = \gamma r\left(h - x - he^{\frac{-\lambda x}{r}}\cos\frac{\lambda x}{r} + \left(\frac{r}{\lambda} - h\right)e^{\frac{-\lambda x}{r}}\sin\frac{\lambda x}{r}\right) \tag{2}$$

$$M_x = -\frac{\gamma r t}{\sqrt{12\left(1-v^2\right)}}\left(\left(\frac{r}{\lambda} - h\right)e^{\frac{-\lambda x}{r}}\cos\frac{\lambda x}{r} + he^{\frac{-\lambda x}{r}}\sin\frac{\lambda x}{r}\right) \tag{3}$$

$$Q_x = \frac{\gamma t\lambda}{\sqrt{12\left(1-v^2\right)}}\left(\left(\frac{r}{\lambda} - 2h\right)e^{\frac{-\lambda x}{r}}\cos\frac{\lambda x}{r} + \frac{r}{\lambda}e^{\frac{-\lambda x}{r}}\sin\frac{\lambda x}{r}\right) \tag{4}$$

where:

N_θ is the radial hoop force

M_x is the bending moment

Q_x is the shear force

γ is the specific weight of water (density times gravity)

r is the radius

h is the height water height

x is the height of the stress to be calculated

v is poisons ratio (the ratio of a materials change in shape in the direction of a stress to the change in shape perpendicular to the stress – as a rubber band is stretched it gets thinner)

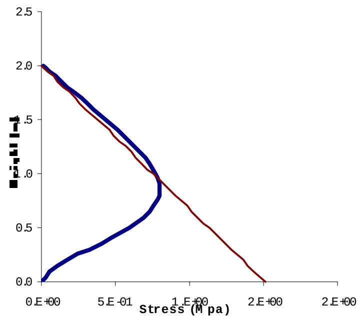
λ is given by

$$\sqrt[4]{3\left(1-v^2\right)\left(\frac{r}{t}\right)^2} \qquad (5)$$

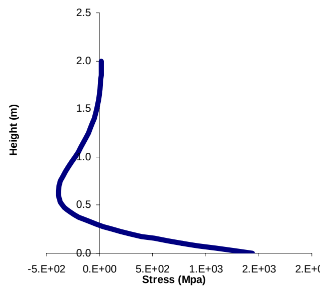
These fairly daunting equations can be easily coded into a spreadsheet and used to provide useful curves for designing tanks. Typical output is shown in Figure 5

Figure 5: Stress curves for cylindrical tank with fixed base

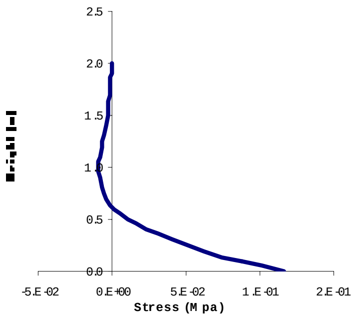
a. Hoop stress



b. Bending stress



c. Shear stress



Design considerations

Design to resist tensile stresses, whether vertical due to bending, radial hoop stresses and shear stresses acting through the wall, obviously includes the use of adequate wall thickness and adequate material tensile strength. It is sometimes assumed that brick and concrete cannot carry *any* tensile stresses without failing, but this is not so. Although it may be prudent to include steel reinforcing in a tank wall to prevent dangerous bursting, it is uneconomic to include so much that the mortar or brick carries negligible tension. If one relied solely on the stiffness of the reinforcing, its movement under water-pressure would almost certainly result in cracking of the mortar or brick matrix, causing perhaps leakage and almost certainly rusting of the reinforcing. Reinforcement that passes from a base into the bottom of a tank's walls will help resist both shear and bending stresses. Extra wall thickness, or filleting at the joint between wall and base is also a useful strategy.

4.3 Stresses due to materials shrinkage

As well as the cyclic stresses due to the water rising and falling inside the tank, there are other stresses due to the material *shrinking* during construction. Cement mortar, concrete and stabilised soil all shrink slightly (about 1 part in 1000) as they cure or dry out. If mortar or other such material is restrained during curing - for example by a metal mould or by attachment to a base - there will be a struggle between the mortar trying to shrink and the constraint trying to stop it. In consequence large stresses can develop in the mortar causing it to crack. To reduce such shrinkage cracking, we could:

- Remove stiff constraints (e.g. putting lime mortar or a rubber strip between the wall bottom and the base plate or using flexible moulds);
- Reduce mortar shrinkage by using a very dry mortar mix or a low cement content: unfortunately the former makes the mix difficult to work and the latter reduces strength;
- In the case of soil, use a low clay content;
- Spread such cracks that form (so that there are many tiny cracks rather than one big one) by putting a metal or fibre mesh inside the mortar: this is particularly helpful in controlling leakage since splitting one wide crack into two narrow ones will reduce leakage flow about 4-fold;

- Choose a shape (e.g. a sphere) where there are no hard attachment constraints;
- Modify the material by the addition of a slightly expansive component that counteracts the normal shrinkage;
- In the case of a render applied only to achieve water-tightness, it is often possible to apply it in two layers and place a sealant such as cement-plus-water between the layers.

5 ECONOMICS OF TANK SIZING

5.1 Economic overview

All households already have some access to water from point sources. For some days per year, many also employ ‘informal’ rainwater harvesting, placing bowls and jugs under eaves or even trees during rainfall.

The introduction of more formal (and productive) RWH will normally be accompanied by three benefits. The most obvious is a reduction in the time spent carrying water from point sources – a reduction more or less proportional to the volume of water no longer carried. The second is an increase in household water consumption wherever it was previously constrained by the effort of collection. The third is a common, although not invariable, increase in water quality. All these benefits rise with DRWH storage capacity, albeit in a way showing diminishing returns.

The increase in water consumption with RWH has not been widely measured. Generally any increase is restricted to the wet seasons. DRWH is not generally capable in the dry seasons of supplying quantities larger than already obtained from point sources: this means that it will be used to supplement, but not to substitute point-source water.

The costs of DRWH are overwhelmingly capital costs, as neither operation nor maintenance usually involves significant expenditure. These capital costs are subject to economies of scale. The sensitivity (elasticity) of tank cost to storage capacity is about 0.6

5.2 Value of water

As with many other goods, water has a declining value with quantity. The first litre per day is worth more than the tenth. By examining the limited data available that relates household consumption per day to the effective unit cost of water (i.e. cost per litre), we might construct a curve such as shown in Figure 6. Each socio-economic group would have its own curve.

The cost line on 6 is horizontal, which reasonably represents the situation where water is fetched, each successive litre requiring the same input of labour. Such a line does not fairly represent harvested roofwater, where the effective cost general rises with daily consumption despite the economies of scale in tank construction. A typical cost v volume characteristic for RWH supply is shown in Figure 7.

Figure 6: value vs. quantity

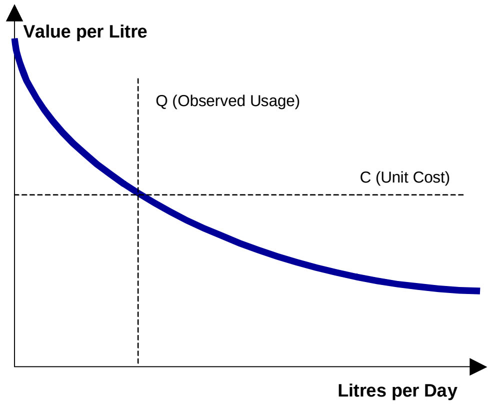


Figure 7: cost vs. volume

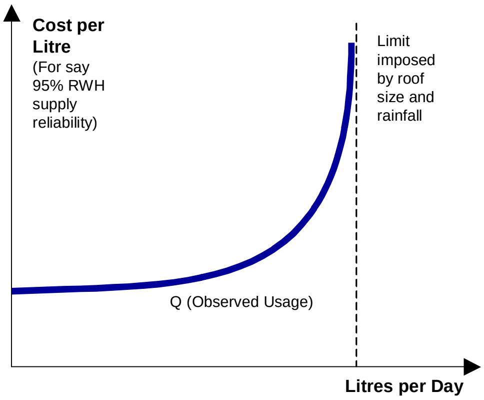


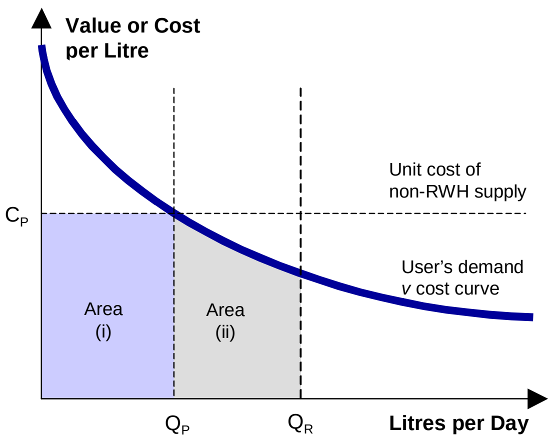
Sometimes we can find examples of water purchase and use them to infer the value of water. Richer households, or those experiencing illness, may pay for water to be brought to the house. More usually we have to infer costs indirectly through conversion of fetching distance/height into time and then time into money. Such costs, like the value of water discussed above, will be lower for poorer households than for richer ones.

5.3 Combining RWH with other water sources

For a given size and location of RWH system and for a given operating strategy, there will be a limit on the water it can supply per day, per week or per year. The maximum per year, corresponding to zero tank overflow, in litres will be the product of roof area (m^2), the annual rainfall (mm) and a run-off / capture factor (typically 0.85).

Consider first the situation where we can disregard seasonal factors, and assume that before RWH arrived, daily consumption from a point source was Q_P (litres/day). Q_P is determined by the interaction of the user's demand (cost v volume) curve and the unit cost C_P of supply from the point source. The daily cost to the user was therefore Q_P x C_P.

Figure 8: Value of rainwater



If the water Q_R available per day from RWH is *less* than Q_P, then the users will draw Q_R from the RW system and the remainder Q_P-Q_R from the point source. The total consumption will not increase and the effective value of the harvested rainwater will be the saving Q_R x C_P .

If the water Q_R available per day from RWH is *more* than Q_P, then the users will increase their consumption from Q_P to Q_R and the rainwater will be worth more than the former total cost Q_P x C_P. Exactly how much more will depend on the user's demand curve. The situation is represented in the diagram below, where Area (i) is the saving (Q_P x C_P) while Area (ii) is the value of the extra water.

Note that Q_R is the daily amount *available* from RWH, whereas Q_P is determined by the price of supply (from non-RWH sources). The total value Area(i) + Area(ii)) is less than (Q_R x C_P) because the extra water is per litre less valuable to the user than the water 'replaced'.

5.4 Seasonal effects and water management strategies

In the last section we ignored seasonal effects, although one can identify the condition $Q_R<Q_P$ as representing a dry season and $Q_R>Q_P$ as representing a wet one. However seasonality is central to the operation and performance of a RWH system. A user can choose to emphasise dry season security or alternatively to emphasise roofwater capture. To some extent the dry and wet season water needs are in competition with each other. Consider the following four water management strategies for an already built RWH system.

To make the strategies easier to visualise, assume a scenario typical of a homestead in the Great Lakes region where mean daily roofwater runoff is R = 100 litres). Assume that 'dry' weeks (runoff less than 350 litres per week) comprise 1/3 of each year and that the RW storage capacity is 700 litres (7 x R or '1 week'). This storage is only modest, but corresponds to perhaps 50 days drinking water or 14 days total water under very careful management.

Strategy 1 – *High Water Capture* – Water is withdrawn at a high rate, Q = 1.5 R, (e.g. 150 litres/day under our scenario) whenever it is available. This will result in fairly low occurrence of tank overflow, but leave little reserve for dry weeks.

Strategy 2 – *High Security* – Water is withdrawn at a low rate, Q = 0.5 R, (e.g. 50 litre/day) whenever it is available. Much water will overflow the tank, so annual capture will be low.

Strategy 3 – *Adaptive* – Water is withdrawn at a rate Q determined by how much is in the tank, thus:

Q = 1.5 R (e.g. at 150 lpd) if tank > 2/3 full;

Q = R if tank < 2/3 but >1/3 full;

Q = 0.5 R, if tank < 1/3 full.

Strategy 4 – *Maximum Security* – Water is saved for the dry seasons and drawn frugally (e.g. 50 litres/day) *only* after nearby point sources have run dry or after 2 weeks without rain.

The trade-offs involved between these alternatives are summarised in the following table, in which the word 'security' is taken to mean the fraction of days the demand is met by RW (the tank does not run dry). The factor K is the dry-season value of water (valued at its cost from the nearest point source) divided by its wet season value. Thus K=1 represents places where point-source water is unvarying through the year, whereas the extreme value K=10 represents places where in the dry months all local sources dry up, so water must be queued for, then carried from, very far away. A typical value of K in the humid tropics might be 2.

Table 3 suggests how we might account for seasonal differences in our economic evaluation, namely by assigning different wet and dry season values for water and operating the system to maximise their sum.

Table 3:System Performance under Different Operating Strategies

Strategy No	Annual consumption	Relative value of annual water harvested		Wet season security	Dry season security
		if K=1	if K=10		
1	high	high	med	high	v. low
2	low	med	med	high	low
3	medium	low	v. low	high	low
4	very low	med	med	nil	med

Table 4 represent the simulation of the four strategies applied to respectively a small DRWH system (storage volume V = 7 x mean daily run-off, R), a medium size system (V/R = 21) and a large system (V/R = 63). Daily rainfall data for 10 years has been used and a roof area of 45 m^2 has been selected to give the assumed mean run-off R = 100 litres/day. For Mbarara, the town used, the dry season (defined by rain in the last fortnight being under 50% of mean fortnightly rainfall) is 36% of the year.

Table 4: Relating RWH system performance to operating strategy and storage volume

Strategy number / type	V / R	Capture Efficiency	Tank Utilisation	Mean daily consumption Q in litres		'Security' (*S*) = fraction of days demand is satisfied by roofwater		
	tank size days	*E*	*U*	Q_1 *K*=1	Q_5 *K*=5	S_w Wet	S_d Dry	All year
Small tank,								
1 High demand High capture	7	**0.70**[1]	36.5	70	**95**	0.75	**0.22**	0.56
2 Low demand High security	7	**0.41**[3]	21.4	41	**80**	na	**na**	na
3 Adaptive	7	**0.66**[2]	34.4	66	**93**	0.94	**0.38**	0.74
4 Max security in dry seas	7	**0.17**[4]	8.9	17	**84**	na	**0.52**	na
Medium size tank								
1	21	**0.91**	15.8	91	**125**	0.90	**0.25**	0.67
2	21	**0.47**	8.2	47	**107**	na	**na**	na
3	21	**0.86**	14.9	86	**138**	1.00	**0.66**	0.88
4	21	**0.26**	4.5	26	**128**	na	**0.73**	na
Large tank								
1	63	**1.00**[1=]	5.8	100	**165**	0.92	**0.38**	0.72
2	63	**0.51**[3]	3.0	51	**123**	na	**na**	na
3	63	**0.99**[1=]	5.7	99	**203**	1.00	**0.98**	0.99
4	63	**0.37**[4]	2.1	37	**182**	na	**1.00**	na

Notes:
1. Data is for Mbarara, Uganda
2. Annual run-off = annual demand
3. na indicates strategy does not allow demand to be met.
4. Highlighted cells indicate best strategy or within 3% of best
5. Strategy 1 gives best $\mathbf{Q_1}$ (highest water capture)
6. Strategy 3 gives best $\mathbf{Q_5}$ (highest benefit if K = 5)
7. Strategy 4 gives best $\mathbf{S_d}$ (highest dry season security)
8. Strategy 3 is always best or second best by all measures.

‘Value’ is calculated assuming first litre per day is worth 1.5 falling via 0.5 at the 100^{th} litre to zero at the 150^{th} litre

Strategy 1 is to withdraw 1.5 times base demand when available (and otherwise what is available)

Strategy 2 is to withdraw 0.5 times base demand when available (and otherwise what is available)

Strategy 3 is to withdraw 1.5, 1 or 0.5 times base demand, according to amount in tank

Strategy 4 is to withdraw nothing in wet season and in dry season base demand when available (and otherwise what is available).As well as water supplied (column 5), a ‘weighted’ water supplied column is shown alongside in which effectively K = 5. This yields the weighting (a ‘wet season litre’ is a cost-equivalent volume): 1.0 dry season litre is deemed to be worth 5.0 ‘wet season litres’

The **bold** columns in the table contain the performance measures of most interest.

Column 3 shows ‘Capture efficiency’, (E) – a high value indicates that most of the roof run-off is being consumed.

Column 8 shows ‘Dry season water security’, (S_d) – the fraction of dry season that tank does not run dry and so demand has been satisfied; note however that under Strategy 1 the dry season demand is maintained very high at 1.5 R, whereas the other strategies are using demand of only 0.5 R for the dry season.

Column 6 shows weighted annual water consumption, Q_5, which is a measure that attempts to combine quantity, and security measures, by valuing wet season water much more highly than dry season water.

Examination of the top part of the table – which is for a small system with V/R only equal to 7 days – indicates that Strategy 1 (in which water is drawn generously whenever available) gives the highest annual water yield E, the lowest level of dry season security S_d, yet a high value for the seasonally-weighted yield W_e .

By contrast Strategy 4 (water is drawn sparingly and only in the dry season) gives the highest dry season security at the cost of the lowest annual yield. The seasonally-weighted yield is however also low. In fact we can dismiss Strategy 4 because even here, where per litre we have valued dry season water at *five times* wet season water, it still gives the lowest output valuation.

Strategies 2 and 3 are intermediate in performance, with Strategy 3 (adaptable) generally outperforming Strategy 2 (fixed low-demand).

From this table we can conclude that unless dry season water has exceptional value – e.g. it is per litre worth more than the 5 times wet season water assumed in the table – Strategies 1 (high usage) and 3 (adaptive) are superior to the other strategies.

The bottom band of the table is for a much more expensive system with 9 times larger storage. With such a large tank, the relative superiority of Strategy 3 is increased. We also see the benefit of the larger store. Comparing say Strategy 3 for the very large tank with that for the small one, we find a 50% increase in water harvested (E), a nearly 4-fold increase in dry season security (S_d) and under the assumed value ratio (K=5) a 120% increase in water value. Table 5 shows the variation in value of water harvested for varying values of K and for various sizes of tank. It confirms that small systems (V/R < 10 days) give a generally acceptable performance unless dry season water is deemed very much more valuable (e.g. K=5) than dry season water. Note the clear ‘diminishing returns’ with increase in tank size. If water value had been plotted against tank *cost* rather than tank *size*, the same pattern of diminishing returns would appear but with a slightly reduced strength.

A small system in the humid tropics, attached to a $50m^2$ roof, might be expected to harvest around 25,000 litres of water per year (say 75% of run-off), averaging about 90 litres per day in the wettest 8 months and 30 litres per day in the driest 4 months.

Table 5**:** Performance under Strategy 3 – Table showing variation of value ratio, capture efficiency and security with tank size

	dry:wet value per litre	Normalised tank size – V/R in days								
		1	3	5	7	14	21	30	60	90
Benefit ratio = value of water harvested ÷ value water demanded	if K=1	0.29	0.49	0.60	**0.66**	0.79	0.86	0.91	0.98	1.00
	if K=2	0.24	0.40	0.49	**0.53**	0.65	0.72	0.79	0.90	0.94
	if K=5	0.18	0.30	0.35	**0.38**	0.48	0.56	0.65	0.82	0.88
Capture efficiency		0.39	0.66	0.76	**0.82**	0.90	0.93	0.95	0.99	1.00
Security		0.15	0.41	0.57	**0.67**	0.81	0.86	0.90	0.98	1.00

Notes:
1. Under this strategy the demand is varied from 0.5 to 1.5 times the mean daily runoff according to how much water remains in the tank
2. V/R is tank size (normalised to mean daily run-off); K is dry-to-wet season water value ratio; the bold column shows the performance of a typical very-low-cost RWH system

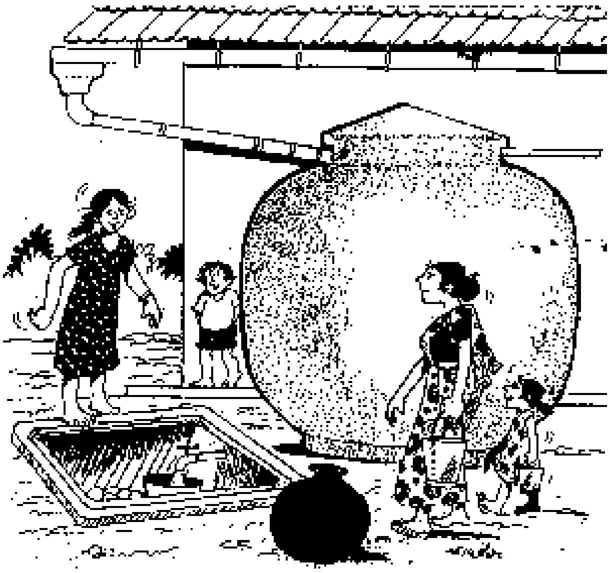
6 ANALYSIS OF EXISTING TANK DESIGNS

In the course of the project a number of tank designs have been investigated by the RHRG. These have been written up as "case studies" and are available on the project web site at:

www.eng.warwick.ac.uk/dtu/rainwaterharvesting/casestudies.htm.

A summary of these designs is set out below

6.1 The Pumpkin Tank, Sri Lanka



The Sri Lankan Pumpkin Tank, and the associated construction technique, was developed as part of a World Bank sponsored Water and Sanitation Programme that was implemented in the country between 1995 and 1998. The Community Water Supply and Sanitation Programme (CWSSP) covered 3 districts within the country – Badulla, Ratnapura and Matara Districts. Hundreds of these tanks have been built in areas where conventional supply schemes, such as piped supplies or groundwater supplies, were difficult to provide.

Catchment (typical) – $32m^2$

Storage – 5 – 7 m^3

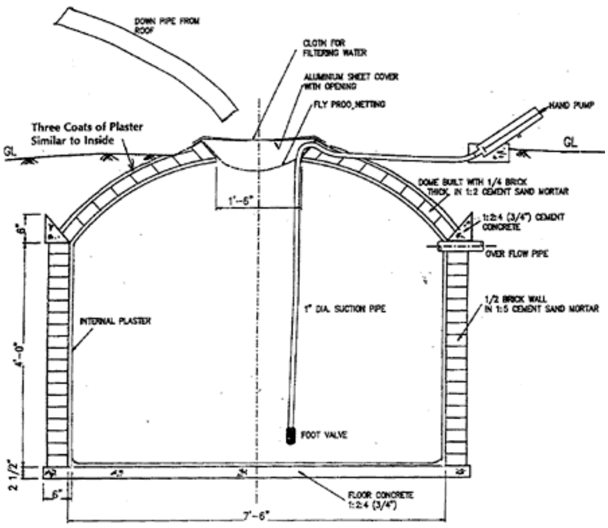
Storage cost - £112 (skilled labour - £19, Unskilled, £21 unskilled)

Material - ferrocement

Lessons

- Doubly curved structures
  - Material economies
  - Specialised techniques needed
  - Ferrocement construction
  - Use of mould for many tanks

6.2 Underground brick dome tank, Sri Lanka



This is another RWH system which was developed by the CWSSP programme in Sri Lanka. The tank, a $5m^3$ underground brick built tank.

Catchment – $28m^2$

Storage – $5m^3$

Storage cost - £125 (skilled labour - £15, Unskilled, £28 unskilled)

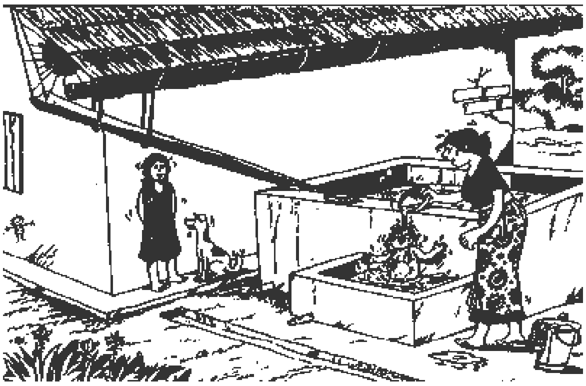
Material - Brick

Lessons

- Brick tank construction
  - Less skilled
  - *but* used as much cement as pumpkin tank

- Brick dome roof
- Low cost pumps for water extraction

6.3 Brick built storage tank, Sri Lanka



This is an example of local initiative in design and manufacture in DRWH. The tank in question was constructed in the village of Ahaspokuna, near Kandy, in the highlands area of Sri Lanka. The tank was built 10 years ago by a local mason for the Rajasomasari family and has since been copied so that there are now several of these tanks in the area.

Catchment – 90m^2

Storage – 3m^3

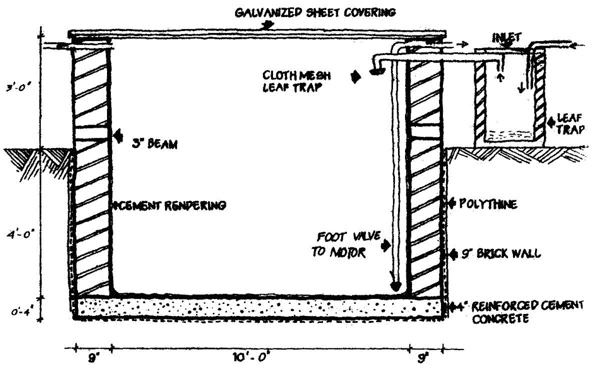
Storage cost - £80 (est.)

Material – Brick with cement render

Lessons

- Square construction
  – Good for bricks
  – Simple for local labour

6.4 Partially below ground brick built tank, Sri Lanka



This tank was built by Mr G. Victor A. Goonetilleke in the hill town of Kandy,. Mr Goonetilleke decided to build his RWH tank after experiencing difficulty in sinking a well to sufficient depth to have a reliable perennial source of groundwater at the site of his newly built home.

Storage – 10m^3

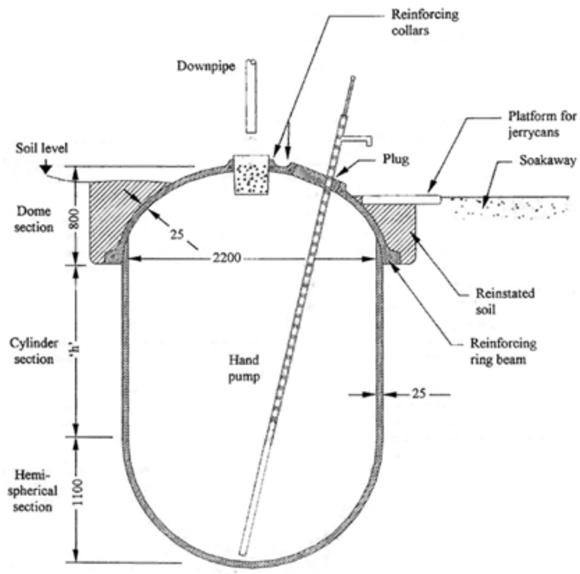
Storage cost - £550

Material – Brick with cement render

Lessons

3 Partially below ground construction – many of the advantages of below ground construction but with several of the advantages of above ground construction

6.5 Underground storage cistern – 4 to 10 cubic metres, Uganda



This tank (or cistern) was developed in Uganda by members of the Development Technology Unit, Warwick University and members of the Uganda Rural Development and Training Programme (URDT), between 1995 and 1997. Work is still continuing on the refinement of the tank. URDT is a service NGO located at Kagadi in Mid-Western Uganda. Several of these cisterns were built and tested with the aim of developing a low cost (under US$150), alley, domestic, water storage technology for the surrounding region.

Catchment – Varying

Storage – 4-10m^3

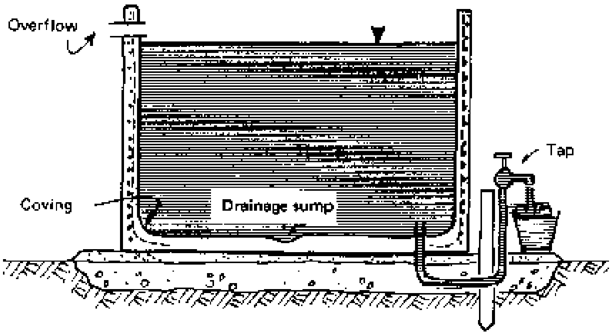
Storage cost – £90 (8m^3)

Material – Cement Mortar

Lessons

- Underground tanks – very thin walls are possible in appropriate soil
- Unreinforced mortar dome roof – lower cost due to no steel
- Ground as formwork – reduced cost amortisation of formwork

6.6 Ferrocement water tank using former



Used for many years in parts of Africa these tanks have been designed to be as simple as possible to build in self-help programmes. The users, who are at first unskilled in this sort of construction, can contribute their time and efforts in collecting sand and water, digging the foundations and preparing the mortar under the general guidance of a trained builder. With experience they quickly learn how to make the tanks without further guidance. A trained builder with 5 helpers takes approximately 3 days to complete the tank. The users often contribute some money towards the cost of the tank, which helps to cover the builders' wages, the cement, reinforcement and the hire of the corrugated iron formwork

Catchment – Varying

Storage – 10m^3

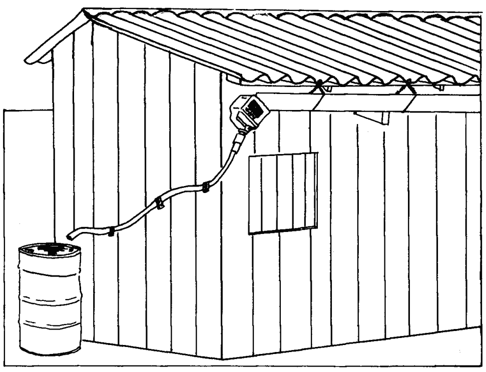
Storage cost – £90 (8m^3)

Material – Ferrocement

Lessons

- Reusable formwork with built-in depth gauge (corrugations)
- Adapted from successful commercial design from New Zealand
- Wire reinforcement graded through structure (more on bottom)
- Reinforcing from base to walls and filleted base join to avoid cracking at base

6.7 RWH in the barrios of Tegucigalpa, Honduras



Health statistics show that the residents of the barrios are suffering from a number of water related diseases that could easily be avoided with provision of a reliable, clean water supply. Unfortunately, more than 150,000 residents have to find their own water. Although technically unsophisticated and lacking some good health practice, the systems show what urban settlement have done to improve their own lot. Many of the systems make use of recycled or scavenged materials and some examples show high levels of initiative.

Storage – $0.2m^3$ used barrels (up to 3) or $1\text{-}2m^3$ open concrete tanks

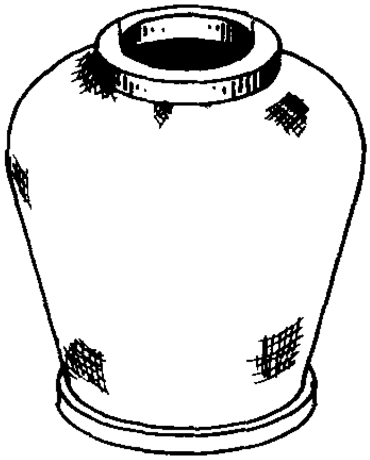
Storage cost – £10 (drum) - £18 “small tank

Material – Steel drum or plastered bricks

Lessons

- Impact of very small storage
- Use of available containers

6.8 Tai Jar



This type of water vessel was originally developed for a large country wide programme in Thailand that has installed over 10 million jars. Small jar making became a successful business with many companies producing up to 30 jars a day. The design has also been adopted in East Africa and South Asia

Storage – $0.5\text{-}2m^3$

Storage cost – £ 30 for a $2m^3$ jar

Material – Pottery or cement

Lessons

- Small tanks used modularly – several houses have more than one and up to 10 are used commercially
- Mass production – lead to much cheaper tanks
- Critical mass – the programme grew exponentially and became self sustaining within a few years

6.9 Plastic Lined tanks

Several experiments have been done using plastic sheets as a waterproof membrane in an otherwise wholly traditional structure. The bamboo tank developed by ARTI in Pune India uses a polythene sheet in a basket structure that is traditionally used for grain storage. In East Africa Rwandan refugees have used a tarpaulin distributed by UNHCR as a liner for an underground tank over which a wattle and daub enclosure is built to protect the water.

Lessons

- Small, portable imported input bolstering principally local technique – greatly reduced cost
- Some questions of durability

6.10 Summary

Table 6: Summary analysis of case study material

7 RHRG RESEARCH INTO MEANS OF REDUCING TANK COSTS

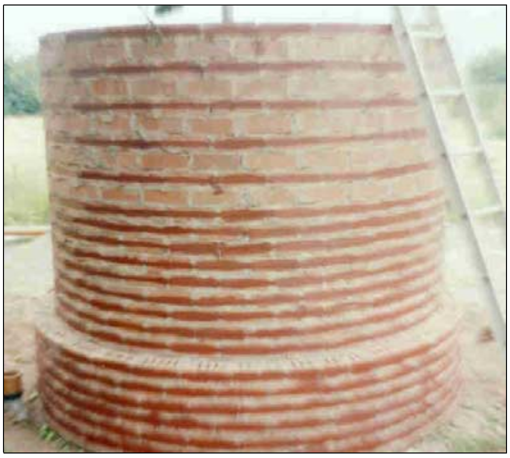
7.1 Research strategy

Having collected information on existing rainwater systems and identified probable areas for design improvement, the RHRG has developed several cheaper tanks, concentrating on materials substitution and material reduction while working mainly with smaller tanks suitable for incremental adoption. The main materials investigated have been:

- Rammed Earth
- Stabilised soil blocks
- Bricks
- Plastic linings

Various underground tanks have also been developed mainly on the partly below ground model. A lift-on tank cover has also been developed to remove the need for formwork from the cover making process.

7.2 Use of externally reinforced bricks



Brick is a material that is used widely in developing countries and is thus readily available. It is ideally suited to wall construction, but not quite so well suited to conventional larger volume tank construction. As it;

- has a poor strength in tension
- has a poor adhesion one brick to another through the mortar and so tensile forces must be spread through the brick runs which will be in sheer with one another
- can need more cement than an equivalent Ferrocement tank due to poorly fitting bricks

One way of improving the suitability of brick to low cost tank manufacture is by using external steel reinforcing to give additional hoop strength to cylindrical brick tanks. If an empty circular tank is wound with steel reinforcing wire on the outside, and the wire is then tightened, we will achieve ‘post tensioning’ whereby the masonry (brick/concrete) is initially in compression and the steel in tension. Putting the steel on the outside not only facilitates the post-tensioning but also makes it easier to protect the steel from being rusted by seepage from inside the tank. Filling the tank with water will result in a lowering of the compressive stress and strain in the mortar and an increase in the tensile stress and strain in the steel. One such tank has been built and was detailed in Milestone Report A2

The technique holds some promise as it is easy to implement, however there is some doubt over the availability of tensioning tape as described in the report. It should, however be possible to use galvanised wire for this purpose although more will be necessary due to its lower tensile strength.

Table 7: Pros and cons of brick tanks

Pros	Cons
• low material cost • suitable material readily accessible locally in many parts of the world • a well-known and widely-used technology in many parts of the world • a simple technology that is easily taught to semi-skilled people	• not ideal for round tanks as extra mortar or special angled bricks are needed • Poor in tension – Needs reinforcing or very thick walls

7.3 Use of rammed earth

The use of rammed earth has been the subject of a previous report to the EU (Milestone A5: *Stabilised Soil Tanks for Rainwater Storage*, submitted September 2000) so only a brief summary will be presented here.

Rammed earth is a technique which is experiencing a resurgence of interest, particularly in developing countries where cement is expensive and in "green" architecture where its low energy use and excellent thermal properties are particularly appreciated. The technique has been used for centuries for the construction of houses many of which are still standing, attesting to its stability and longevity.

Just as it's name suggests this technique involves earth being rammed between two shutters, using a rammer or tamp. The shuttering is removed to reveal the wall. Walls are usually constructed in sections of a few feet long by a foot or two deep with shuttering moved along to form a continuous wall. The shuttering is then raised and placed on top of the first 'lift' to construct the subsequent 'lifts'.

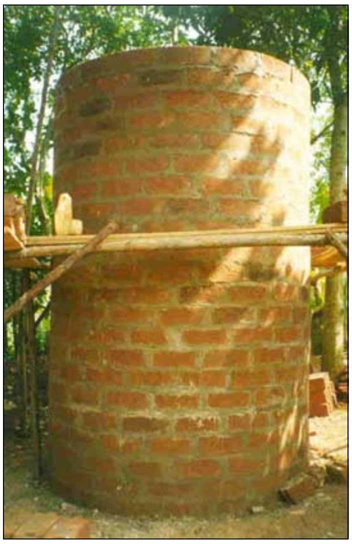
Several experiments with rammed Earth have been undertaken by the RHRG both in the lab and in the field. The material has proved capable of withstanding the forces typical of a tank however there are some practical problems. The pros and cons of Rammed earth tank construction are listed in table

Table 8: Pros and cons of rammed earth tanks

Pros	Cons
• very low material cost • suitable material readily accessible locally in many parts of the world • a well-known and widely-used technology in many parts of the world • a simple technology that is easily taught to semi-skilled people	• not suitable for below-ground tanks or cisterns • in the case of leaks serious problems can develop, especially if unstabilised earth is used • high labour input

The main problem with rammed earth is its wet strength. The tank must be fitted with a waterproof lining to hold the water. If this liner becomes damaged and *any* water leaks, then the tank will almost certainly fail as any water ingress will ultimately seep out along with some soil, this process is continued until a hole forms ultimately growing large enough to destroy the tank's structural integrity.

7.4 Use of stabilised-soil



Stabilised soil has also been covered in a previous report (Milestone A5: *Stabilised Soil Tanks for Rainwater Storage*, submitted September 2000)

Stabilised, compacted, soil block technology involves compacting a suitable soil, which is often mixed with a small percentage (typically 5 – 10%) of cement, using a manual or hydraulically assisted ram or press. This compaction reduces the voids in the material and hence it susceptibility to attack from water. Special moulds can be manufactured to produce blocks of different shapes for special purposes.

Work has been carried out on stabilised soil blocks for tank construction in two locations (Uganda and Sri Lanka) In the case of the cylindrical tanks manufactured in Uganda, curved blocks were produced. For a cylindrical above-ground tank. In Sri Lanka a square underground tank was produced.

The Uganda work involved the building of two experimental cylindrical water tanks in collaboration with Dr Moses Musaazi, a lecturer at Makerere University. Both were built above ground of curved stabilised-soil blocks with end interlocking, 280mm x 140mm x 110mm high, made with an Approtec

(Kenyan) manual block press. The soil used was a red somewhat pozzolanic local soil previously known to make strong blocks. The tanks were built on concrete plinths, lined with ‘waterproofed’ mortar (3 parts sand, 1 part cement and .02 parts ‘Leak Seal’ waterproofing compound). There was no metal reinforcing.

Tank 1 was 2m high, with an internal diameter 1.3m, wall thickness 140mm (+ 15mm render) and used blocks incorporating 6% cement. It has been filled with water and briefly withstood a maximum head of 2.m at the wall bottom before failing catastrophically (and spectacularly). 2, for test purposes, has been built to 5m high, has internal diameter 1.0m and the same wall thickness, but with only 3% cement. It has been filled with water and therefore withstood a head of 5.0m at the wall bottom. The inconsistency of the result could be attributed to an undersupply of cement to the blocks which made up tank one resulting in a low wet strength, coupled with a cracking of the mortar used to line the tank.

The pros and cons of stabilised soil construction tank construction are listed in table 7

Table 9: Pros and cons of rammed earth tanks

Pros	Cons
• Reduced cement content resulting in inexpensive blocks •	• Low wet strength • Reduced cement content must be balanced against lower strength requiring thicker walls • Needs specialised tooling for compacted blocks • Low tensile strength of block joints

7.5 Lining tanks with plastic bags

Plastic linings can considerably reduce the cost of the tank by removing the need for any building work to be watertight. Indeed they can be simply placed in a hole to form a very cheap and portable tank (although a cover should be constructed). Plastic liners also allow removal for inspection, cleaning, maintenance and occasional repair.

Work on plastic linings by the RHRG includes the development of a technique for welding 250 micron construction or damp proof membrane (DPM) plastic sheet to make ‘bags’ (similar to large bin liners) that fit inside the tank structure to form a waterproof lining. The welds themselves have proved successful with the weld both watertight and stronger than the plastic itself. The technique uses simple tools and can be taught in a couple of hours to a reasonably skilled craftsperson. One skilled person should be able to make a bag in a single day and productivity can be greatly enhanced by batch production. However, while the welding technique has been successfully developed, there are still problems to be overcome in relation to the quality of ‘off-the-shelf’ plastic sheet and failure of the lining due to abrasion. Observations in the field suggest that plastics with a woven structure may be more resilient, however these will not weld with the technique developed at Warwick.

The availability of plastic tubes from local markets is quite wide spread and a 600litre "plastic tube tank" was also developed in the course of the project. Details of this tank can be found in DTU Technical Release *TR-RWH08 Plastic Tube Tank (600 litres) – Instructions for manufacture*. (Rees & Whitehead, 2000b)The 87cms diameter tube is the largest that was found at the time but the design could be easily modified for different sizes of tube. The tank is based on the partly below ground concept and consists of a brick parapet wall, which incorporates the inlet basin and handpump and the lower section ground excavation, lined with two plastic liners one inside the other. The tanks have developed slow leaks reducing their effectiveness but are still holding water and making a significant contribution to household water where they have been installed.

Table 10: Pros and cons of plastic linings

Pros	Cons
• Greatly reduced cost • Portable • No clambering on or in the tank is required during construction. • No curing time is required. • Can be removed for cleaning./inspection • Can be batch produced	• Fragile – likely to tear, subject to pin holes • UV degradation • Joining requires specialised techniques

7.6 Simple underground tanks in stable ground

The RHRG has also experimented with creating underground tanks using stabilised soil with bamboo reinforcing and a plastic liner for waterproofing. The work (undertaken by the Open University in Sri Lanka) .The tank was designed to contain 3600 litres of water. It is trapezoidal with 100cm x 100cm square cross-section at the top and 80cm x 80cm square cross-section at the bottom of the tank. Strips of bamboo are used both as a support to the tank walls and to protect the lining material, which is 500 gauge polythene sheet. During the development soil samples were tested for strength and durability and a 1:12 cement:soil ratio was found to be optimum with the local soil. This will, however differ with location.

The problems of covering such pits can still cause cost problems absorbing more than 2/3 of the cost of such a tank. Tanks have also been broken due to raising water table, punctured by tree roots and are vulnerable to infiltration by runoff.

Table 11: Pros and cons of simple underground structures

Pros	Cons
• Greatly reduced cost as surrounding ground gives support allowing lower wall thickness. • More difficult to empty by leaving tap on • Can be made unobtrusive	• Water extraction is more problematic – often requiring a pump • Leaks or failures are more difficult to detect • Contamination of the tank from groundwater and surface runoff • Tree roots can damage the structure • There is danger to children and small animals if tank cover is left off • Flotation or breaking of the cistern can occur if groundwater level rises

7.7 Partly-below-ground tanks

Several of the problems of underground tanks can be overcome by siting the tank partly above ground and partly below ground. These tanks have been described in Milestone Report A3. Details can also be found in the DTU Technical release *TR-RWH 01 Partially Below Ground (PBG) Tank for Rainwater Storage – Instructions for Manufacture,* (Rees, 2000b) available at: the DTU website. Over 20 of these tanks have been built in East Africa and feedback suggests that the tanks are easy to construct by masons with some training, at a reasonable cost.

Table 12: Pros and cons of Partially below-ground tanks

Pros	Cons
• Lower material requirements • Difficult to empty by leaving tap on • Reasonably unobtrusive • Surrounding ground gives support allowing thinner walls and thus reduce costs	• Requires a pump • Leaks or failures are difficult to detect • Contamination of the tank from is possible • Tree roots can damage the structure • Flotation of the cistern may occur

7.8 Lift-on tank covers

The lift on tank cover developed by the RHRG has been detailed in Milestone Report A2 and in DTU Technical Release *TR-RWH 04 – Low-cost, thin-shell, 2m diameter ferrocement tank cover - Instructions for manufacture (Rees, 2000a).* The thin-shell ferrocement tank cover is designed in such a way that it can be manufactured without the use of a mould or shuttering. It can also be manufactured remote from the tank to which it is to be fitted and moved into place once complete. The aim is to reduce the cost of the tank (cover) by eliminating costly shuttering or moulds and by reducing the quantity of material used to manufacture the cover. It also means that the cover can be removed at a later date for maintenance, refurbishment or cleaning. The cover can be manufactured by two persons (one skilled and one unskilled) in a single day (with some time required after that for curing) using tools required for the construction of a simple cylindrical ferrocement tank.

The design is based on a frame known as a reciprocal frame, that has spokes that, when loaded, put little radial loading onto the structure on which it sits. The frame is covered with a wire mesh that is then rendered with a sand cement mix.

Table 13: Pros and cons of lift on lank covers tanks

Pros	Cons
• low cost – reduced use of materials • no shuttering or mould required • strong and lightweight – the tank cover is designed to be strong (through good quality control) and light at the same time • good quality control can be achieved through easy working environment • can be manufactured by two people in a single day (one skilled and one unskilled) • no clambering on top of tanks required during construction • can be cured easily – in the shade and at ground level • can be batch produced at one site	• Needs skilled craftspeople • Needs good quality control to be effective • Available in one-size-only as frame angles must be recalculated for other sizes

8 COSTS ANALYSIS OF RWH TANKS

The aim of this exercise is to compare tanks from different parts of the world and to carry out a costing exercise so as to assist those considering DRWH to make an informed choice. Such choices are usually complicated by the fact that material costs, labour costs, per capita income, currencies and exchange rates all vary from one country to another. Cost of storage per litre also varies as tank size increases. To take into account this variability an effort has been made to normalise some of the figures.

- 8 tanks have been costed for each of three countries i.e. Uganda, Sri Lanka and Brazil using bills of materials from the designs and material cost information obtained from each of the countries in 2000/2001.
- All tank costs have been converted to $5m^3$ equivalent using sensitivity to size of 0.6.

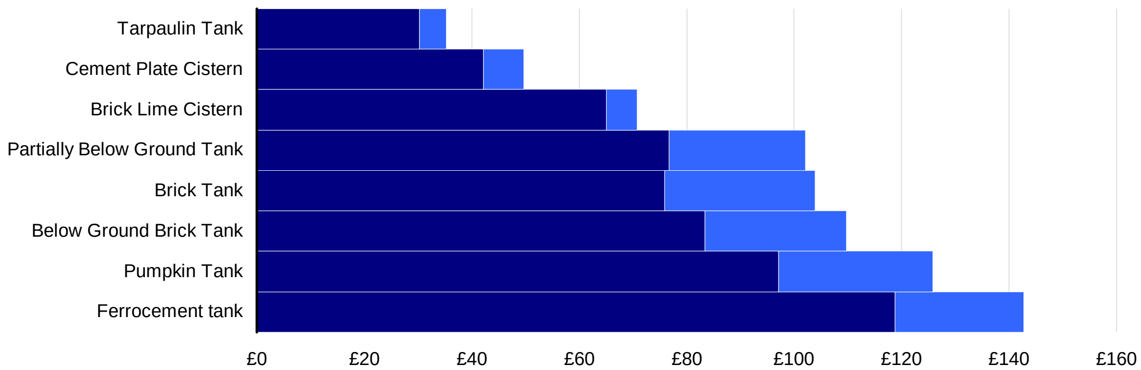
The tanks under consideration are taken from 4 countries in 3 continents. The countries are Kenya, Uganda (Africa), Sri Lanka (Asia) and Brazil (South America). The tanks are listed in Table 14 and the final costings are in Figure 9

Table 14: Tanks used for costing exercise

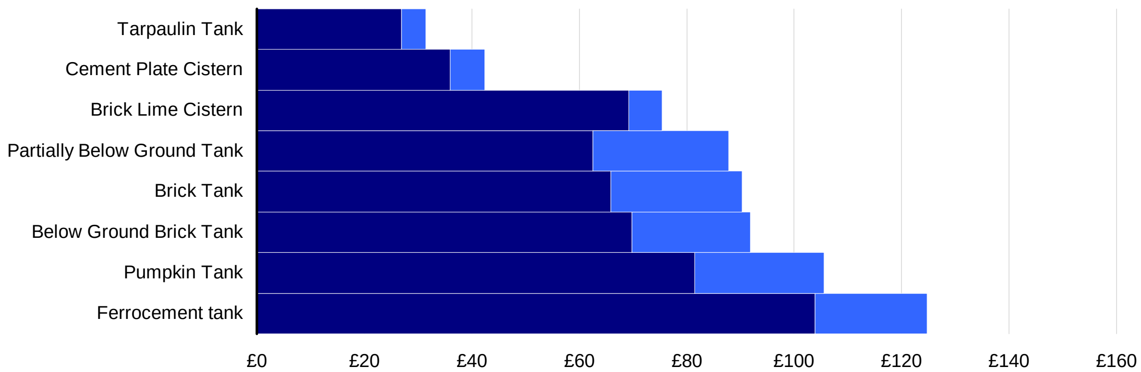
	Tank name	Tank size(s)	Source of information
1	PBG Tank	10,800 litres (size can be varied)	DTU Technical Release 01
2	Ferrocement tank	3,000 and 11,000 litres	Eric Nissen-Peterson, ASAL, Kenya (Nissen-Petersen & Lee, 1990)
3	Small brick jar	750 litres	DTU Technical Release 07 (Rees & Whitehead, 2000a)
4	Tarpaulin tank	4,000 – 5,000 litres	ACORD, Uganda and DTU Web Page
5	Ferrocement Pumpkin Tank	5,000 litres	Lanka RWH Forum and CWSSP Reports, Sri Lanka (Hapugoda, 1995)
6	Below ground brick tank	5,000 litres	Lanka RWH Forum and CWSSP Reports, Sri Lanka (Hapugoda, 1995)
7	Cement Plate Cistern	10,000 and 20,000 litres	Johann Gnadlinger, IRCSA. Data from Juazeiro, Bahia State, 1998 (Gnadlinger, 1999)
8	Brick lime cistern	10,000 and 20,000 litres	Johann Gnadlinger, IRCSA. Data from Juazeiro, Bahia State, 1998 (Gnadlinger, 1999)

Figure 9: tank costs in three countries

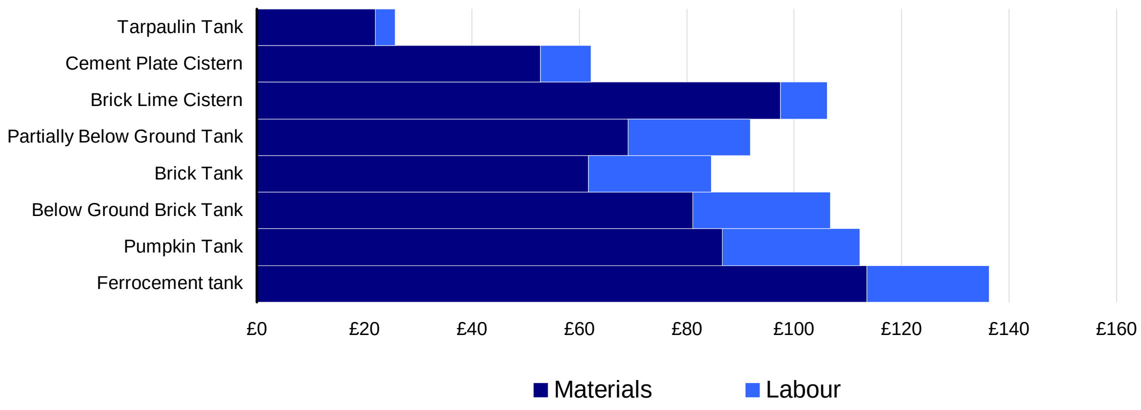
a Brazil



b Sri Lanka



c Uganda



As can be seen the cost of building the tanks differs by quite some margin:

- The traditional ferrocement tank fares most badly, this is probably due to the design being quite old and suffering many years of "improvements" at various hands
- The Pumpkin tank would appear to provide some savings mainly through its more optimised shape and also due to the youth of the design
- The partially below ground tank also provides good economies with reduced material usage and similar labour costs to other cement tanks
- The brick tanks show some materials savings but a slightly higher labour content tends to favour countries where labour is cheap and materials expensive such as Uganda
- By far the cheapest tank is the tarpaulin tank, due in part to its extensive use of "free" local materials and also because of its quick construction
- The cement plate cistern is also an inexpensive option particularly in countries with cheap cement such as Brazil and Sri Lanka. Its unique construction using closely controlled sections of concrete assembled together on site results in substantial savings in material thickness. In more developed countries, this would be an excellent option as it is both durable and desirable as a household asset

Further insight is gained by discounting the labour content of the tanks as the community itself can often provide this. The Brick lime cistern is a case in point here. In Sri Lanka it is a fairly inexpensive option, however its low labour content means that for a self-help project it is less attractive (in Uganda it is the second most expensive in terms of material use!).

9 CONCLUSIONS

Rainwater harvesting tanks represent a mature technology. Their use goes back many centuries and development has been going on throughout history. This does not mean, however, that there is no room for improvement of the technology. Modern techniques and materials have great potential for the manufacture of rainwater tanks. Some of the most promising areas for cost reduction are:

- Plastic bag tanks such as the tarpaulin tank and the DTU tube tank
- Mass produced parts such as the cement plate cistern and lift on covers

- Partially below ground structures to combine the economies of below ground tanks with the safety and desirability of above ground tanks
- Considering the diseconomies of scale inherent in large tanks and using smaller tanks to provide partial supply or seasonal supply.

In considering cost reduction local conditions play a large part.

- Labour and material costs vary widely throughout both the developing and developed world resulting in different designs becoming cheaper
- Conditions may favour one design over another e.g underground tanks are only suitable for areas with stable soils and low water tables, plastic bag tanks are only suitable where insects are not a problem

These caveats notwithstanding the designs tried within the EU programme and many encountered in the field have demonstrated the cost of tanks can be significantly lowered. Domestic rainwater harvesting remains almost unique in that it allows householders to provide their own water supply without the need to wait for outside intervention and the challenge is to produce a system within the means of every household. With appropriate dissemination, the designs presented in this paper should go some way toward this.

ACKNOWLEDGEMENTS

The preparation of this thesis was a result of both direct investigations and wide ranging consultations involving a number of people.

While one cannot mention everybody, I would like to specifically record and express my deep gratitude and sincere appreciation to the following:

- Dr. Terry H. Thomas, my research supervisor for his many constructive inputs and invaluable help. His approach and guidance enabled me to remain focussed on the correct track right from the beginning of the research to the very end. Without his constant support and timely interventions, this thesis would have been difficult to accomplish on schedule.
- Professor Peter Carpenter, Dr. Phil Purnell and Dr. Derek Petley, all of the School of Engineering who variously contributed to making the research experience at the University of Warwick a worthwhile pursuit.
- Mr. Colin Banks, Mr. Tony Smith and Mr. Graham Conham for their help in allowing me to use their specialised laboratory space and equipment while conducting the main experimental investigations. Pam Paterson for all the time spent on streamlining the whole thesis.
- Dr. Jackson Mwakali, Dr. Mosses Musaazi and Dr. Barnabas Nawangwe of Makerere University for their contributions during the fieldwork. Further appreciation also goes to Engineers Kimeze Ssebbugga and Wilfred Okello both of the Central Materials Laboratory of the Ministry of Works and Housing in Uganda for assisting me with the documentation as well as inspection of CSB structures in the country.

- Members of the Commonwealth Scholarships Commission in the United Kingdom for sponsoring me; the Central Scholarships Committee in Uganda for nominating me; and Professor John Ssebuwufu, Vice-Chancellor of Makerere University for strongly recommending me for the award.

I remain deeply indebted to you all and to those yet unnamed collaborators who also assisted me during the course of study.

DECLARATION

This declaration serves to confirm that this thesis is the original and exclusive work of the author alone. The thesis does not include either in part or in whole, any previous material submitted by any other researcher in any form not acknowledged as required by existing regulations. No material contained in this thesis has been used elsewhere for publication prior to the production of this work.

This declaration also formally affirms that this thesis is being submitted for the degree of Doctor of Philosophy of the University of Warwick only and not to any other similar institutions of higher learning for the same purposes.

DEDICATION

This thesis is especially dedicated to the following:

My father, Claudio, and mother, Sylvia	-	for their extraordinary foresight, devotion, and sacrifice in educating all their children.
My wife, Hilda and children, Brian and Rupert, and to all my brothers and sisters	-	for their love, support and patience.

ABSTRACT

Adequate shelter is a basic human need, yet about 80% of the urban population in developing countries still live in spontaneous settlements as they cannot afford the high cost of building materials. The compressed and stabilised block (CSB) has been identified as a low-cost material with the potential to redress the problem and reverse the shelter backlog. While its other properties are well understood, the durability of the material remains enigmatic. The principal objective of this research was therefore to investigate the durability of CSBs, especially as used in the humid tropics.

The thesis examines the interplay between three main factors: constituent materials used (cement, soil, water); quality of block processing methods employed; and the effects of natural exposure conditions (physical, chemical, biological). Through a multi-pronged methodology involving literature reviews, laboratory experiments, petrographic analysis and an exposure condition survey, block properties and behaviour are rigorously investigated. The findings are presented under the two main division of the thesis: Part A and Part B.

Part A introduces a review of the literature on the main theoretical concepts of durability and cement-soil stabilisation. It discusses various deterioration modes, and examines in more detail mechanisms of stabilisation using Ordinary Portland cement. Part A also identifies and highlights critical stages of the CSB production cycle, and recommends a strict adherence to proper testing and processing procedures.

Part B presents the results of direct investigation methods used. Findings from the fieldwork confirmed that premature deterioration was widespread in exposed unrendered blocks, with defects exhibited mainly as surface erosion and cracking. Quality checks on site materials and practice established an urgent need for improvement through the provision of appropriate standards and codes. Laboratory experiments which compared the properties of traditional blocks (TDB) and blocks improved by the inclusion of microsilica (IPD), established that the latter significantly out-performed the former. A new quick predictive surface test, the slake durability test, which is more reliable and repeatable than existing tests, is proposed.

The thesis concludes that it is possible to significantly raise the strength, improve the dimensional stability and wear resistance of CSBs to the extent that they can be safely used in unrendered walls in the humid tropics. This improvement is achieved via better intergranular bonding, reduction in voids and lowered absorption. Using the slake durability test, it is now tenable to freely discriminate, classify, and compare not only blocks but other like materials of any category and storage history as well. New quantitative durability gradings are recommended for future incorporation into CSB standards. The findings are likely to contribute to the widespread use of CSBs. The research, however, also raises a number of new questions which are listed for further work.

MPa	=	Mega Pascal

MS	=	Microsilica
Mwc	=	Mix-water content
MWS	=	Mid wall section
NAB1	=	Namuwongo abandoned building 1 (8 years)
NAB2	=	Namuwongo abandoned building 2 (12 years)
NFF	=	North facing façade
OBS	=	Ordinary builders sand
OMC	=	Optimum moisture content
OPC	=	Ordinary Portland cement
PFA	=	Pulverised fuel ash
PSD	=	Particle size distribution
RBS	=	Rock block sample
RPC	=	Rapid hardening cement
S	=	Amorphous silica
SDI	=	Slake durability index (also I_d)
SDT	=	Slake durability test
SFF	=	South facing façade
SL	=	Service life
Soil 'S'	=	Artificial laboratory blended soil
SSA	=	Specific surface area
SSC	=	Soluble salts crystallisation
ST	=	Soil type
TDB	=	Traditional block
TVP	=	Total volume porosity
TWA	=	Total water absorption

UCR	=	Unhydrated cement residues
UWS	=	Upper wall section
w/c	=	Free water to cement ratio
WAD	=	Wetting abrasion and drying
WCS	=	Wet compressive strength
WFF	=	West facing facade

CHAPTER 1

INTRODUCTION

In Chapter 1, the background to the research, its aims and objectives, methodology used, and the structure of the thesis are described.

1.1 BACKGROUND TO THE RESEARCH

This section presents in outline form the general context in which the research is based, namely a brief history of compressed and stabilised blocks (CSB), their advantages, and the problems that have emerged since their introduction.

The majority of developing countries are today faced with an ever increasing problem of providing adequate yet affordable housing in sufficient numbers. In the last few decades, shelter conditions have been worsening: resources have remained scarce, housing demand has risen and the urgency to provide immediate practical solutions has become more acute. Adequate shelter is one of the most important basic human needs, yet 25% of the world's population does not have any fixed abode, while 50% of the urban population live in slums (ESCAP/RILEM, 1987; ILO, 1987). Indeed 80% of urban settlements in developing countries consist of slums and spontaneous settlements made of temporary materials (Keddi & Cleghorn, 1980; ILO/UNIDO, 1984). With the population in developing countries growing at rates of between 2% and 4% per year and the population in their major cities growing by double these figures, demand for low cost housing far outstrips the capacity to supply (UNCHS, 1981). No developing country without strategies for low cost materials is likely to meet its shelter targets (Webb, 1983; Hamdi, 1995).

Developing countries planning to expand their housing stock for the low-income groups will inevitably need to identify the lowest feasible unit housing costs. The main costs of shelter provision are for building materials (about 60%), machinery, manpower and loan interest repayments (BRE, 1980; Ashworth, 1994; Maclean & Scot, 1995). Strategies are therefore urgently needed to develop low-cost, readily available and durable building materials. A naturally abundant material such as soil that is found on most of the surface of the earth should be a significant resource for building in developing countries.

Research and development of stabilised soil as a building material is not new. The use of CSBs can be traced back 50 years (Fitzmaurice, 1958; Enteiche & Augusta, 1964; Fathy, 1973; Webb, 1988). From the early 1950s attempts were made to develop the material as an alternative walling unit to the modern and more expensive fired bricks and concrete blocks. The promotion of the material was originally introduced via the United Nations (UN Bulletin No. 4, 1950; Fitzmaurice, 1958). The idea of compacting earth to improve its quality and performance in the form of moulded blocks however dates back to the 18^{th} Century (Houben & Guillaud, 1994). The addition of a binder to stabilise the soil is more recent.

Apart from the early work of the United Nations, the history of the spread of the CSB is not well documented. During the 1950s use of the material was widely disseminated worldwide. The 1960s and early 1970s were however stagnant years. This was to change with the 1976 Vancouver Assembly of the United Nations Conference on Human Settlements (UNHCS, 1976; UNIDO, 1980). Noting with concern that the worlds population was expected to double by the year 2000, and worse still, to quadruple by the year 2030 (representing the largest single population growth in human history), the conference resolved to focus on the development of low-cost housing. Further momentum was to be given 12 years later following the declaration of the year 1987 as the International Year of Shelter for the Homeless (UN/IYSH, 1987). Subsequent proclamations were to follow in 1988 under the theme 'Global Strategy for Housing by the Year 2000'. The key targets of these resolutions were the guaranteed access to decent and durable housing for all from the beginning of the new millennium. Renewed world-wide interest was soon to provide an immense impetus that has ensured the now vibrant spread of CSBs throughout the developing world. It was within this international context and drive that the author became involved with the material in 1987 following the donation to Uganda in that year of several block presses and ancillary materials by the International Labour Organisation (Okello, 1989; Schmetzer & Kerali, 1994; Kerali, 1996).

Continued interest in CSBs will in future evolve around the several merits and attractions associated with its use. Firstly, as the basic raw material is soil, its source will remain abundant. This facilitates direct site-to-service application, thereby lowering costs normally associated with acquisition, transportation and production. Home ownership can then be delivered at comparatively low costs. Secondly, the initial performance characteristics of the material such as the wet compressive strength (WCS), dimensional stability, total water absorption (TWA), block dry density (BDD) and durability are technically acceptable. They are also comparable to those of rival materials (ILO, 1987; Houben & Guillaud, 1994; Houben et al, 1996). Houses constructed of CSBs also uniquely proffer better internal climatic conditions than other modern materials (Fullerton, 1979; Hughes, 1983). Thirdly, promoting the use of CSBs generates more direct and indirect employment opportunities within the local populace than would be the case with other materials. Fourthly, use of the material contributes directly to the social, cultural and educational advancement of the population (Schumacher, 1973; Anderson et al, 1982; Aksa, 1984). Their use also contributes to the training and re-training of artisans and to the provision of new skills. Use of the material through the provision of local infrastructure such as schools, community centres, health centres and administrative units results in the promotion of human interactions and social development. Finally, use of the material is environmentally friendly, appropriate and correct since it utilises the otherwise unlimited natural resource in its natural state. Moreover, this is achieved with little resultant depletion of other resources, or pollution and requires no excessive energy consumption and wastage as is the case with clamp fired bricks. The elimination of the need for wood fuel resources is seen as a major attraction over such bricks. The use of CSBs is thus in keeping with current sustainable development strategies (VTA, 1977; Plinchy, 1982; Lawson, 1991; Perera, 1993; Norton, 1997).

Despite the above advantages however, as with most relatively new materials, shortcomings associated with their use have recently begun to emerge, especially in tropical environments. These regions are characterised by frequent and intense rainfall, high relative humidity and high diurnal temperature changes (Bilham, 1962; Atkinson, 1970; Eaton, 1981). CSBs are produced from soil as the bulk constituent (over 90%). Soil is known to have poor resistance to erosion and to disintegration in water, a low tensile strength, low resistance to abrasion, high water absorption and retention capacity, and is dimensionally unstable during cyclic wetting and drying (Ellison; 1944, Carter & Bently, 1971; BOR, 1974; Das, 1983). The vulnerability of soil has in turn led to blocks showing considerable defects over short periods under conditions of normal and severe exposure in the humid tropics (Lunt, 1980; Agarwal, 1981; Eaton, 1981; Tibbets, 1982; Spence & Cook, 1983). Whereas the initial building costs might be low, the subsequent high maintenance costs, or even early rebuilding costs are not acceptable to many. Some promoters have also done harm to the image of the material by claiming a high degree of long-term technical performance only to be contradicted by premature deterioration only a few years later (Hammond, 1973).

Although the problem is more acute in the humid tropics than in the arid zone, it nevertheless has not been seriously addressed by research. Interest in studying the durability of CSBs is therefore likely to remain a major research concern for the foreseeable future. It is the long-term durability of the block, rather than any other factor that will be the key to their widespread acceptance (Gooding, 1994). It is therefore the goal of this research to investigate the feasibility of producing a high intergranular strength block of low permeability, which is inert, dimensionally stable and durable, even under conditions of exposure to wetting, abrasion and drying.

1.2 AIMS AND OBJECTIVES

Following on from the discussions in the preceding section, the objectives of this thesis are threefold. Firstly, to investigate the main constituent materials and the block production process, secondly to examine the main block properties and their performance, and thirdly to make recommendations for improved specification, testing and protection of CSBs for the duration of their service lifetime.

The scope covered under each of the above objectives are summarised below:

1. *Constituent materials and block processing methods:*

   (a) to investigate all present theoretical and practical methods by which soil and cement are classified, selected, and tested for CSB production.

   (b) to closely examine the mechanisms by which cement and associated binders and additives effect stabilisation in soils by increasing strength, dimensional stability and durability.

(c) to investigate the block production process with a view to identifying the critical sub-processes that influence the quality and performance of the block as a product.

2. *Surface and bulk properties and performance:*

(a) to study experimentally the effect of altering important variables like: soil type, cement content, cement replacement materials, mix-water content, moulding pressure and curing conditions on the properties and performance of blocks.

(b) to compare the performance of traditional and improved blocks as defined by the absence and presence of partial cement replacement materials respectively in the mix composition of CSBs.

(c) to review the concepts of durability and identify the main deterioration mechanisms involved, understand their methods of progression and propose appropriate remedial action.

(d) to identify the key surface and bulk properties on which durability is thought to depend, and monitor the performance of block categories mentioned in (b) in conditions simulating the action of the main deteriorating agents using accelerated tests.

(e) to collect in-service performance data from condition surveys and other records in order to estimate the service life of blocks.

3. *Improved design and specification for durable blocks*

(a) to recommend, from data and evidence obtained from 1 and 2 above, new approaches for achieving more appropriate, affordable and durable blocks.

(b) to develop and specify new initial and accelerated predictive tests for blocks that can be conducted on site, in laboratories and under in-service conditions.

(c) to recommend alternative surface and bulk improvement and protective measures for use of blocks under severe exposure conditions.

(d) to suggest suitable minimum performance requirements and thresholds for incorporation into future standards.

(e) to disseminate findings and flag questions for further research through publications, seminars and conferences.

The achievement of the above objectives are evaluated in the concluding parts of this thesis.

1.3 METHODOLOGY

There is very limited information available on the long term behaviour of CSBs. This is partly because no prior research has been conducted in the area and partly because inspection and maintenance records on the performance of blocks are not available. In view of such circumstances, the use of a combination of various approaches was considered to be inevitable. These approaches included:

1. *Literature review*: to establish the level of current thinking and knowledge and to provide the intellectual context for the research.
2. *Laboratory experimentation and testing*: of key surface and bulk properties of blocks as well as monitoring their performance using accelerated tests. Two categories of blocks were evaluated: traditional and improved blocks.
3. *Petrographic examination of CSB microstructural features*: using thin sections
4. *Exposure condition survey in the humid tropics*: done through:

(a) Inventorisation of CSB buildings and characterising their exposure conditions.

(b) Visual inspection of buildings to identify defect types and their severity.

(c) In-service condition measurement of the main defect types.

(d) Quality tests on constituent materials: soils, cement and water.

(e) Visits to block production sites for preliminary work-study assessment.

(f) Questionnaires and interviews for opinions, experiences and knowledge from stakeholders.

1.4 STRUCTURE OF THE THESIS

The body of this thesis consists of eight chapters presented in two parts, A and B. The organisation of the chapters is as follows:

Chapter 1 provides an introduction to the whole thesis. It discusses the background to the research and the context in which it is based. This Chapter also summarises the main aims and objectives of the research and explains why the different methodologies listed had to be used for the research. Chapter 1 ends by providing guidelines on the organisation and structure of the thesis as a whole including the ordering of the main parts, chapters, references and appendices. These are now described each in turn.

Part A: *Concepts of Durability and Stabilisation*

Part A consists of two chapters, namely Chapter 2 and Chapter 3.

Chapter 2 introduces the fundamental theoretical concepts of durability and deterioration in CSBs. The Chapter emphasises the fact that understanding of the main concepts of durability and deterioration in blocks is both necessary and yet long overdue. This Chapter identifies the principal deterioration agents and their perceived effects and attempts to rank them according to their severity. It also discusses the various deterioration mechanisms related to water, temperature and chemical reaction respectively. The main significance of Chapter 2 is that concepts previously not recorded in CSB literature are developed. It further emphasises the multidisciplinary nature of the research topic and reviews the wide store of knowledge accumulated from recent advances in durability research of cementitious materials. By presenting the subject in this manner, a more comprehensive understanding of the concepts of durability and deterioration in CSBs is achieved. The main surface deterioration mechanism in blocks (water-related surface wetting, abrasion and drying) is identified for further direct experimental investigation in Part B of the thesis.

Chapter 3 reviews and builds on the current understanding of cement-soil stabilisation principles and practices. This Chapter also examines the properties of the main constituent materials that form blocks (soil, cement, water) and reviews the effects of varying their proportions on the performance of blocks. The nature of each of these constituent materials, the manner in which they are selected and proportioned to form mixes for CSBs are closely analysed. The Chapter examines the adequacy of the theories of cement hydration and hardening, and the effects of the various cement hydrates on the durability of the block. It also reviews the block production process and its influence on the initial performance characteristics of CSBs. The main feature of Chapter 3 is therefore the identification of the main production variables affecting the properties and performance of the CSB. These variables are examined experimentally in Part B of the thesis.

Part B: *Main Investigation Methods and Findings*

Part B of the thesis consists of Chapter 4, 5, 6 and 7.

Chapter 4 describes the fieldwork undertaken in Uganda and the results obtained. It presents findings from the following: inventory of the types and numbers of CSB buildings; characteristics of their exposure environment; visual inspection of defect types and severity; in-service measurement of the main defects; quality tests on soils, cement and water; work-study evaluation of block site production practices, and results from questionnaires and interviews. The significance of Chapter 4 is that the defect types reported on were a result of genuine weathering conditions. Since the full effects of the entire range and distribution of deterioration agents acting on the blocks in their full scale size and within the restraints of adjoining blocks and mortar could be observed and limited measurements taken, the results obtained were fairly reliable and useful for generalisations to be made. The same applies to findings from block production site and quality of the constituent materials examined. The results from interviews and interactions with stakeholders are also discussed in Chapter 4.

Chapter 5 describes the main experimental design and sample preparation methods used for laboratory tests. It explains why the experimental soil type was fixed for all types of tests while the stabiliser content and type, mix-water content, moulding pressure, curing conditions were varied for the different categories of block samples prepared. Chapter 5 also presents the two main categories of block types produced for further experimentation: improved blocks (containing cement and microsilica) and traditional blocks (containing cement only and cement plus lime). It is the comparison of the properties and performance of these two types of blocks that constitutes the core of the experimental work in this research. Chapter 5 also shows the main block sample sizes produced and provides test results on the laboratory experimental soil which was blended for the research. It was from the samples produced as described in Chapter 5 that further surface and bulk property tests were conducted.

Chapter 6 investigates block bulk properties and compares the performance of improved and traditional blocks. The properties examined experimentally include: wet compressive strength and dry compressive strength, total water absorption, block dry density, and total volume porosity. The effect of varying the main input variables on these properties are analysed. Chapter 6 records the main features of the standard tests used, and argues for the need to establish more appropriate calibrated tests for CSBs. Factors likely to affect the various test types are discussed. The implications of particular test results and their correlation to other block properties are discussed.

Chapter 7 reports on the microstructural features of block surfaces and discusses the main surface test method used and the results obtained. It explains how thin-section micrographs were obtained to identify the general surface features of CSBs. This Chapter also argues for the need for a more reliable surface test method and describes a new accelerated surface test method. The results of surface performance tests using this method on improved and traditional block samples, as well as those from comparable materials, are discussed. A new block classification system based on their index values is presented. Factors considered likely to influence the results such as equipment type, sample dimensions, pre-treatment, duration of slaking and nature of the slaking liquid are all described. Chapter 7 also discusses the correlation between different block properties based and their slake durability index.

Chapter 8 is the final chapter of the thesis, integrating and summarising the main conclusions and recommendations from Parts A and B. The Chapter also highlights the implications of the research findings and identifies areas for further research.

At the end of the thesis, references and appendices are presented. The appendices illustrate and support sections of the thesis that could not be included within the main body of the write-up. Summaries of experimental methodology and full tables of results are included in the appendices.

PART A:

LITERATURE REVIEW ON DURABILITY AND STABILISATION

CHAPTER 2

CONCEPT OF DURABILITY IN CSBs

2.1 INTRODUCTION

Cement based building materials like CSB's and concrete were originally promoted as having an indefinitely long service life, and that they would require only minimum maintenance. Many cement based materials have indeed given excellent service. However, as these structures continue to be left exposed, it is becoming evident over time that even normal exposure conditions are actually more deleterious than originally thought (Baker et al, 1991; Sjostrom et al, 1996). Occurrences of undesirable, unpredicted premature deterioration where defects are clearly visible even to the casual observer, are becoming common. Defects in CSB structures are mainly presented as surface erosion, volume reduction, cracking and crazing, surface pitting and roughening, and detachment of render. These deterioration phenomena have been predominantly witnessed in the wet humid tropical regions of the world. No similar adverse reports have been documented from the hotter and drier regions (Spence & Cook, 1983).

In this chapter, it is noted that while much research has been undertaken in the recent past on initial properties of CSBs, very little similar research has been done on its durability. Recent advances have however been made in the durability research of comparable materials such as concrete. These are now well documented, and moves to redress identified shortcomings are following. By contrast as mentioned before, no durability research work has been conducted for decades in the case of CSBs. Yet the urgency is even more acute. Interest in the durability of CSBs is likely to become a major concern in the foreseeable future given the potential of the material in alleviating shelter backlogs in developing countries (Gooding, 1993).

Durability research is a complex undertaking. This is because in practice several causes of deterioration will occur simultaneously. These are compounded by cumulative as well as synergistic actions. In recognition of such intricacies, the objectives of this chapter are several, namely to:

- identify the most critical deterioration agents, their effects, and severity ranking;
- understand the main mechanisms involved, their modes of progression and propagation;
- suggest measurement techniques to quantify the main outputs of deterioration;
- recommend selected remedial measures

Chapter 2 is presented in four main sections. After this introductory section, the main expressions of durability and deterioration are discussed. This is followed by a discussion of the main deterioration mechanisms likely to occur in CSBs. A brief conclusion then follows.

2.2 EXPRESSION OF DURABILITY AND DETERIORATION IN CSBs

The terms durability and deterioration are perhaps the two most commonly used words in the field of construction materials. This section attempts to describe the basis of these two terms, and examines their relevance to the performance of CSBs.

Durability

The word durability originates from the Latin word '*durabilis*' which means 'lasting' (Franklin & Chandra, 1972). It can be used in the context of most building materials to mean resistance to weakening and disintegration over time. The term has been described in various ways by different authors although the substance appears to remain the same in all cases. According to BS 7543 : 1992, durability is defined 'as the ability of a building and its parts to perform its required function over a period of time, and under the influence of agents'. But according to BSI CP3 1950, 'durability is a measure, albeit in an inverse sense, of the rate of deterioration of a material or component'. More recent definitions state that 'durability may be regarded as a measure of the ability of a material to sustain its distinctive characteristics, and resistance to weathering under conditions of use for the duration of the service lifetime of the structure of which it forms part' (Baker et al, 1991; Sjostrom et al, 1996; Glanville & Neville, 1997). These definitions are too general to be of any practical use with CSBs.

The author proposes that the definition and concept of durability be based on three key parameters, namely:

- intended function of the material,
- the standardised conditions of its use, and
- the time the material is required to fulfil its functions

The *intended function* of a CSB is as an internal and external walling unit. The primary desirable characteristics of walling units are strength, dimensional stability and resistance to weathering (ILO, 1987; Carroll, 1992). These properties are to a large extent governed by the choice of constituent materials, and by the quality of the manufacturing process used in their production (Webb, 1988). In terms of intended function therefore, the ability of a block to sustain its distinctive characteristics under service conditions for the service lifetime of the structure is very important. Unfortunately, the values of initial performance characteristics of a block are not likely to remain constant over time. Variations in properties can come about due to the evolution of the block fabric as it undergoes changes induced by the effects of its exposure conditions. The changes can lead to loss of performance, implying that every material has its durability limit. The durability limit is the point at which loss of performance leads to the end of the service life of a material (BS 7543, 1992). The threshold for satisfactory performance for CSBs is yet to be defined.

Standardised conditions of use ought to be included in the definition of durability. As walling units, CSBs are used on the exterior of buildings. They are therefore exposed to physical, chemical and biological elements. Some of these agents can have deleterious effects on blocks even under normal conditions of use. The fact that CSBs when used in the humid tropics (characterised by heavy and intense rainfall) are more vulnerable to surface erosion than similar blocks used in dry areas, supports the reasoning that conditions of use be included in the definition of durability (Fitzmaurice, 1958; Spence & Cook, 1983). Harsh conditions of use can lead to wear, cracking, dampness and undesirable dimensional changes. However, CSBs are still required to resist the effects of exposure conditions for the service lifetime of the building. The requirement for resistance will vary according to the different types of agents involved. For each of the different deterioration agents identified, it will be helpful to specify the particular aspect of durability required. For example 'abrasion-durability, slake durability, heat durability, chemical durability' etc., all require matching durability thresholds. The main reason is that the mechanisms for each deterioration agent are different. Moreover, not all types of agents are likely to be in operation in different parts of the world. As can be expected, different tests will also be required to measure the effects of the different deterioration agents.

The *time* the block is expected to fulfil its intended functions (in the definition of durability) should also be specified more clearly to meet the users requirements. In the case of building structures, the time ought to be expressed in terms of years of satisfactory life. Guidelines on building life categorisation are provided in BS 7543 : 1992. These range from 10 years in the case of temporary buildings to over 120 years in the case of high quality buildings. The effect of exposure conditions leading to loss of performance is likely to be gradual but not abrupt. The rate of loss of performance or quality of a block is also likely to depend primarily on the actual conditions of exposure: blocks left exposed in the humid tropics will be more vulnerable to rapid deterioration than similar blocks used in arid regions (Fitch & Branch, 1960). Since blocks are meant to be maintainable materials rather than replaceable materials, specification of expected performance limits over a certain period of time and under specified conditions of exposure, are long overdue.

Deterioration

Deterioration has been defined by several authors as 'the time-related loss of quality of a material, usually under the influence of environmental agents' (BS1 CP3 1950; BRE, 1980; Baker et al, 1991). Premature deterioration has also been defined as 'failure to achieve the predicted service life' (BS 7543, 1992). The predicted service life of a block can be obtained from recorded performance or from accelerated tests. Unfortunately, such records are not available.

Failure due to the inability of a newly made block to fulfil its functions has to be clearly distinguished from failure brought about by alterations in properties over the service lifetime of a block. Indeed most building materials will have some of their properties altered over time although their durability may not always be called to question. The durability of a block can therefore be regarded as its ability to resist deterioration. It can be treated as the reciprocal of deterioration under pre-defined conditions (Sjostrom et al, 1996).

Due to deterioration however, the durability of a block is unlikely to remain constant. It may in fact change considerably. The implication is that durability of a block and its deterioration are likely to influence each other mutually but negatively. As can be expected, the more a block deteriorates, the less durable it is likely to become over time. For example bulk properties of a block such as water absorption and permeability are related to the type of microstructure and density of the block. However, the microstructure and density of a block may alter appreciably due to weathering (deterioration). This alteration can in turn increase the water absorption and permeability of the block. Such increases are likely to accelerate the rate of deterioration due to softening and dissolution of any unbound soil particles in the block. Further loss of performance can then be expected. The limit at which the loss of performance can be considered unacceptable is not yet well defined in CSBs. Unfortunately, even if it was, the limit may not be easily applicable without further qualification. This is because depending on the constituent materials used in a block, and on the quality of the processing methods used, no two blocks might be easy to compare. Unacceptable deterioration will therefore vary from block to block, and from property to property. Block properties that diminish over time reflect the past history of the block, both during and after manufacture.

2.3 DETERIORATION MECHANISMS IN CSBs

As is the case with most other building materials, deterioration mechanisms in CSBs are varied and complex. From the literature and experience gained through the use of the material, laboratory tests, building inspection records and the exposure condition surveys, three main deterioration modes can be identified, namely:

- Water related deterioration
- Temperature related deterioration
- Chemical based deterioration

These are now discussed each in turn in the following sections.

2.3.1 WATER RELATED DETERIORATION IN CSBS

Water related deterioration mechanisms account for most of the observed premature deterioration defects in CSBs (Fiztmaurice, 1958; UN, 1964; Lunt, 1980; Agarwal, 1981; Spence & Cook, 1983; ILO, 1987; Norton, 1997). Water also serves as a common denominator for other deterioration mechanisms occurring in blocks. The main sources of water linked to such deterioration mechanisms are rain, rising damp and condensation. The action of water in causing deterioration in blocks can occur in any one or all of the following ways:

- solvent action
- abrasive action
- swelling action
- catalytic action

The first two in the above list, namely solvent action and abrasive action are discussed in this section. The last two, namely swelling action and catalytic action are discussed in Section 2.3.3 (chemically related deterioration). For each action, an attempt is made to describe its nature, where it occurs, when it occurs, why it occurs and how it is likely to occur in a block. Where possible, references to similarities and differences with associated mechanisms in concrete materials are examined.

The *solvent action* of water is mentioned in the literature as one of the most common deterioration mechanisms occurring in many building materials (Sjostrom et al, 1996). The ability of a block surface to easily get wet, and the capacity of the block to absorb and retain water for sufficiently long periods of time, are two properties likely to leave the material vulnerable to the solvent action of water. The composition of a block fabric itself might also contribute to its vulnerability. Over 90% of the block bulk consists of soil, with the other 10% or less consisting of cement. In a stabilised block matrix, the process of cement-stabilisation is known not to affect all the constituents in the block (Herzog & Mitchell, 1963; Houben & Guillaud, 1994). Moreover, the hydration reaction between OPC and water which is responsible for the binding action in the block also produces soluble by-products such as calcium hydroxide (Illston, 1994). The microstructure of a block consists of materials which are juxtaposed with capillary pores. The block is therefore able to attract water and retain it. As water permeates the block, any unstabilised soil fraction present, together with the freed calcium hydroxide from the hydration reaction of cement, can be expected to dissolve. Dispersal and subsequent leaching out of these substances can then follow. Repeated action of this nature over the years can lead to overall softening of a block fabric. Such action can also have the effect of weakening and altering the microstructure of the hardened cement matrix in a block. The microstructure of a block is therefore likely to continue evolving throughout its service lifetime. This is a detrimental trend since the softening and leaching action is irreversible. The severity of the action can be expected to increase during the rainy seasons, and to depend on the proportions of materials present in the block which are vulnerable to dissolution and softening. Unfortunately, as this form of deterioration progresses, it has the adverse potential of making the block more vulnerable to other forms of deterioration such as the erosive action of rainwater droplets. The solvent action of water in causing deterioration is not investigated experimentally in this thesis.

Surface abrasion by rainwater has been identified from literature sources as one of the most common deterioration mechanisms associated with water (Atkinson, 1970; Agarwal, 1981; Eaton, 1981; Fullerton, 1979; Ola & Mbata, 1990). Fortunately however, surface erosion only occurs in areas prone to frequent and intense rainfall such as obtains in the humid tropics. The mechanism of surface erosion in blocks might not yet be well understood but the phenomenon is thought to proceed as follows. When rainwater strikes an exposed block surface, it will directly impact on it, with part of it turning into a spray. While the effect of the impact can be likened to the removal of loose particles, the effect of the spray is more likely to first wet the block surface. It has been estimated that up to 75% of the energy of a raindrop is dissipated on impact (Ellison, 1944; Goldsmith et al, 1998). The erosivity of raindrops depend on the state of bonding of the block surface, and on the characteristics of the rain. The state of bonding of a block surface is discussed in Chapter 3. The main characteristics of rain are defined by the drop size, its distribution, fall velocity and impact kinetic energy (Gunn & Kinzer, 1949; Laws, 1941; Hudson, 1963; Wilson, 1993). It is therefore the interaction between the raindrop size, velocity and shape, storm duration and wind speed that is likely to control the erosive power of the raindrop. It would be reasonable to expect that the higher the impact velocity of a raindrop and the weaker the state of bonding at the block surface, the greater would be the effect of surface erosion. Conversely, the lower the impact velocity of a raindrop, the greater is the effect of the raindrop forming sprays on the surface of the block. Any detached soil particles, (usually assumed to be from the unstabilised fraction of the block surface fabric), can then be easily removed by the resulting wall surface flow. The effect of surface abrasion is irreversible. The defects linked to this process are discernible even to the casual observer. They include recessed wall surfaces and volume reduction caused by mass loss. Indirect effects of surface erosion include lowering of surface hardness, lowering of compressive strength, loss of rigidity, lowering of density and increase in permeability. The loss of mass from a block surface can have other more serious consequences. Given the mechanism of quasi-static compression used in forming blocks, their inside core is the part least affected by compaction (Gooding, 1994; Houben & Guillaud, 1994). This part is therefore considered to be its weakest link. As can be expected, exposure of the interior due to recessed surfaces can lead to the speeding up of the rate of deterioration. Extra measures are therefore needed to strengthen the block surface in order to protect its bulk from exposure.

Unlike in CSBs, the phenomenon of surface erosion (to the extent it occurs), has not been reported in concrete literature. Given the low amount of OPC used in CSBs (5-8% by weight) as compared to concrete products (12-14% by weight), weaker inter-particle bonding in the former can be expected. Moreover, even with the low amount of cement used, full hydration of the binder might not be fully achieved. This is because unlike in concrete where the water-cement ratio can be pre-determined accurately, the effective water-cement ratio in CSBs is still difficult to define. Moreover the water required for the hydration of cement is shared between the cement and the highly hydrophilic clay in the soil. The water is also required to be at an optimum level to fully lubricate the soil particles to achieve maximum densification. The equilibrium between these three requirements for the mix-water are not yet fully understood. Until this is done the incomplete hydration of OPC will continue to lead to weaker block fabrics. A denser, homogeneous and impermeable block surface would probably minimise the effect of surface erosion more than one which is not. In this thesis, the performance of block surfaces produced by changing input variables such as cement content, compaction pressure, cement replacement materials, etc., are investigated experimentally (Chapters 6 and 7). The severity of surface erosion is also investigated through a case study conducted in Uganda (Chapter 4).

2.3.2 TEMPERATURE-RELATED DETERIORATION IN CSBS

As CSBs form the exterior part of buildings, they will inevitably experience regular temperature variations. The daily maxima and minima, diurnal temperature differences and temperature levels will vary depending on the geographic location of the CSB building (BRE, 1980; Wilson, 1993). High ambient temperatures are common in tropical and sub-tropical regions of the world (Hammond, 1972; Spence & Cook, 1983; McIllveen, 1998). Maximum daily ambient temperatures averaging 40°C to 50°C occur in such areas especially between late mornings and early afternoons, often peaking at midday on cloudless days. At night, temperatures may drop to below 0°C. The diurnal temperature variation can therefore exceed 50°C (Anderson, 1982). Moreover, sunshine and night hours are long, typically averaging 12 hours each day most of the year. Such extremes provide contrasting settings for temperature related deterioration to occur in CSBs.

Temperature variations of such magnitude can cause both reversible and irreversible changes in the physical and chemical properties of blocks. These changes are likely to influence the durability of blocks in three main ways, namely:

- expansion and contraction of the block fabric
- shrinkage and drying (of clay and hardened cement paste)
- catalytic action (for chemical reactions)

Expansion and contraction of a CSB fabric due to temperature variations is likely to be detrimental to the properties of the material in the long run. Similar dimensional changes are also reported in concrete research (Baker et al, 1991; Glanville & Neville, 1997). Deterioration is likely to result from stress levels induced within the block. CSBs have a positive coefficient of thermal expansion, typically ranging between 0.010 mm/m°C and 0.015mm/m°C (Rigassi, 1995). It is the absorbed radiation which is responsible for the temperature rise in blocks. The amount of radiation absorbed depends on the specific heat (C) and the thermal conductivity (λ) of the block. Typical values for blocks range between 0.65 and 1.00 kj/kg for the former and between 0.23 and 1.04 W/m°C for the latter (Houben et al, 1996). The values vary from block to block depending on the moisture condition at the time of the temperature change and testing, and on the composition of each block. At high temperatures, a block can easily expand. But the expansion can be restrained by adjoining blocks as well as the embedding mortar. The expansion of a block can induce significant internal stresses (compressive and tensile). Since blocks are weaker in tension, such stresses can be expected to be more harmful to its fabric. Further, as stress and strain tend to occur together, any restraint of movement for the expanding block introduces a stress corresponding to the restrained strain (Neville, 1995; Case, Chilver & Ross, 1998). If this stress and the corresponding restrained strain within a block are allowed to develop to such an extent that they significantly exceed the bulk strength or its strain capacity, then interfacial bonds that bind and hold the soil particles within its fabric together can be weakened. In more extreme conditions, they might even be severed apart altogether. Cracks are then likely to appear and propagate on the surface of a block. Not only can such cracks facilitate entry of moisture, but they are also unsightly.

Conditions at night represent the complete reverse of the situation during the day. Contraction of a block can be expected to take place, at temperatures about or below zero degrees Celsius. This occurs in an attempt to revert to the pre-expansion order. The effect of cooling is rather late since irreversible damage to the block fabric is likely to have already occurred due to expansion. It is such continuous, cyclic and repeated phenomena of expansion and contraction that can eventually degrade the block (Torraca, 1988). The effect of expansion and contraction of blocks due to high temperatures are not investigated experimentally in this thesis. A case study to link various cracking patterns to this mode of deterioration was however undertaken (Chapter 4).

Shrinkage and drying of CSBs can also be associated with high ambient temperatures. According to literature sources, block surfaces left unprotected from direct sunlight can absorb considerable amounts of solar radiation, raising surface temperatures beyond that of the surrounding air temperatures (BRE, 1980). Surface temperatures as high as 100°C and shade temperatures as high as 60°C have been reported in parts of the humid tropics (BRE, 1980). Such high temperatures can cause dimensional changes to occur in a block resulting in a fractional reduction in its volume .

Two different mechanisms of shrinkage are believed to take place in a block (BRE, 1979). These are shrinkage due to the expulsion of water from its capillary pores, and shrinkage due to the withdrawal of moisture from the clay fraction and the hardened cement paste. While the former is considered to be a reversible process, the latter are irreversible. At high ambient temperatures, moisture can be lost from a block through evaporation. Unbound water filling the capillary pores in a block are expelled in the process. Any dimensional changes that follow are likely to be insignificant. This reversible process has been reported as not being harmful to the block fabric.

However, even after the expulsion of all capillary pore water, there can still remain some water within a block fabric. This can occur in the form of strongly adsorbed water within unstabilised clay platelets and the hardened cement gels. This water can only be gradually withdrawn at high temperatures over long periods of time. The withdrawal is a slow process, but more significantly an irreversible one in the case of the hardened cement paste (Van Olphen, 1997; Torraca, 1988; Glanville & Neville, 1997). The mechanisms of withdrawal for clay and hardened cement paste are different but are not discussed further in this thesis. The effects of shrinkage and drying in CSBs are not investigated experimentally in this thesis. Defects arising due to their action were however evaluated during the fieldwork (Chapter 4).

The *catalytic action* of temperature variations in initiating and propagating chemical reactions is a well known phenomenon in most cement based materials. The phenomenon is also widely reported in concrete literature (Baker et al, 1991; Bungay & Millard, 1996; Jackson & Dhir, 1996). Most chemical reactions that would not have occurred within a block at low ambient temperatures are more likely to take place at higher temperatures. As stated earlier, fluctuations of temperature can influence moisture movement within a block. The combination of the presence of moisture within a block, and high temperatures has been known to provide the catalytic setting responsible for reviving otherwise dormant chemical activity.

Temperature variations are associated with the control of the rate of chemical activity. Reactions facilitated by this type of mechanism include soluble salts crystallisation, oxidisation, leaching, etc. It is reported that an increase in temperature of only 10°C can double the rate of chemical reactions in most cement based materials (BRE, 1980). Increasing the rate of deleterious chemical activity can be potentially harmful to a block in the long run. The mechanisms of the various chemical reactions linked to temperature variation are discussed in Section 2.3.3.

In summary, temperature related deterioration in blocks are likely to affect the following block properties: shape, dimensions, strength, surface hardness, rigidity, permeability, brittleness and appearance. The severity of deterioration will depend on the degree of cloud cover, degree of shading from direct sunlight, geographic location, orientation of the building façade, moisture condition of a block and its texture, opacity and colour of the block (BRE, 1980). The influence of some of these factors were investigated during the fieldwork that formed part of this research (Chapter 4). To minimise the effects of temperature variations, surface protective measures ought to be adopted. These can include use of reflective coating, surface render, low roof overhangs, etc., which can all be specified whenever blocks are thought to be especially vulnerable to high ambient temperatures.

2.3.3 CHEMICAL-RELATED DETERIORATION

The deterioration of CSBs can also be linked to the effects of chemical activity. According to literature sources, mechanisms associated with chemical action in CSBs remain the least investigated (Houben & Guillaud, 1994). Yet sources of potentially reactive chemicals in a block are soil and cement. Soils which constitute most of the bulk of a block contain minerals as well as contaminants (Lunt, 1980). Some of these substances can remain dormant and stable when not in active contact with environmental elements (rainwater, high temperatures, relative humidity, gasses). Ordinary Portland cement as the main binder in blocks also contains potentially unstable chemical constituents even in the hardened cement paste phase. Contact with environmental agents can catalyse chemical reactions in cement hydrates (Illston, 1994).

The precondition for chemical reaction to start in most cement based materials is the presence of moisture (Lea, 1970; BS 7543, 1992). Due to seasonal moisture variations from heavy rainstorms and humid conditions in the tropics, chemical reactions can be expected to occur within a block during its service lifetime. The rate of such reactions is likely to be influenced by variations in ambient temperatures as discussed in Section 2.3.2. Environmental conditions found in the humid tropics therefore provide the best possible setting for chemical activity to occur in a block. Based on the nature of their action and resulting effects, deleterious mechanisms of chemical action can be broadly categorised into three groups, namely:

- leaching out effect (clay and calcium hydroxide)
- expanded product formation (internal stress generation)
- direct decomposition (of the cement binder)

These are now each briefly discussed in turn.

Leaching out effect

Leaching is a phenomenon that involves the washing out of soluble substances from a material (Jackson & Dhir, 1996). There are two key sources of soluble substances in blocks: the calcium hydroxide found in the hardened cement paste, and the clay fraction likely to be found in residual unstabilised or partially stabilised matrix of a block (Houben & Guillaud, 1994; Young, 1998).

Calcium hydroxide ($Ca(OH)_2$) is known to easily dissolve in water (Illston, 1994; Neville, 1995). The dissolution process is irreversible once started, and is known to be facilitated by high temperatures, and the presence of carbon dioxide. Moreover, block properties such as water absorption and permeability, are likely to ensure that adequate moisture is absorbed and circulated within a block. Dissolved calcium hydroxide can be removed out of a block in either of two ways. It may simply be washed out of a block through surface flow on saturation during rainstorms, or it may be expelled onto the block surface by evaporation due to high temperatures. The phenomenon of leaching out of calcium hydroxide is also widely reported in concrete literature (Baker et al, 1991; Illson, 1994; Lea, 1976; Taylor, 1998; Young, 1998). There is no justifiable reason to expect that similar occurrences would not occur in CSBs.

Residues of unstabilised soil (usually clay) have been found in a stabilised block fabric (Herzog & Mitchell, 1963; Houben & Guillaud, 1994). Even within the recommended limit of less than 30% by weight of a block which is generally tolerated, the presence of clay is a potential source of problems. Owing to its fineness and high specific surface area (Chapter 3), not only can clay grains obstruct the stabilisation process, but they are also likely to compete for the mix-water required for the hydration of cement (Van Olphen, 1977). Clay can also coat the surfaces of coarse soil fractions (fine gravel and sand). Such coatings can inhibit the binding effect of cement on these particles. During rainy seasons, a block can rapidly absorb rainwater. The attraction of water by clay minerals has been explained by various mechanisms but ion exchange appears to remain the dominant mechanism (Carter & Bently, 1971; Franklin & Chandra, 1972; Ingles & Metcalfe, 1972). The amount and type of clay in a block can affect the degree of dispersion or flocculation. Kaolinite clays whose structure comprises platelets at a fixed distance are more stable in water, but are still capable of being disrupted. Ilite and montmorolinite clays on the other hand, which mostly contain interlayer potassium favour hydration in their dispersal (Houben & Guillaud, 1994). The swelling of clay lattice is known to assist in the mechanism of dispersal. Dispersed clay in a block fabric can easily be washed out as moisture permeates and circulates within it during rainy seasons.

The combined effect of leaching out of both calcium hydroxide and dispersed clays from a block is likely to be more severe in CSBs than in concrete. Extensive leaching is known to increase the porosity of a material (Neville, 1995). This can cause a block to become progressively weaker, and more permeable. A weakened block surface is more vulnerable to the direct abrasive action associated with driving rains. Since these mechanisms are likely to occur for the duration of the service lifetime of a block, deterioration over time can be expected.

The effects of leaching can however be minimised in blocks if certain preventive measures are taken early enough. These include the following:

- the use of pozolans and lime in combination with OPC during stabilisation. Pozolans and lime have the ability to fix both the calcium hydroxide present in hydrated cement paste and in any excess clay respectively (Hilt & Davidson, 1960). This approach is investigated experimentally in this thesis (Chapters 6 and 7).
- use of denser and more homogenous blocks of low permeability (less than 1.10^{-5} mm/sec) and of low water absorption capacity (less than 15%).
- careful soil selection that avoids use of soil with excessive clay content (<30% when OPC is used as the sole stabiliser).

- adequate curing of blocks.

Expanded product formation

Certain categories of chemical activity that can influence the durability of CSBs are associated with the formation of expanded products within a block. According to literature sources, such expanded products can occupy a greater volume within the block than the compounds which they replaced. By forcibly trying to occupy space that is not readily available, internal stresses can be generated within a block. Reactions of this category are well documented in concrete literature (Lea, 1970; Lea, 1976; Neville & Brookes, 1994; Illston, 1994; Neville, 1995; Sjostrom et al, 1996; Taylor 1998; Young et al, 1998). Apart from the occasional mention of the harmful effects of organic matter and other soil contaminants, no similar documentation of this phenomenon is covered in CSB literature. Yet the potential for such effects may be even greater in CSBs.

The three main categories of reactions likely to affect the durability of CSBs through expanded product formation include:

- Sulfate attack (on cement hydrates)
- Alkali-aggregate reactions (involving silica and carbonates)
- Soluble salts crystallisation (within the voids in a block)

Sulphates occur widely in natural soils in most parts of the world (Scot, 1965; Ingles, 1962; Ingles & Metcalfe, 1972; Jackson & Dhir, 1994). The type of sulfates vary greatly. But the common ones in soil are calcium, sodium and magnesium sulfates. These are mostly found in clayey soils rather than in sandy soils. The inclusion of significant amounts of sulfates in CSBs cannot be ruled out since no tests have so far been devised for their detection during soil selection. In the presence of sufficient amounts of moisture, sulfates present in soil can readily dissolve in water and react with certain hydrated cement products namely, calcium hydroxide and calcium aluminate (Neville, 1995). The dissolution of sulfates in water can create a sulfate solution within a CSB fabric. The sulfate solution might then react with both the $Ca(OH)_2$ and the hydrated C_3A to form calcium sulfate (gypsum), and calcium sulphoaluminates compounds (ettringite) respectively (Neville, 1995). The volume of these two by-products is much greater than that of the original substrates in the block. As these products expand in order to occupy more space within a block, and when this expansion is restrained by adjacent particles and phases within the core of the block, significant internal stresses are generated. The generated stresses are capable of disrupting bonding within the block. This can in turn result in a weakened block of lower strength, rigidity and hardness. The reactions are irreversible and their deleterious effects are noticeable within only a few years of their occurrence. The damage in blocks is commonly presented as defective edges and corners. These can also be followed by spalling and cracking of the block surface.

The severity of sulfate attack on CSBs depends on a number of factors. They include: type and amount of sulfates present in the soil, type of cement used, and the bulk properties of a block. The effect of sulfate attack on CSBs is not investigated experimentally in this thesis.

Alkali-aggregate reactions (AAR) can also be expected to occur in CSBs. According to literature sources, the reaction is essentially an inter-constituent material reaction also with the potential to form expanded products in a block. The reaction can occur between the active silica and carbonate containing soils and the alkalis (Na_20 and K_20) present in minute quantities in OPC (Glanville & Neville, 1997). Alkalis may also be present in remote amounts in most soils (ILO, 1987). Two kinds of alkali-aggregate reactions, both potentially harmful to blocks, are distinguished:

- Alkali-silica reactions (ASR)
- Alkali-carbonate reactions(ACR)

These phenomena and the mechanisms involved are also widely reported in concrete (Neville, 1995).

Defects on blocks resulting from AAR reactions will most likely appear as map cracking and spalling, occurring mainly on the surface of the block. Cracking of the star shaped pattern is the most common, but not necessarily the only type (Palmers, 1988). Factors likely to influence AAR reactions in CSBs include the following:

- availability of moisture
- high temperature environments (10°C-40°C)
- concentration of alkalis in cement and soil
- concentration of active silica and carbonates in soil
- porosity and permeability of the block

From the above factors, the main preventive measures for AAR in CSBs should involve procedures that attempt to lower the alkali content in the cement while it is still in the plastic state. The addition of pozolans to the soil-cement-water mix at the time of stabilisation could be helpful. The main reason for using pozolans is that they easily combine with the alkali content of the cement and soil, thus effectively lowering the alkali content. AAR can therefore be avoided in CSBs by using low alkali cements, non-reactive soils and pozolans blended with OPC (Glanville & Neville, 1997).

Soluble salts crystallisation (SSC) can occur within the pores and voids spaces of a block. According to literature source, the crystallisation of salts results in expanded product formation (Neville & Brooks, 1994). As before, such products have the potential to generate significant internal stresses within the pores and void spaces in a block. The phenomenon is widely reported in concrete literature (Sjostrom et al, 1996). Soluble salts are commonly found in most soils especially sandy soils. Sandy soils won from rivers can also contain appreciable amounts of soluble salts. Amounts as little as 6% of the mass of the sand are enough to trigger off such reactions (Neville, 1995). The most common salts are usually sulfates and chlorides (Neville & Brookes, 1994). Although these salts could easily be removed by washing of sand, the procedure is rarely followed in most developing countries. Sand is normally imported from various sources to improve the particle grading of soils needed for stabilisation (ILO, 1987; Rigassi, 1995). The soluble salts are however not reactive in the solid form in which they are normally present in the sand. They will only become reactive in solution. The alternate wetting and drying of block surfaces provides an ideal setting for such reactions. The mechanism of SSC is thought to be as follows.

When soluble salts in solution are present in a block fabric, they are likely to permeate into its capillary pores. Due to high temperatures leading to evaporation, moisture is driven off from the solution causing the salts to crystallise within the pores and voids spaces of the block. The volume of the crystals increase as the pore spaces get filled. But any further increase can be resisted by the rigid block fabric. This leads to the creation of significant stresses within the pores in the block. The induced stresses can cause cracking and disintegration at the surface of the block. Progressive deterioration of the block surface can then take place as moisture and temperature variations occur over the service lifetime of the block. The deterioration mechanism is known to be unaffected by the type of cement used (Jackson & Dhir, 1994). Limits on the soluble salts content of soil (especially its sand component) should therefore be specified during soil selection for CSB production.

Due to the threat from SSC, use of CSBs below the foundation level is still prohibited (Rigassi, 1995). Moreover, even blocks used at short distances above ground level in the lower courses of a wall may also be vulnerable to deterioration from SSC. The lower layers of a wall can be plastered to minimise such incidences.

Direct decomposition of the cement binder

Direct decomposition of cement within a CSB can occur due to attack from acidic conditions. No OPC is known to be resistant to acid attack (Neville, 1995). The direct decomposition of OPC can lead to the progressive break up of the bonds that hold the CSB fabric together and progress towards the interior. The phenomenon is widely reported in concrete literature (Jackson & Dhir, 1994).

In summary, apart from attempts to attribute common defects in blocks under service conditions to each of the chemical actions described, no attempt was made in the thesis to experimentally investigate their deleterious effects on blocks. Defects assessment conducted during the fieldwork confirmed the occurrence of chemically induced deterioration in blocks (Chapter 4). Further future research is recommended in the area of chemically induced deterioration in CSBs.

2.4 CONCLUSION

From the preceding discussions in Chapter 2, it can be concluded that the concept of durability and its expression are not well covered in CSB literature. It is proposed that expressions of durability in CSBs should revolve around three factors, namely: intended function of a block, the expected service conditions, and the time taken to satisfactorily fulfil the functions.

It was established through literature reviews in Chapter 2 that even under normal service conditions, deterioration agents can still influence the durability of a block. Under more severe conditions of exposure such as in the humid tropics, the effects of deterioration agents can lead to the premature deterioration of blocks. The durability of a block can therefore be regarded as its ability to resist deterioration. It was noted that due to deterioration, the durability of a block is not likely to remain constant, but can vary over time. Performance characteristics which were initially deemed satisfactory at the time of production can alter appreciably for the worse over time. Durability and deterioration therefore influence each other mutually but negatively.

According to literature sources, it was noted in Chapter 2 that the principal agents likely to influence the performance of a block while in service include: rainwater, temperature, and chemical action. The exact mechanisms of these actions are not yet fully understood. Their combined and interdependent action in causing loss of quality in a block is thought to be highly likely. It was further noted that water and temperature related deterioration mechanisms represented the main forms of deterioration in CSBs in the humid tropics. Water-related action not only causes loss in mass on the block surface due to wetting and abrasion, but also contributes to the initiation and propagation of otherwise dormant chemical activity. Water related deterioration was found to occur in various forms: solvent action, abrasive action, swelling action, catalytic action and dampness. Temperature related deterioration on the other hand causes volume changes which lead to the creation of cracks and weakening of the block fabric. Various mechanisms involving expansion and contraction, shrinkage and drying, and catalytic action were discussed. It was noted that high temperatures are linked with the speeding up of harmful chemical reactions. The combined action of wetting-abrasion and drying are investigated experimentally in this thesis (Chapter 7). It can be concluded that the mechanisms of water and temperature related deterioration are neither well covered nor properly understood in current CSB literature.

It was discussed in Chapter 2 that chemical action related deterioration mechanisms in blocks remained the least investigated and documented of all deterioration modes. Yet such reactions are potentially possible in CSBs due to the various minerals found in soils and OPC hydrates. Three categories of potential chemical reactions with deleterious effects were identified: reactions resulting in expanded product formation (sulfate attack, alkali-aggregate reactions, soluble salts crystallisation), reactions resulting in the direct decomposition of the cement binder (acid attack), and reactions resulting in the leaching out of substrates ($Ca(OH)_2$ and clay minerals). It will not be possible to experimentally examine these chemical action related deterioration mechanisms during this research. However, defects arising from their effects are investigated through the field exposure condition survey described in Chapter 4. Further research is recommended on all aspects of chemically-related deterioration mechanisms.

From these brief conclusions, the objectives of Chapter 2 were met.

CHAPTER 3

CEMENT-SOIL STABILISATION

3.1 INTRODUCTION

In Chapter 3, current documented principles and practice of cement-soil stabilisation as applied to the production of CSBs are discussed. Soil requires to be stabilised because the material as found in its natural state is not durable for long-term use in buildings. By properly modifying the properties of soil, its long-term performance can be significantly improved (Bureau of Reclamation, 1975; Dunlap, 1975; Herzog & Mitchell, 1963). Soil stabilisation processes focus on altering its phase structure, namely the soil-water-air interphase. The general goal is to reduce the volume of interstitial voids, fill empty voids, and improve bonding between the soil grains. In this way better mechanical properties, reduced porosity, limited dimensional changes, and enhanced resistance to normal and severe exposure conditions can be achieved (Gooding & Thomas, 1995).

The objective of this chapter is to closely examine current methods of soil stabilisation in general, and their application to CSBs in particular. The chapter describes the fundamental theoretical background on which subsequent experimental investigations which follow in Part B of the thesis are based. The approach used in Chapter 3 is to first identify and examine each of the three main constituents of CSBs (soil, cement, water), then evaluate existing methods used for combining them during the block production process.

Chapter 3 is presented in five sections. After this introductory section, subsequent sections describe the following: main constituent materials, cement-soil stabilisation principles, the block production process, and conclusion.

3.2 MAIN CONSTITUENT MATERIALS USED IN THE PRODUCTION OF CSBs

The three main constituent materials used in the production of CSBs are:

- Ordinary Portland Cement (for binding the soil particles)
- Soil (for the skeletal structure of the block)
- Water (for the hydration of cement and lubrication of soil particles

These three materials each have unique properties. Before discussing how they are combined to form blocks, a description of their nature and properties is presented. This approach is considered relevant because in the past, the individual properties of these materials were more or less taken for granted, with unfortunate consequences for blocks. The quality of material used and their proportioning can significantly affect the durability of blocks. Each material is therefore discussed in turn in Sections 3.2.1, 3.2.2 and 3.2.3 that follow.

3.2.1 ORDINARY PORTLAND CEMENT AS THE MAIN BINDER

Ordinary Portland cement (OPC) plays such a critical role in the performance of CSBs that the following aspects of the binder are briefly examined:

- Function of OPC in CSBs
- Physical properties of OPC likely to affect its performance
- Basic chemical constituents of OPC
- Hydration reaction of OPC following the addition of water

- Properties and influence of the hydration products on the durability of blocks
- Use of cement replacement materials

Functions of OPC in CSBs

Ordinary Portland cement is an important ingredient and variable in a CSB. Without its inclusion, compressed blocks would be no different from common sun dried mud blocks and would simply disintegrate on contact with water, or when subjected to moderate impact loads. Compared with concrete products where 12-18% by weight of cement is used, only about half of that amount (5-8% by weight), is required in stabilised blocks (ILO, 1987; Webb & Lockwood, 1987; Houben & Guillaud, 1994). Though not commonly recommended, amounts as low as 3% and as high as 10%, have been used depending on the nature of the soil requiring stabilisation (Rigassi, 1995).

The function of OPC is to strongly bind the constituent materials (soil particles) together, in a dense, strong, dimensionally stable and durable unit. Other common binders currently in use include lime, gypsum, pozzolans, resins and bitumen (Apers, 1983; Stulz & Mukerji, 1988). Discussions in this thesis will be restricted to the use of OPC as specified in BS 12, 1971 and ASTM C 150-92. OPC has been selected for two reasons. Firstly it has a unique and superior binding capacity. Secondly, it is widely available in most parts of the world.

The uniqueness of OPC in comparison with other binders is based on its ability to achieve extremely high strengths in only a short period of time (about 28 days). OPC stabilised blocks remain dimensionally stable even when in contact with water in a manner not possible for comparable unstabilised blocks produced in a similar way. Uncontrolled swelling and shrinkage are appreciably contained when OPC is used.

For stabilised blocks, variations in OPC quality and amount can drastically affect its properties and behaviour more than any other input variable (Gooding, 1994). The effect of varying the amount of OPC on the performance of CSBs are investigated experimentally (Chapters 6 and 7).

Unfortunately the manner of current coverage of OPC in CSB literature leaves a lot to be desired. The coverage is so limited, scanty and routine that widespread and incorrect use of the binder is now becoming the order of the day (Fullerton, 1979; BRE, 1980; Spence & Cook, 1983). Problems associated with the misuse of OPC are also described in Chapter 4 (findings from the fieldwork). Due to poor coverage, critical phenomena in cement chemistry such as the need for adequate amounts of water to ensure complete hydration of cement, and proper conditions to ensure preservation of moisture within the block to facilitate completion of the hydration process, are overlooked. For these and other reasons to be mentioned later, this section attempts to redress the shortcomings brought about by the narrow coverage of the subject in CSB literature.

Physical properties of OPC

Two of the most important physical properties of OPC are its:

- Specific surface area (SSA), and
- Particle size distribution (PSD)

The SSA and PSD of cement are important to CSB production because they govern the manner in which the binder stabilises soils. These physical properties are directly related to the process of manufacture of the binder. The basic source materials for OPC are a mixture of about 75% limestone ($CaCO_2$) and about 25% clay (Lea, 1976). These are intimately mixed, then ground together. In the modern manufacture of

OPC, the ground mixture is fed into a rotary kiln against a counter flow of hot air, and heated to about 1450-1800K (Neville, 1995; Taylor, 1998). The resulting melts from the mixture coalesce to form clinker, of approximate dimensions 5-10 mm. After being allowed to cool, the clinker itself is then mixed with about 3-5% gypsum ($CaSO_4$) (Taylor, 1998; Young, 1998). The gypsum is added to control the otherwise spontaneous capacity for initial setting. The mix is finally finely ground to give the powdery form in which OPC is traded. There can be as many as 1.1 x 10^{12} particles or grains of OPC per kilogram after the grinding process (Neville & Brookes, 1994). It is the grinding process that determines the SSA and the PSD of OPC. These are now discussed each in turn, with implications for the stabilisation of soil emphasised in each case.

The *specific surface area* (SSA) of OPC is in the range 300-350 m^2kg^{-1} (Lea, 1976; Illston, 1994; Jackson & Dhir, 1996; Taylor, 1998). This is lower than that of rapid hardening cement (RPC) which falls in the range 400-450 m^2kg^{-1}. Since the hydration reaction of cement while stabilising soils starts from the surface of the grains and then proceeds inwards, the higher the SSA, the faster can the rate of reaction be expected. The hydration reaction proceeds uninhibited if the cement grain surfaces are free. However, due to the large range of particles of varied SSA in soil, the likelihood of surface blinding is high. Fine sand and medium silt have SSA between 0.02 and 0.23 m^2g^{-1}, while clay grains have between 10 and 1000 m^2g^{-1} (lowest in kaolinite, highest in montmorollinite) (Akroyd, 1962; Grimshaw, 1971; Head, 1980). Interference due to the blinding of cement grains by any of these substances, and thereby inhibiting hydration, is likely but undesirable. Moreover, the large SSA of clay present in soil ensures that they can attract water in the mix otherwise exclusively meant for the hydration of cement, thus reducing the amount of water going directly to hydrate cement. This can impair the hydration process, with negative implications for strength development in CSBs. For this reason for example, use of clay contaminated aggregates is prohibited in concrete production (Jackson & Dhir, 1996). It would however, be highly uneconomical and impractical to try to eliminate clay from its parent soil before use in CSB production.

The *particle size distribution* of OPC is characterised by an almost uniform type of grading (or packing characteristics). Cement grains do not contain every size fraction between the maximum and minimum particle sizes. Approximately 90% of the cement grains in OPC measure more than about 5μm, with only 1% measuring less than about 90 μm (Weideman et al, 1990; Glanville & Neville, 1997). The average size of most OPC cements is about 10 μm. This can be compared to the size of the very fine clay particles in soil with average size less than 2 μm (Houben & Guillaud, 1994). The detrimental effect of the presence of clay has been mentioned already. Despite the potential setback, the use of clay in CSBs is likely to continue to be tolerated.

Basic chemical constituents of OPC

Identification of the main constituents of OPC, and description of their role in influencing the hydration reaction leading to the stabilisation of CSBs has received no previous coverage in CSB literature. From concrete literature sources, the summary of the main constituents, together with their approximate quantities and role in the hydration reaction, are shown in Appendix A.

The listed constituents of OPC are impure reactive minerals which exist as multi-component solid solutions (Weidemann et al, 1990; Taylor, 1998). The implication is that the reactions of these ingredients following the addition of water, and mixing with soil particles, is likely to be quite complex. As can be expected, not only will each of the ingredients react separately with water, but they can also influence the manner in which the others (including raw soil minerals), react with each other. In view of this, the exact mechanism of cement stabilisation of soil remains poorly understood and is likely to become a subject of active research for years to come.

Hydration reaction of OPC on addition of water

The hydration reaction that ensues when water is added to unreacted OPC grains follows two distinct phases: setting, followed by hardening, to form a cement paste (Young et al, 1998). The mechanism of the reaction involving the main phases in unreacted cement (C_3S, C_2S, C_3A and C_4AF), occurs at different rates for each phase. The process is reported to evolve as follows (Lea, 1976; Weidemann et al, 1990).

When water is added to the OPC grains, the reaction begins from the surface of the grains, then progresses inwards. This results in the formation of gels and ettringite (Taylor, 1998). The C_3S and C_2S form gels, while the C_3A form ettringite. Due to the increased contact between the formed gels on adjoining grains, and due to the interlocking of the ettringite crystals, cohesion develops signifying the start of the setting period (initial setting). This occurs within about 45-60 minutes of water being added (Illston, 1994). The implication of this is that the soil-cement-water mix should be compacted before the initial setting begins. The water continues to diffuse into the gels, causing pressure to build up within, resulting in rupture of the gel. The ruptured gel peels away from the grain, forming gel foils and fibrils as wells tubules in the case of C_3A. This exposes the grain surface locally to further hydration. The process then repeats itself. As each grain sprouts a multitude of these fibres and as they continue to grow and multiply, they start to interlock even more closely and rigidly than before. This signifies the end of the setting period. The final set occurs approximately 12 hours after water was initially added (Illson, 1994). The paste is however, still weak and therefore of low compressive strength. The implication of this is that freshly demoulded green blocks will remain weak at this stage and should therefore be handled with extreme care.

The paste then starts to harden. The continued hardening of the paste is due to the further multiplication, growth and stronger interlocking of the gel fibres, ettringite and portlandite crystals. Hardening is effectively 'completed' about 28 days after the initial contact with water. Although further hardening takes place after this at a decelerating rate, the defining timing is specified as 28 days. At 28 days, the paste, and by implication the block, should be hard enough to be used. The chemical reactions involving the four phases in OPC are summarised as follows (Lea, 1970; Illston, 1994; Neville & Brookes, 1994; Young, 1998; Taylor, 1998):

<u>For C_3S</u>:

$$2\,C_3S \quad + \quad 7\,H_2O \longrightarrow C_3S_2H_8 \quad + \quad 3\,Ca(OH)_2 \quad \Delta H\ 500 J.g^{-1}$$

tricalcium silicate + (water) → calcium silicate hydrate + calcium hydroxide heat of hydration

<u>For C_2S</u>:

$$2\,C_3S \quad + \quad 5\,H_2O \longrightarrow C_3S_2H_8 \quad + \quad 3\,Ca(OH)_2 \quad \Delta H\ 250 J.g^{-1}$$

dicalcium silicate + (water) → calcium silicate hydrate + calcium hydroxide heat of hydration

The reaction is accompanied by a high rate of heat evolution (exorthermic reaction), silicate polymerisation, rapid increase in [OH^-], and a concomitant rise in pH number to 12.6 (Neville, 1995). Both silicates are reported to require approximately the same amount of water for their hydration. The C_3S silicates generate about twice the amount of $Ca(OH)_2$ than the C_2S silicate. The release of $Ca(OH)_2$ has direct implications on the durability of CSBs (Chapter 2). The calcium silicate hydrates are fine amorphous particles in a colloidal state, often represented simply as C-S-H to emphasise their indeterminate nature as no specific formula is considered to be that accurate (Taylor, 1998).

<u>For C_3A</u>:

The reaction involves not only water, but also gypsum and the extra ettringite produced as a result of the interaction. The two reactions are thought to proceed as follows:

1. $C_2A \; + \; 3\,C\bar{S}H_2 \; + \; 26\,H_2O \longrightarrow C_6\,A\bar{S}_3\,H_{32} \qquad \Delta H = -1350 J.g^{-1}$

(tricalcium aluminate) + (gypsum) + (water) → (ettringite)

The excess ettringite formed reacts with more C_3A,

2. $C_6\,A\bar{S}_3\,H_{32} \; + \; 2\,C_3A \; + \; 4\,H_2O \longrightarrow 3\,C_4\,A\bar{S}H_{12}$

(ettringite) + (tricalcium aluminate) + (water) → (monosulphoaluminate)

Monosulphate aluminate is known to be the most stable phase in a mature cement paste (Young et al, 1998).

<u>For C_4AF</u>

The reaction involves both water and $Ca(OH)_2$ as produced before. Thus,

$$C_4\,AF \; + \; 2\,Ca(OH)_2 \; + \; 14\,H_2O \longrightarrow C_4\,(A, F)\,H_{13} \; + \; (A,F)\,H_3$$

(ferrite) + (calcium hydroxide) + (water) → (tetracalcium aluminate hydrate) + (ferric aluminium hydroxide)

The $C_4 (A,F) H_{13}$ is structurally related to the monosulfoaluminate, while the $(A,F) H_3$ remains amorphous (Taylor, 1998; Young et al, 1998)..

Properties and influence of the hydration products

As can be expected, the products of the hydration reaction of OPC can have major influences on the properties of the hardened cement paste and by implication, on the behaviour of CSBs. A summary of the hydration products and their likely impact on the durability of CSBs are shown in Appendix B. From this summary, various ways of improving the properties of hardened cement paste, and by implication the block, can be examined.

It is widely reported in concrete literature that the volume fraction of the cement hydrates, gel pores and capillary pores determine the properties of concrete (Baker et al, 1995; Sjostrom et al, 1996; Neville, 1995; Young et al, 1998). Given the similarities between concrete and CSBs, the same influence is likely to apply in the case of the latter. The role of hardened cement paste in both materials appears to be central to this hypothesis. The volume fraction of solids, gel and capillary pores are in turn determined by two factors : the water cement ratio (w/c) and the degree of hydration (α) (Illson, 1994; Taylor, 1998).

It is the w/c ratio that controls the porosity of hardened cement paste. Theoretically, the production of CSBs of high strength and of low permeability can therefore be achieved by:

- Lowering the water cement ratio
- Assuring a high degree of hydration

Low *w/c ratio* can be achieved by adequate proportioning of the main raw material ingredients; soil, cement and water. A particularly low w/c ratio can also be achieved in mixes by using partial cement replacement materials (CRM) (Neville, 1995). In situations where blocks are to be exposed to aggressive environmental conditions, such approaches are likely to be more beneficial than the short-term economics of increase in production costs. This is because mixes incorporating fine cement replacement materials are likely to result in high performance blocks which are more dense and more durable than blocks produced in the traditional manner. This theory is investigated experimentally in this thesis and the results are discussed in Chapters 6 and 7.

A *high degree of hydration* of cement paste in a block can be achieved by making sure that proper curing is done. The degree of hydration represents the fraction of the original cement grains which have hydrated. This requires that a sufficient length of time is dedicated for curing alone. During this time the green demoulded blocks should not be allowed to dry out quickly. This should help avoid causing the water still in the green blocks to evaporate, thus remaining available for the hydration reaction to continue. Adequate curing and low water/cement ratio are therefore potentially significant ways of improving the properties and performance of CSBs. The effect of varying curing conditions on the properties and performance of CSBs are investigated experimentally, with the results discussed in Chapters 6 and 7.

Modification of CSB properties using cement replacement materials

As discussed earlier, the properties of hardened cement paste can be improved by the partial replacement of OPC with CRMs. In this sub-section, the manner in which CRMs are able to modify properties of hardened cement paste, the types of CRMs available, their physical and chemical properties, and the mechanism of the reactions involved, are presented.

CRMs, sometimes referred to as mineral admixtures or additives, can be used as substitutes for some of the OPC in a block. CRMs modify properties of OPC by altering its setting and hardening behaviour (Neville, 1995). Improvements in strength and durability of the hardened cement paste is reported to be due to the pore-filling effect of the CRMs, which effectively lowers both the capillary and gel porosity in the resulting product (Young, 1998). Further, the transition zone between the sandy fraction of the soil and the cement paste, usually a major point of weakness, is likely to be considerably strengthened by the pozolanic reaction of CRMs. Amounts as low as 10% to 20% of the cement content are required. For blocks expected to be used in harsh environmental conditions, CRMs could be used only on the surface areas to reduce costs.

The *main types* of CRMs include the following (Jackson & Dhir, 1996; Neville & Brooks, 1994):

- Pulverised fuel ash (PFA), or fly ash
- Ground granulated blast furnace slag (GGBS)
- Microsilia, or condensed silica fume (CSF or MS)
- Natural pozolans, e.g. volcanic ash
- Calcined clay and shale
- Risk husk ash

The most commonly used of the above are the PFA, GGBS and CFS. They are all available as industrial materials, or as blends with OPC. The basic physical properties and chemical composition of PFA, GGBS and MS as compared to OPC are described in Illston (1994) and Neville (1995). The three CRMs contain a substantially greater amount of silica (SiO_2) than OPC (PFA, 48%; GGBS, 36%; MS, 97%; OPC, 20%).

Most importantly, most of the silica contained is in the active amorphous form (Neville, 1995) (a pozzolan by definition is a material that contains active silica, SiO_2). The silica is in its amorphous or glassy form in disordered structures. This is distinguished from the uniform crystalline structure form of silica found in sand. The latter is not chemically active and is therefore regarded as being dormant. It is only MS, with 97% SiO_2 and no CaO in its composition which entirely comprises active silica. For this reason, it is this CRM which is discussed further, and its effect on cement is investigated experimentally in Chapters 6 and 7.

The *physical properties* of MS make it one of the most effective CRMs. Firstly by having a significantly lower specific gravity than OPC (2.2 compared to 3.15), the substitution of the latter on a weight by weight basis with the former is likely to result in a greater volume for the resulting paste. This pore filling effect is just what is needed for surface layers of CSBs to prevent easy penetration of moisture. The pore filling effect is also known to enhance strength properties (Taylor, 1998). Secondly, by having a particle size range about three magnitudes of order below that of OPC (0.01-0.5 μm compared to 0.5-100 μm), the MS has the potential of ensuring more dense packing of the binder. Added to this, with its considerably higher specific surface area (15,000 compared to 350 m^2kg^{-1}), the speed of hydration is likely to be significantly higher. This is probably due to the small MS particles acting as nucleaic sites for the deposition of the C-S-H on the hardened cement paste. This can be quite useful in CSB production as it can effectively lower the water cement ratio in a damp mix. The lower the w/c ratio, the higher the strength (Webb & Lockwood, 1987; Baker et al, 1994; Taylor, 1999).

The *mechanism of the reaction* of the pozzolan mixed with OPC is as follows (Taylor, 1998). The pozzolan itself is not known to be cementitious on its own but in a finely divided form, and in the presence of moisture it can chemically react with the $Ca(OH)_2$ liberated during the reaction of the silicates in OPC. The reaction forms a fresh secondary set of calcium silicate hydrates whose properties are the same as those of the primary reactions. This represents one of the most significant reasons for partial substitution of OPC with CRMs. As was mentioned earlier, the $Ca(OH)_2$ liberated during the hydration reaction of OPC is a potential source of instability for the CSB. Being soluble in water, it can easily be leached out from the block, increasing its porosity and weakening the bond strength (Chapter 2).

The chemical equation representing the mechanism of the reaction is thought to be as follows (Illston, 1994):

$$\underset{\left[\begin{array}{c}\text{amorphous}\\ \text{silica}\end{array}\right]}{S} \quad + \quad \underset{\left[\begin{array}{c}\text{Calcium}\\ \text{hydroxide}\end{array}\right]}{Ca(OH)_2} \quad + \quad \underset{\text{(water)}}{H_2O} \longrightarrow \underset{\left[\begin{array}{c}\text{calcium silicate}\\ \text{hydrate}\end{array}\right]}{\text{C-S-H}}$$

The C-S-H from the secondary reaction can contribute to further strength development, and by implication to the durability of the cement paste within a CSB fabric. The effect of MS on the properties and performance of CSBs are investigated experimentally in this thesis and the results discussed in Chapters 6 and 7. Blocks containing MS are referred to as improved blocks (IPD) (Chapter 5).

3.2.2 CHARACTERISATION OF SOIL FOR CSB PRODUCTION

As stated earlier in the thesis, soil alone constitutes over 90 of the bulk of a CSB. Existing CSB literature appear to adequately cover fundamental theories of soil properties and behaviour.

According to BS 1377 Part 1: 1990, soil is an assemblage of discrete particles in the form of a deposit, usually of mineral composition, but sometimes of organic origin, which can be separated by gentle mechanical means, and which include variable amounts of water and air. Soil is also referred to as the loose material that results from the long-term transformation of the underlying parent rock by the simultaneous and evolutionary interaction of climatic factors and other physico-chemical and biological processes (Casagrande, 1947; Das, 1994; Houben & Guillaud, 1994; Craig, 1998). Most of soils consist of disintegrated rocks, decomposed organic matter and water soluble mineral salts. These descriptions confirm that soil is a highly variable and complex material in nature. Although soil properties can be modified to improve their performance, not all soils may be suitable for stabilisation as found. The decision on suitability requires the identification of the main constituents in the soil likely to have a direct bearing on its properties and behaviour (Head, 1980).

As the characteristics of a soil can affect the performance of a CSB, the review of literature discussed in this section will focus on the following:

- Composition of soils
- Classification of soil (to determine type and suitability)
- Current criteria for selection of suitable soils

Composition of Soils

Soil consists of three main phases, namely, solids, liquids and gasses (Das, 1994; Craig, 1998). The solids form the bulk of the material, while the liquids and gasses mainly fill the void spaces. The relative proportions of the three phases can have a significant influence on the behaviour of a soil. In this section only the composition of the solids fraction are discussed. Soils are made of varying proportions of four types of solids: gravel, sand, silt and clay (Fitzmaurice, 1958; Enteiche & Augusta, 1964; ILO 1987). Each of these different solids are briefly described in turn in the ensuing paragraphs.

Gravels are the larger granular particle sizes in a soil forming its skeletal structure. They range in size between 2mm and 20mm (BS 1377 Part 2: 1990). They are the cohesionless part of a soil resulting from the direct disintegration of underlying parent rocks and pebbles (Pettijohn, 1957). Gravels have a rough texture and may be found in almost all shapes, including rounded, angular, irregular, etc. (BS 1377 Part 2: 199). Due to their loose packing and stability, they are important for CSB production as they limit shrinkage and capillarity in a soil. Amounts of gravel in excess of 10% are not recommended for use in CSB production (Rigassi, 1995). The allowable maximum size fraction for gravel used for CSB production is not standardised. Some literature sources recommend 15 mm to 20 mm (Houben & Guilland, 1994), while others recommend 6mm (ILO, 1987). As will be shown later, the maximum size fraction has a considerable influence on the bonding properties of a soil-cement mix (PSD).

Sand particles in a soil range in size between about 0.06mm and 2mm (BS 1377 Part 2: 1990). The sandy fraction comprises granular grains of silica or quartz from the disintegration of sandstones and crystalline rocks. Sandy soils are very stable, lack cohesion, are non-sticky with a gritty texture. They also have a very high degree of internal friction and do not shrink. Because of these properties, they can provide the much needed mechanical strength to soil. Their pressure also limits swelling and shrinkage in a soil. According to literature sources, the specific bulk density of sands vary between 2500 kg/m^3 and 3000 kg/m^3, but their specific surface area is about 23 cm^2/g, and specific heat about 800 J/kgK (Jones, 1984; Houben & Guillaud, 1994). The recommended proportion of sand in soils for CSB production varies but is mainly between 70 and 80% (Lunt, 1980; Rigassi, 1995).

Silts are made up of particles whose size range varies between 0.002mm and 0.06mm (BS 1377 Part 2: 1990). Apart from the difference in size, silts are almost identical in nature to sandy particles. Their internal friction is however noticeably less than that of sand. Their specific surface area is about 454 cm^2/g and density between 1600 and 1800 kg/m^3 (Head, 1980; Houben & Guillaud, 1994). They have a smooth texture, are sticky and lightly cohesive, but their shrinkage capacity is not significant. Due to their lack of cohesion, gravels, sands and silts should not be used on their own for CSB production (reasons discussed under clay). According to literature sources, the recommended silty fraction in a soil for CSB production should be between 10 and 25% (Rigassi, 1995).

Clay particles form the finest fraction of soils with average sizes less than 2 μm (Scot, 1963). Their physical and chemical characteristics are not similar to those of the other three soil fractions. The specific surface area of clay is about 800 m^2/g, while their specific heat is about 965 J/kgK (Houben & Guillaud, 1994). Due to their fine grained nature, clays are cohesive and will form a coherent mass at suitable moisture contents (Vickers, 1983; BS 1377 Part 1: 1990). Clays are known to contribute to some of the important engineering properties in a CSB, and for this reason, are discussed in more detail. They are basically hydrated alumino-silicates of irregular but often hexagonal shapes (Torraca, 1988). Large clay molecules comprise a series of sheets or wafers of alumina and silica which are not electrically neutral (Van Olphen, 1977). The sheets have chemical make-up which varies according to the type of clay. Three major clay types exist; namely kaolinite, illites and montmorollinite (ILO, 1987; Houben & Guillaud, 1994). Within these three major types, there are about 20 different sub-groups of clay (Scot, 1963).

Kaolinite and montmorollinite represent the opposite extremes in the behaviour of clay when in contact with water. Kaolinite which is almost pure clay, is the most stable and therefore the least expansive of clay types. Since the two layer wafer has a fixed distance of about 7 A°, they are held together firmly. Its linear contraction is small, ranging between 3% and 10% only (Houben & Guillaud, 1994). Because of these properties, kaolinite clay was selected and used for blending the experimental soil type used for laboratory tests in this thesis (Chapter 5).

Illites and montmorollinites consist of type 2-1 structures which are more weakly held together. They are not stable in water and are highly vulnerable to swelling and shrinkage. Their linear contraction values are high, ranging between 4% and 11% and between 12% and 23% respectively (Das, 1994). The linear contraction value of the latter is more than twice that of kaolinite. No further tests are conducted in this thesis using these two clay types.

Generally, the presence of clay in moderate amounts in a soil is desirable (Smith & Smith, 1998). Being cohesive, they impart plasticity to the soil when under moist conditions. Plasticity is due to the thin film of absorbed water which adheres strongly to the clay layers thus linking the particles together (Grimshaw, 1971; RILEM, 1972). In this way, the clay minerals acts as natural binding agents for the cohesionless granular fractions of a soil (gravel, sand, and silt). This quality is particularly valuable during the production of CSBs. Green blocks after demoulding are still weak as the cement binder may not yet have had sufficient time to set. The presence of clay as a natural binder thus helps in the handleability of CSBs at this stage of the production process (Spence & Cook, 1983).

Clay minerals also have other properties which are unfortunately considered undesirable in a block. Being hydrophilic they have a very high affinity for water.

As the wafers attract water, clay particles can slide over each other resulting in an apparent increase in volume (due to dispersion). Conversely, as the clay wafers dry out, they shrink, causing cracks to appear in the clay mass, thus effectively irreversibly breaking their bond strength (Hilt & Davidson, 1960). Extreme swelling and shrinkage are not desirable properties in blocks. It is the uncontrollable swelling and shrinkage of clays which depend on moisture and temperature variations that makes them unique, and thus difficult to deal with. For this reason, most CSB literature sources recommend controlling the amount of clay in soils to be used for block production. Amounts of clay in excess of 40% is not recommended for soils for CSB production using OPC (Rigassi, 1995). In such cases, the use of lime is recommended due to its ability to fix the clay through a pozolanic reaction (Ingles, 1962; Spence & Cook, 1983; BS 1924, 1990).

Soil Classification

The classification of a soil is the first requirement needed to identify it. Knowledge of the soil type and properties can facilitate the optimisation of its use in CSB production. According to literature sources, soil classification is performed on particles nominally less than 60mm (Dunlap, 1975). Soils are classified in various ways depending on the prevailing local or regional standards in the particular part of the world. Whatever the geographic location, however, some common procedures are usually adopted in the classification of soils.

Soil classification methods are based on either one or a combination of the following: particle size distribution, plasticity, compactability, cohesion, and organic matter content (Casagrande, 1947; Fitzmaurice, 1958; Head, 1980; Vickers, 1983). Unfortunately, soil classification systems are not yet uniformly applied internationally. At the moment, the two classification systems widely used are based on the particle size distribution and on the plasticity of a soil (Lunt, 1980). According to these two methods, the soil size grading and its plasticity are divided into clearly defined ranges. For each range, a descriptive name and letter is assigned to the identified soil type to distinguish it from the others.

In the *particle size distribution* classification system, the term particle refers to an individual mineral grain within the disturbed soil mass. According to this system, the following size ranges are given (BS 1377: Part 2, 1990):

Name	Subdivision	Diameter of Particles (mm)	
Gravel	Course Medium Fine	60 20 6.0	20 6.0 2.0
Sand	Course Medium Fine	2.0 0.6 0.2	0.6 0.2 0.06
Silt	Course Medium Fine	0.06 0.02 0.006	0.02 0.006 0.002
Clay			<0.002

Table 1: Soil classification according to particle size distribution
(BS 1377 Part 2 1990; ILO, 1987)

In this system, each of the terms gravel, sand, silt and clay refers to a range of particles or grain sizes in a soil (table 1). In actual reality, soils are not found in this rigidly defined state. The normal natural state of soil is such that it is composed of grains from two or more particle size ranges. For example, a soil may be described as sandy CLAY, implying that the soil has significant amounts of sand and clay size ranges. In such a case, the size range with the higher percentage of particles is the last named range in the soil description (in capitals). The main terms used in this system are G for GRAVEL (60-2mm), and S for SAND (2-0.06mm). The qualifying terms are W for well graded and P for poorly graded (Pu, uniform; Pg, gap graded).

In the *soil plasticity* classification system, the soil is identified by its behaviour when in contact with water. The system is mostly used for the finer fraction of a soil, i.e. clays and silts smaller than the 425 μm sieve only (Houben & Guillaud, 1994). The soil is then classified using a soil plasticity chart (Stulz & Mukerji, 1988; Das, 1994). The advantage of this system is that it recognises the formation, and therefore the behaviour of soil groups can be predicted easily.

Use of both the particle size and plasticity based classification systems are recommended in analysing soils for CSB suitability. The crucial point is that either system should be able to describe the soil in a manner clearly understandable by engineers. The identification of a particular soil can be considered complete with the inclusion of its colour, particle shape and composition, soil name based on its grading and plasticity, and the soil group symbol. The approach is useful in that it clearly recognises the difference between the coarse and fine soil fractions.

Experience has also shown that within each class of soil, similar characteristics are displayed. With coarse grained soils (gravel and sand) for example, the similar characteristics are dependent not only upon the size of the particles, but also on the manner in which the sizes are distributed within the soil mass. With fine grained soils (silt and clay), it is the moisture content of the soil and the clay mineral type which play more significant roles in determining the behaviour of the soil (Ingles & Metcalf, 1972).

Current criteria for selection of suitable soils

The varied composition and properties of a soil in its natural state introduces difficulties during the selection of the material for stabilisation. As stated earlier, not all soils found in their natural state will necessarily be suitable for CSB production. In this sub-section the basic suitability requirements are outlined and the existing criteria for selection based on literature sources are summarised.

Basic suitability requirements are varied with a broad set of requirements proposed in CSB literature. For a soil to be suitable for stabilisation, its particle size distribution, plasticity and compressibility should be desirable. Existing suitability criteria require that the soil be:

- well graded with a continuous or dense gradation. It should be neither gap-graded nor uniformly graded. The size of the maximum soil particle should be less than 6 mm in diameter (ILO, 1987). Particle sizes greater than this size may easily get dislodged from the block fabric due to poor bonding. The gravel and sandy fraction should be densely packed not only to provide the skeletal structure of the block, but also to take up applied loads. The silt and clay fraction in a soil should be adequate enough to provide sufficient cohesion. As stated earlier, this is valuable when demoulding green blocks and when handling them during wet curing. In addition to the amount of clay in a soil, its type should also be ascertained. Not all clays have the same degree of shrinkage and swell. This property of clay is a potential source of disruption for the future performance of a block. Generally, when using OPC as the stabiliser, best results can be obtained with predominantly sandy soils. When using lime as the binder, best results can be obtained with predominantly clayey soils. It is however still possible to improve any poor gradation of a soil prior to stabilisation. This can be achieved by adding the missing fraction, or by removing the excessive fraction. The removal of excessive coarse fraction can be done by sieving the soil, while removal of fines from the coarse fraction can be done by washing it.

- of low plasticity index, thus able to exhibit low rather than high cohesion. Sandy soils of low clay content (about 10% or less) do not have an appreciable plastic limit. The clay content once again is the critical factor. Soils of high plasticity can have liquid limit in excess of 50% (Fitzmaurice, 1958; Houben & Guillaud, 1994). The corresponding clay content in such cases may be in excess of 40%. The plasticity index of a soil can be altered by modifying its particle size distribution. The plasticity index can be lowered by adding sand, and raised by adding clay (Rigassi, 1995). Adequate plasticity facilitates shaping a soil as it determines its ability to remain in close association, thus contributing to moulding and handling.
- compacted at its optimum moisture content for the maximum dry density to be attained (Guillaud et al, 1995). At the maximum dry density, the porosity of the soil is at its minimum. This increases both its shearing strength and compressive strength on loading. For every soil, reduction in porosity attained at maximum dry density will depend on the gradation of the soil, its optimum moisture content and on the compaction energy used (Ingles & Metcalf, 1972; Vickers, 1983).
- free of soluble salts and organic matter. These impurities can have harmful effects on OPC both during hydration and even after hardening. Presence of organic matter higher than about 1% represents a potential hazard (Houben & Guillaud, 1994). Organic matter is harmful because it contains nucleic acids,

tarturic acid and sometimes glucose. These substances can interfere with the proper setting of OPC, thus weakening the hardened cement paste (Neville, 1995). Soluble salts and sulfates can react with moisture in a soil and hardened cement past resulting in expanded product formation in a block (Chapter 2). Soils with soluble salts and sulfate contents higher than about 3% should not be used for CSB production (Rigassi, 1995). At the moment, there are no available tests specified in the literature to determine the presence of sulfates in soils to be used for CSB production. The criteria is also not well documented in most CSB literature.

Comparison of existing criteria for suitability is now possible because over the past few decades, several authors have published various recommendations. These have been successfully used in the past for the selection or rejection of soil for stabilisation. It is however noted that some of the suggested criteria, while based on similar properties, still differ from each other. Such dissimilarities only confirm the premise that the variability of a soil makes selecting a suitable soil a difficult exercise. Nevertheless, although the effect of climatic type and infinite variability of soils may influence some of the existing guidelines, most of the criteria still appear relevant to date. It is however, still rare to find authors recommending 'comprehensive' criteria based on all the four main soil properties, namely: particle size distribution, plasticity, compressibility, and chemical mineralogy. The summary of existing criteria for soil selection is shown in Appendix C.

The *adequacy of the criteria* for soil selection is still debateable, but the summary in Appendix C shows convergence on two main soil properties, namely: the particle size distribution and the plasticity of a soil. The guidelines are useful as basic criteria, but should not serve as rigid specifications for soil selection. This is because even soils that may fall out of the recommended ranges can, with modification, still be used to produce good blocks.

The size of the maximum size fraction (6 mm) and its distribution, and the clay content (and type) emerge as the major factors to consider in soil suitability selection. The chemical composition of a soil and its potential influence on the durability of the cement paste that bonds blocks, is likely to gain prominence as a new factor in the near future. Criteria limiting the presence of soluble salts and sulfates in soil samples are likely to become critical in light of recent scientific findings regarding their long-term harmful effects (Lea, 1976; Lunt, 1980; Neville, 1995). It is further noted that certain special soil types such as lateritic soils may not conform to these guidelines (Hammond, 1972; Ringsholt & Hansen, 1978; Stulz & Mukerji, 1988). Chemical tests for their composition is recommended in addition to the summarised criteria in Appendix C. The validity of the various criteria are not investigated further in this thesis.

3.2.3 QUALITY OF WATER FOR MIXING AND CURING

Water is required in CSB production at two critical stages: during the mixing of soil with cement and during the wet curing of green blocks. Existing CSB literature appear to place more emphasis on the quantity of water required, rather than on its quality (Webb & Lockwood, 1987). Water is basically needed for the hydration reaction leading to the gradual hardening of Portland cement. In the opinion of the author, both the quality and quantity of water ought to be given equal consideration. In most developing countries where CSBs are to be used, water is still a scarce resource, forcing many producers to use raw water from a variety of sources (Smith & Webb, 1987). The likelihood for the use of water with high levels of impurities cannot therefore be ruled out. Investigations during the fieldwork revealed widespread incidences of use of water of unknown quality (Chapter 4). In this section, the sources and suitability criteria for water are briefly discussed.

Sources

The main sources of raw water in developing countries include rainwater, rivers, lakes, swamps, groundwater, seawater, and rarely, tap water. Naturally occurring water may contain different substances such as dissolved solids, dissolved gases, suspended solids, bacteria, fungi, algae, protozoa (BRE, 1980). Apart from the few tap water sources where treatment works process the water (through screening, coagulation, aeration, flocculation, clarification and disinfection in that order, thus making the water potable), all other water sources in developing countries are unlikely to be treated. The quality of water used therefore remains unknown. High levels of impurities found in untreated water sources can be detrimental to the performance of a block (Parry, 1979). There use is likely to result in low strength, dimensionally unstable, and less durable blocks being produced (ILO, 1987). The effects of water of unknown service record on block properties are investigated experimentally in Chapter 4. Problems associated with use of water of unknown quality are also widely reported in concrete literature (Neville, 1995).

Suitability criteria

The suitability of water used for CSB production should be ascertained if good quality blocks are to be produced. Current specifications generally require that the water needed for the proper hydration of cement should be fit for drinking purposes (ILO, 1987; Rigassi, 1995). The criteria for potable water may not yet be absolute, but the following guidelines for quality are considered useful (BS 3148, 1980; ASTM C 94-

92a, 1992);

- Water with a high concentration of sodium or potassium should be considered unsuitable for use in cement hydration (due to dangers of AAR reactions)
- Water with pH of between 6.0-8.0, which does not taste saline or brackish, may be suitable for use in cement hydration
- Water containing humic acid or other organic acids should not be used (affects hardening of cement paste in the blocks)
- Use of sea water is not recommended (presence of chlorides >1000 ppm)
- Water with silt as suspended solids may be used even if concentration of 2000 ppm is found as long as the water is first left to stand in a settling basin or tank for at least 24 hours.

Since water sources are scarce in most developing countries, ways to comply with the above guidelines without rejecting the water should be sought. At the moment no known on-site test methods exist to determine the suitability of water for CSB production. Preliminary treatment methods for raw water of unknown sources could include screening, temporary storage, removal of algae, boiling and cooling.

3.3 CEMENT-SOIL STABILISATION PRINCIPLES

3.3.1 BACKGROUND

The stabilisation of soil to improve its properties for building purposes is an ancient practice. The procedures were passed on from generation to generation without necessarily understanding the main mechanisms involved. It was only from the 1920s that systematic scientific approaches were to emerge (Rigassi, 1995). Attempts were then made to replace the longstanding ad-hoc techniques previously adopted for soil stabilisation. Unfortunately, despite all the recent scientific advances made, soil stabilisation still remains an inexact science (Dunlap, 1975).

By soil stabilisation is meant the modification of soil properties by varying the soil-water-air interface (Fitzmaurice, 1958; UN, 1964; Ingles & Metcalfe, 1972). This is done to achieve more lasting characteristics than hitherto possible when the soil was still in its natural state. Some of the methods used to modify soil can result in irreversible changes, while others may result in reversible changes. The latter are likely to occur due to the lack of resistance offered by soil to environmental agents, especially water (PCA, 1970; Aksa, 1984). Evidence of poor resistance can be seen in most of the Third World where houses built of soil require to be regularly maintained during and after rainy seasons (Agarwal, 1981; Fullerton, 1979; BRE, 1980). Perennial problems of this type can be effectively overcome by stabilising the soil. Addition of a suitable stabiliser, especially a binder, can enable the soil retain its shape and dimensions. The soil will also gain in compressive strength and durability (Fitzmaurice, 1958).

As several input variables are involved, soil stabilisation is likely to remain a complex process. For effective stabilisation to be achieved the soil should be modified to give it the properties it lacks. There are several options for stabilising a soil, but the courses of action likely to be more effective should consider targeting its interstitial voids and improvement of bonding between its particles. Thus, it is generally accepted that:

- by reducing the volume of interstitial voids in a soil through mechanical compaction, direct action is taken to significantly reduce its porosity (Rigassi, 1995). Reduction in porosity is an effective way of increasing density and shear strength in a soil. By filling the voids in the soil which cannot be eliminated completely through compaction, direct action is also taken to reduce its permeability (Houben & Guillaud, 1994). Reduction in permeability has the positive effect of restricting circulation and retention of water within the soil fabric.

- by improving the cohesion and bonding in a soil, action is taken to cement and link the soil particles together. In this way dimensional stability, increase in compressive strength and improved durability can all be expected to be achieved. The method also ensures that changes in volume that would normally occur due to shrinkage and swelling are significantly reduced. Improved bonding also minimises the vulnerability of the soil to surface abrasion and erosions caused by rainwater and wind (DoHUD, 1979; Evans, 1980).

These two approaches are investigated experimentally in this thesis (Chapter 5).

3.3.2 CEMENT SOIL STABILISATION METHODS

Current soil stabilisation methods can be broadly categorised as follows:

- Mechanical stabilisation (by using a compressor)
- Physical stabilisation (by improving the soil grading)
- Chemical stabilisation (by using a binder to improve bonding between the soil particles)

Normally a combination of all three methods are used (Ingles & Metcalf, 1972). Each method is now discussed in turn to examine the degree of effectiveness in the stabilisation of soil.

Mechanical stabilisation involves compressing the soil particles together to increase density and reduce porosity. Compression leads to the redistribution and rearrangement of soil particles. It is the compaction energy used which forces the particles together and in the process most of the air is eliminated from the soil voids. Compaction is best achieved when the grain size distribution of a soil is continuous, not uniform or gap graded. The presence of grains of different sizes facilitates the occupation of voids left by other soil particles. Unfortunately, the effect of mechanical stabilisation when used alone is easily reversed, especially when the soil comes into contact with water (Jagadish et al, 1981). Water causes the lubrication the soil grains, forcing them to move about within the otherwise densified but still unbound fabric. It therefore follows that in addition to densification, the use of a binder will normally be required mainly to overcome the reversible effect of contact with water (Norton, 1986).

Physical stabilisation involves modification of soil properties by introducing the missing size fractions (Rigassi, 1995). The texture of a soil can be altered by calculated and controlled mixing of the different fractions together. When this is done, most of the voids that existed prior to physical stabilisation are closed due to closer packing of the grains. An anisotropic network is created limiting the movement of the grains in a soil (Ingles and Metcalf, 1972). Unfortunately, as was the case with mechanical stabilisation, the effect of physical stabilisation alone is not permanent (Rigassi, 1995). On saturation with water, soil grains are easily dispersed, or washed away. For better results, physical stabilisation of soil should therefore be combined with the other two methods (PCA, 1971).

Chemical stabilisation involves the addition of a binder or bonding agent to a soil. The binder modifies the soil properties through cementation or linkage of its particles (Houben & Guillaud, 1994). Both cementation and linkage are a result of chemical reactions involving the binder and water. Cementation creates a strong and inert matrix that can appreciably limit movement in a soil. The voids in the soil are also filled with insoluble by-products of the hydration reaction while some soil particles are coated and firmly held together by the binder (Ingles, 1962). The key binder that acts in this manner is Ordinary Portland cement. The full mechanism of the reaction as presently understood is discussed in the next section. It is generally reported in CSB literature that the effect of chemical stabilisation is more permanent, and may take several years or even decades to partially reverse. For this reason, chemical stabilisation of soil is so far considered to be the superior method of choice. It is also well established that the effect of chemical stabilisation is significantly increased by improving the soil grading and compacting the mix (Dunlap, 1975; Gooding, 1994). Combination of the three methods is therefore strongly recommended, and is used in the production of all experimental samples used in the research. The use of cement admixtures and lime in addition to OPC are also investigated experimentally (Chapters 5, 6 and 7). Other known chemical stabilisers include: pozzolanas, gypsum, bitumen, resins, whey, molasses, etc., (IIHT, 1972; Stulz & Mukerji, 1988; Houben & Guillaud, 1994). Use of these other binders are not discussed further in the thesis.

3.3.3 MECHANISM OF CEMENT-SOIL STABILISATION

The stabilisation reactions that follow from the addition of water to a soil-cement mix leads to the formation of a number of by-products (Ingles, 1962; PCI, 1970; BS 1924 Part 1, 1990). Since soil as the bulk constituent contains different fractions of gravel, sand, silt and clay, each of these fractions will respond to the reaction with cement in different ways. Moreover, as cement itself contains different minerals, each of them will also react differently. Not only will they interact amongst themselves, but they are also likely to affect the manner in which the others react (Weidemann et al, 1990). The main reactions involved and the nature of the resulting microstructure are described in the sub-sections which follow.

The Main Chemical Reactions

According to CSB literature sources, two main chemical reactions can be distinguished; a primary reaction involving the hydration of cement with water, and a secondary reaction involving the clay minerals and the liberated lime from the primary reaction (Houben & Guillaud, 1994). The hydration reaction between cement and water results in the formation of hydrated cement paste and conventional mortar (embedding gravel and sand fractions). The secondary reaction also results in the formation of a binder like by-product (Spence & Cook, 1983).

The mechanism of the reaction is thought to be as follows:

1. Primary reaction involving OPC constituents:

$$\left.\begin{array}{l} C_3S \\ C_2S \\ C_4AF \end{array}\right\} + H_2O \longrightarrow C\text{-}S\text{-}H \quad + \quad C_4A\bar{S}H_{12} \quad + \quad Ca(OH)_2$$

$$(\text{Cement}) \quad + \quad (\text{Water}) \quad \left(\begin{array}{l}\text{Calcium}\\ \text{silicate}\\ \text{hydrate}\end{array}\right) \quad + \quad (\text{monosulphoaluminate}) \quad + \left(\begin{array}{l}\text{Calcium}\\ \text{hydroxide}\end{array}\right)$$

The main products of the above reaction are: calcium silicate hydrates, monosulphoaluminates and calcium hydroxide. It is the first two, namely the C-S-H and $C_4A\bar{S}H_{12}$ that are responsible for strength development in a block (Ingles & Metcalf, 1972). It is the gravel and sandy fractions in the soil that are affected by this reaction. Both the C-S-H and $C_4A\bar{S}H_{12}$ are known to have high binding capacity. The binding forces they generate are responsible for intertwining and embedding the gravel and sand fractions creating a strong network within the soil fabric. This inert and anisotropic network introduces rigidity not previously present in the soil. Due to the network, movement of the coarse soil fraction is resisted and subsequently becomes highly limited. The net effect results in the development a particulate composite structure. As can be expected, the properties of the composite are influenced by the amount of cement used relative to the soil fraction, and by the nature of the bye-products resulting from the reaction. The reaction is known to liberate free lime which then sets off the secondary reaction with the clay component in the soil.

2. Secondary reaction involving freed lime and clay

A. S	+	$Ca(OH)_2$	$\longrightarrow$	C-S-H	+	C-A-H
(Clay)		(Calcium hydroxide)		(Calcium silicate hydrate)		(Calcium alumate hydrate)

The two main products of this reaction (the C-S-H and the C-A-H) both have binding capacity not very different from the ones of the primary reaction. This reaction is mainly pozzolanic with the gelatinous amorphous hydrates equally contributing to hardening of the block. Following the reaction, a stable chemical bond develops between the clay crystals, through a mechanism known as linkage. The reaction proceeds slowly but is dependent on the quantity and quality of clay, and on the amount of free lime available (Spence and Cook, 1983; Houben and Guillaud, 1994). The amount of calcium hydroxide released is limited by the lime saturation factor (LSF) of the OPC. The LSF is fixed at the time of manufacture of the OPC, often ranging between 0.66 and 1.02 (Spence and Cook, 1983). Restriction of the upper limit is mainly done to control the amount of free lime in the cement paste which is otherwise associated with unsoundness and undesirable expansion.

The Resulting Particulate Composite Matrix

As a result of the preceding reactions, the particulate composite fabric that constitutes the block is thought to comprise the following matrices (Herzog & Mitchell, 1963; Ingles & Metcalf, 1972; Dunlap, 1975; Lea, 1976; Houben & Guillaud, 1994):

- cement hydrates (calcium silicates, calcium aluminates, sulphoaluminates, ferrites)
- conventional gravel-sand-cement mortar
- calcium hydroxide ($Ca(OH)_2$)
- unhydrated cement residues (UCR)
- stabilised clay
- unstablised soil (gravel, sand, silt, clay)
- capillary pores

The proportions of each of these matrices in the block and the strength of bonding between the cement hydrates and coarse soil fraction are thought to influence the compressive strength, dimensional stability and durability of a block (Mitchell & El Jack, 1978; Lunt, 1980; Rigassi, 1995). The various by-products are also summarised in Appendix B.

For better performance of a block, it is desirable that the cement hydrates coat a high proportion of the coarse soil fraction, as well as filling the spaces between the particles. For this to be achieved, an optimum proportion is needed between the sand and cement. It can generally be expected that the lower the cement content, the higher the resulting voids content in a block. A high voids content (porosity) is often associated with a weak block (Houben & Guillaud, 1994). This phenomenon is investigated experimentally in this thesis (Chapters 6 and 7). It is potentially possible that with the low amounts of cement used, the voids content of a block fabric is likely to remain high. Moreover, the low quantity of binder used can also result in the presence of a greater proportion of unstabilised soil in a block fabric. Such an outcome would be highly undesirable due to vulnerability to deleterious effects of water, temperature and relative humidity (Chapter 2).

The presence of the matrix of calcium hydroxide in a block is a potential source of instability. Calcium hydroxide is soluble in water and is therefore likely to be leached out during the service lifetime of a block (Chapter 2). Moreover, calcium hydroxide is also known to react readily with the CO_2 from air to form expansive products. Though the reaction is very slow, the expanded products formed can easily contribute to the disintegration of a block over time (Chapter 2). A means of eliminating the presence of $Ca(OH)_2$ in a block by providing a substance with which it can react (microsilica) to form a secondary binder is investigated experimentally in this thesis (Chapters 5, 6 and 7).

An attempt is also made to examine the microstructure of block samples in the course of this research. This is done using petrographic examination of thin sections (Chapter 7).

3.4 STABILISED BLOCK PRODUCTION PROCESS

3.4.1 BLOCK PRODUCTION CYCLE

The production process of CSBs is broadly similar to that of concrete blocks. Similarities exist between the products, manufacturing process and in the organisational control methods. The processing method represents a major input variable. It can significantly influence the quality and long term behaviour of a block (Rigassi, 1995). Yet most of the CSB literature sourced appear to take this variable for granted. For these reasons, the separate treatment of the processing method as is done in this section was thought to be necessary.

CSBs are produced by compressing a damp mix of soil and cement in a press mould. After demoulding, the green blocks are not used immediately, but are first allowed to cure. This is because the strength of a block, just as it the case with concrete blocks, increases with age (Apers, 1983; Ruskulis, 1997). The duration of curing is dictated by the specification for the type of stabiliser used; 28 days when OPC is used and 56 days when hydrated lime is used (BS 12, 1971; BS 890, 1972; Lea, 1976). The production of CSBs can be organised as a small scale cottage concern or as a much larger mechanised industrial unit. Whatever the approach adopted, the production cycle is likely to remain similar, and can be categorised into four basic stages, namely:

- Soil extraction (and preparation)
- Mixing (soil, cement and water)
- Moulding (of the block)
- Curing (of the green blocks)

The order of the production process stages is not commutative and should therefore follow one after the other. This is illustrated by the schematic shown in figure 1.

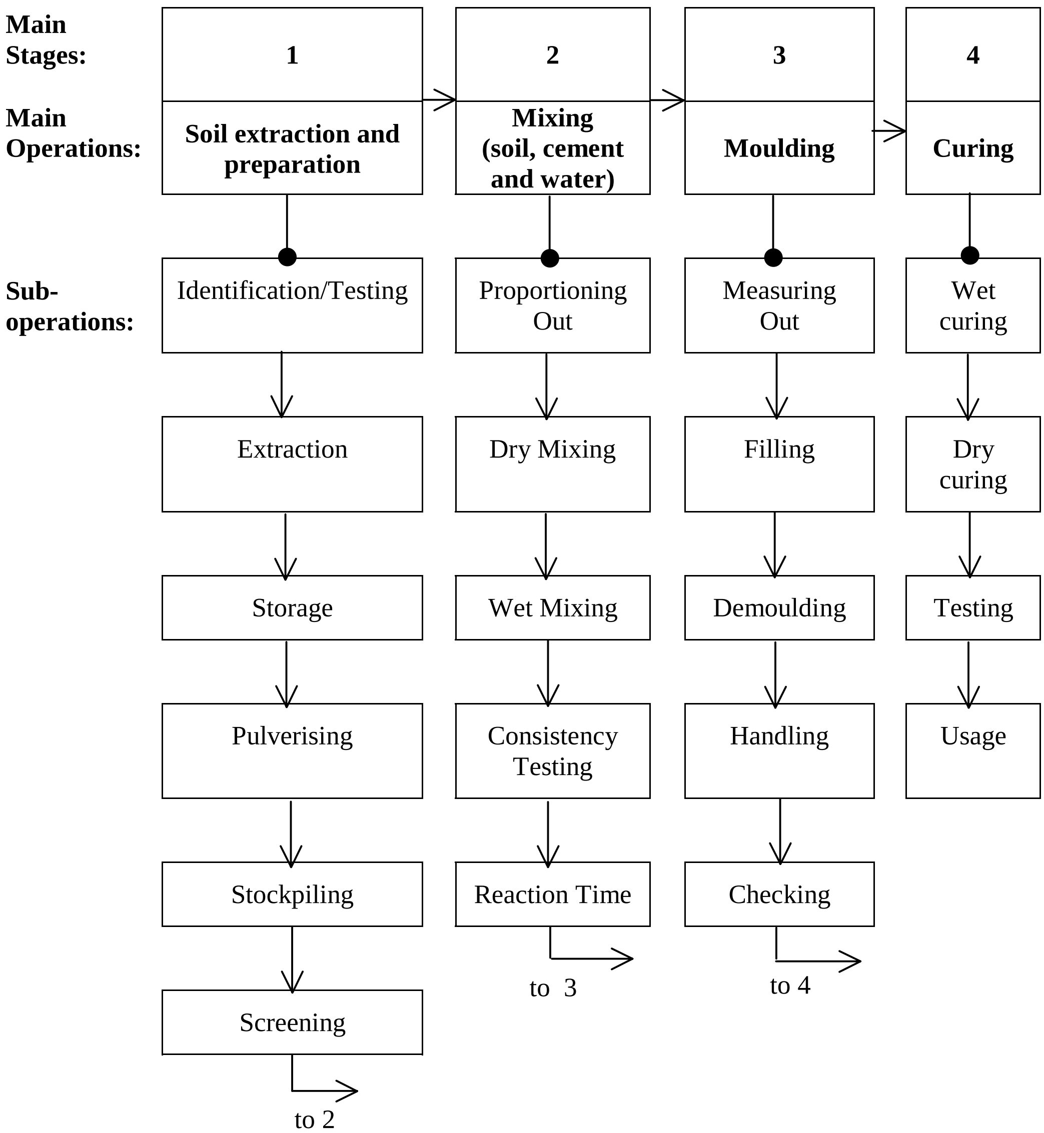

Figure 1: Schematic showing the main stages and operations of a CSB production cycle.

(Adapted from: Houben & Guillaud, 1994; Rigassi, 1995; Houben et al, 1996)

The schematic in figure 1 shows that within the four main production stages, there are several sub-operations. These operations are so interdependent that the sequencing adopted has to follow the order shown since each preceding operation must be completed before the next one can start (Webb & Lockwood, 1987). For efficient productivity, a block production site should be organised taking into account the unique nature of the various operations with a view to harmonising them. This has often been underrated with the result that key operations are missed or interfered with. In such cases both the quality of the block and the productivity of the site can be adversely affected.

As the properties and performance of a block are heavily dependent on the outcome of each of the production cycle processes, each stage is now discussed in turn. The experience gained by the author during the production of block samples for experimental investigations in the course of this thesis, and prior to this, during the manufacture of blocks for large CSB building projects in Uganda between the period 1987 and 1994, are also drawn upon. The discussions are presented in Sections 3.4.2 to 3.4.5 that follow.

3.4.2 SOIL EXTRACTION AND PREPARATION

Soil to be used for CSB production should preferably be extracted from or near the proposed building site (Williams, 1980). Indeed this is one of the major attractions of using CSBs for building purposes (DoHUD, 1955; Fitzmaurice, 1958; Denyer, 1978; Agarwal, 1981). Sourcing the main raw material in this manner can significantly minimise expenses normally associated with transportation (Cinva-Ram, 1957; ILO, 1987). Prior to extraction however, the soil at the potential site has to be properly identified and classified (Norton, 1997). It is only after this has been done, with the results being acceptable, that subsequent procedures including extraction, may follow.

Identification of soil at the proposed extraction site may be facilitated if information on local soil types, or information based on experience can be obtained. Documented sources may include maps, previous construction records, etc. Even then, the soil will still need to be identified using field indicator tests followed by laboratory tests in that order (Akroyd, 1962; Stulz & Mukerji, 1988; BS 1377, 1990). Details regarding both types of soil tests are discussed in Chapter 4 and Chapter 5. As stated earlier, the soil needed for CSB production should contain some coarse fraction (fine gravel and sand), and some fines fraction (silt and clay). The clays in the fines fraction significantly contributes to binding the fine gravel, sand and silt together (Lunt, 1980). If the soil is deemed satisfactory either for direct use as it is, or following blending with the missing soil fractions, then the extraction process can commence.

The soil is best extracted from the sub-soil level and not from the top-soil level (from about 300 mm downwards from the surface) (Webb & Lockwood, 1987). Disregarding of top-soil layers ensures that undesirable inclusion of organic matter, normally dominant at this level, is avoided. Another important consideration before soil extraction can commence is whether the ground to be used as a pit can indeed supply enough soil for the particular size of the project. The pit should be located in an area large enough to generate and sustain the supply of sufficient raw material to satisfy the building requirements. In short, the process of soil extraction should only begin after it has been established that the soil is suitable, or can be modified to become suitable and that it is available in sufficient quantity (ESCAP/RILEM/CIP, 1987; ILO, 1987; Gwosdz & Sekivale, 1998).

The soil may then be extracted either manually or by mechanical means. Manual extraction involving labourers using basic hand tools such as shovels and picks has the disadvantage of low output. Experience of the author also showed that daily output in such cases rarely exceeded 3 m^3 per day per man. Yet when motorised mechanical means are used (excavators, bucket loaders), the output significantly can increase to about 100 m^3 per machine per hour. The high cost of hire or purchase of such equipment, coupled with the need to create jobs, might however continue to dictate that manual labour be used for the foreseeable future. Which ever approach is adopted, after the extraction of soil, further preparatory operations are still required. This is because freshly extracted soil is not immediately suitable in the natural state in which it is found (due to the presence of solid concretions in lumps or large pieces, or friable aggregations in powdery form). Further, the soil when freshly dug out, depending on its natural moisture content, may still be wet, moist, damp or even dry. It is not advisable therefore, to immediately use soil in any of these forms for block production without further preparations. The main objective of preparing the soil is to transform it into a more useable form of known moisture content and of the correct size functions (Cinva-Ram, 1957).

Soil preparation after extraction involves drying out, temporary storage, pulverisation, stockpiling and screening. Storing and stockpiling simply follow the key operations of drying and pulverisation. The just extracted soil can be dried out by spreading it out in thin layers on a hard level surface. By drying out the soil, an attempt is made to gradually free the soil particles from their entanglement and to obtain a material of almost even minimum moisture content. To achieve this fast enough, the thinly spread out soil should be regularly raked through in order to turn it over repeatedly. The same drying out operations were used for the ordinary builders sand used for manufacturing block samples for the experimental investigations in the course of this research (Chapter 5). The drying operation can be verified as satisfactorily completed through visual examination of any changes of colour of both the top and bottom layers. If the bottom soil is still of dark complexion even after several turning-over operations, it simply means the drying process has yet to be continued. When both the bottom and top layers of the spread out soil show a uniformly light colouration than when first obtained, then the soil can be considered to be dry enough. At this stage it should also be easy to break up any remaining soil lumps by hand. These should mostly be clay lumps, since it is such fines that are responsible for forming nodules. Nodules of diameter greater than 10 mm should not be allowed (Arrigone, 1986; Houben & Guillaud, 1994). Simple hand tools such as wooden hammers, hoes, pincers, etc., can be used to pulverise and break up soil lumps. Pulverisation and breaking up of lumps in this manner also helps speed up the drying process (by increasing the surface area). The pulverised soil can then be screened.

Screening of soil is a crucial process. Screening may be done by sieving using wire mesh sieve screens of agreed maximum aperture sizes. Recommended aperture sizes for sieves to allow the maximum size fraction of soil to be included in a block vary. Two recommended size ranges are reported in the literature: 5 to 6 mm (Webb & Lockwood, 1987; ILO, 1987), and 10-15 mm (Houben & Guillaud, 1994; Rigassi, 1995). The maximum soil size fraction used for block making in the course of this research was 5 mm (fine gravel and below). The process of sieving also serves to eliminate any undesirable materials still in the soil after the general preparations have been done. But the objective remains to rapidly ensure that only soil below the required maximum size fractions are the only ones obtained. The screen used may be a fixed one set at an oblique angle, or it may be a suspended one on top of a collecting bin. In the former case the soil is thrown at the screen while in the later case it is poured through it. When a fixed screen was used in Uganda, the rate of screening was about 1 m^3 per hour per person (Kerali, 1996). If no screen is available on site, it is still recommended that some form of removal, even by hand, be conducted. Large objects are usually easy to detect and to remove by hand.

After screening, the soil can then be stockpiled awaiting use. From this stage onwards, the soil should be covered in order to keep it dry and prevent clay lumps reforming once again. In the event that the soil obtained is predominantly of one type or size, then controlled mixing with other soil types and size fractions imported from nearby quarries should be done. This will improve the grading of the soil. For example, a predominantly sandy soil could be mixed with some clay (recommended minimum 10% and maximum 30%). Controlled mixing such as this will also help avoid unnecessary rejection and wastage of soil. During this research for example, the ordinary builders sand which was supplied, was mixed with pure Kaolin clay (15%) to form the soil of the desired design properties (Chapter 5).

In the preparation of soil samples for this thesis, it was not necessary to go through all the steps mentioned here. It was only necessary to dry out the soil on the laboratory floor, screen it through the 5 mm circular sieve screen, then store it in a well covered bin. The bins were kept in a dry area of the laboratory. Further discussions on the procedures are presented in Chapter 5.

3.4.3 MIXING OF SOIL, CEMENT AND WATER

This stage of the production process initially involves the dry mixing together of the main constituent materials (soil and cement), before wet mixing with water to hydrate the OPC. The sufficient distribution of OPC throughout the soil, and the homogeneity and uniformity of the resulting block, can be significantly affected by the procedures adopted at the mixing stage. Considering that over 90% of a block comprises soil, and that only less than 10% comprises cement, achieving an even distribution of the latter in the former is far from being straightforward. Yet the procedure is often underestimated, with severe implications for the quality of the resulting block. The main operations during the mixing stage include: proportioning out, dry mixing, wet mixing, consistency testing and hold-back time (retention time).

Proportioning out of soil and cement in their dry state is the first crucial step which requires care. The total volume of the separate dry ingredients to be mixed should be based on a practical criteria (Mukerji & Worner, 1991). From experience, the proportioning criteria is normally based on the hourly output of the press being used. This means blocks have to be produced in separate batches, requiring mixes to be prepared only in sufficient quantity to be consumed by the press within approximately one hours operation. Large batches are undesirable for several reasons. If larger batches are mixed without immediate compaction following, the water may evaporate causing the cement to set prematurely. This can easily be expected especially in hot tropical climates (Fullerton, 1979; BRE, 1980; Spence & Cook, 1983; Norton, 1986; Stulz & Mukerji, 1988). Moreover, with large batches, it is also very difficult to achieve an even and homogeneous mix. Use of large batches also increases the risk of moisture variations developing in a mix. OPC is known to set within about 45 minutes (Lea, 1972; Illston, 1994). If within this time the wet mix has not yet been compacted, then a significantly weakened block might be produced (Lunt, 1980). Moreover, as cement is usually scarce and therefore expensive in developing countries, wastage of the binder through premature setting should be foreseeable and avoidable. This can be done as stated earlier by proportioning materials based on batch sizes that can be compacted within the hour (Mukerji, 1994).

Proportioning out of dry soil and cement can be done either by weight, or by volume measurements (Webb & Lockwood, 1987). It is important that the materials being proportioned out remain in the same dry physical state. With volume measurement proportioning, either a single gauge box, or two different gauge boxes may be used. The use of a single gauge box which is meant to measure both soil and cement is common. The amount of cement and soil required for an hourly batch of blocks is then measured by filling, levelling and emptying the gauge box up to the required number of times for each separate material. This method is not without its failings. Apart from contamination, problems may arise if the moisture content of the soil will vary. When this happens, so will its specific surface area. Variation in specific surface area of a soil will result in different amounts of soil being measured out each time. This remains a major area of concern. Attempts should be made to ensure that the moisture content of the 'dry' soil remains constant. This is achievable through covering of the dry samples and avoiding humid environments. The mode in which the gauge boxes are filled is also a potential source of error. All loose material should ideally be filled in and tampered to avoid under-filling with the top also be levelled off to avoid over-filling. During the proportioning out of dry materials in the course of this research, proportioning was done by weight, not by volume (Chapter 5).

As stated earlier, following proportioning, the soil and cement should be mixed in two separate stages; first in a dry physical state, then in a wet state, in that order. Dry state mixing is best done by spreading the cement evenly over the spread out dry soil. The two are then mixed together thoroughly till a uniform homogeneous colour is observed. Samples of the mix can be scooped up and visually examined to certify that uniform colouration has approximately been achieved. Uniform colour of the mix is therefore the only useful control tool or indicator at this stage. Since no other obvious test exists, mixing of the two dry materials should therefore continue until a uniform colour is obtained. Mixing can be done manually or by mechanical means. For the experimental investigations during this research, dry mixing was done using mechanical means (Chapter 5). Mechanical mixing is preferable over manual mixing for several reasons. With hand mixing, the same high level of concentration that should be maintained throughout is not humanly possible all the time. It is not uncommon to find mixes produced earlier in the day being more uniform than those produced later in the clay by the same person(s). Exhaustion, familiarity, lack of concentration or interest, lack of knowledge of the implications, coupled with inadequate constant supervision, may all contribute to insufficient mixing.

After dry mixing to uniform colour, water can then be added to the still dry soil and cement mix. The purpose of the water is to hydrate the cement and to enable the mix to be compacted at optimum moisture content. Determination of the right amount of water to achieve both aims remains an area requiring more investigation in future. If mixing is to be done manually, then the determined amount of water should first be lightly sprinkled using a shower rose head container. This should be done in such a way that it just moistens the surface of the well spread dry mix. The water should not be poured onto the mix all at once, as was observed on some sites (Chapter 4). Neither should it be poured onto a heap of the mix as is also commonly and wrongfully done. This is to avoid creating particles of damp soil that may roll down the side of the heap while growing even larger in size. Contact with water should be made uniform and widespread. The mix is then turned over before more water is added to the soil and cement mix. The wet mixing operation has to be done repeatedly until two things happen: the damp mix achieves a uniform colour and it also passes the 'drop test'. Even on achieving uniform colour, any lumps still in the mix should be broken down. Lumps can form if the mixing time is too long, the moisture content is too high, or when incorrect mixing procedures were followed. Both dry and wet mixing should ideally be done within 3 to 4 minutes (Houben & Guillaud, 1994; Rigassi, 1995). For clayey soils, the moisture content of the mix should preferable be slightly higher than the OMC: for sandy soils, it should preferably be slightly lower than the OMC (Houben & Guillaud, 1994). In the absence of any other consistency test similar to the slump test used for concrete products, the drop test remains the only satisfactory indicator for approximating the OMC of the damp soil and cement mix (ILO, 1987). The slump test as used in concrete production may not work as a consistency test for CSB production due to the near-dry mix state required for the latter.

Unfortunately, passing the drop-test may not necessarily mean that further control measures be set aside. During the production of blocks in the course of this research, it was noted that in some of the mixes which had passed the drop test, excess water was observed dripping on the sides of the mould during compression. Similar experiences were recorded in Webb & Lockwood (1987). The amount of water in the mix had to be reduced as mentioned earlier. In the experiments conducted during the thesis, the blocks made from mixes where the water dripped by the side of the mould were not rejected. They were kept aside and labelled accordingly. The surprising outcome when these blocks were tested for wet compressive strength twenty-eight days later, was that values obtained were 25 to 30% higher than for the blocks made from the reduced water content mixes. The difference between the mean dry and wet compressive strength were also reduced. The only feasible explanation of this unexpected outcome was that the excess water in the mix contributed to the maximum hydration of cement. The issue of OMC and the sufficiency of water for hydration of cement is recommended for further future research (Chapter 8).

The time between wet mixing and compaction in the mould should be as short as possible when OPC is used as the stabiliser. A period of between 5 and 10 minutes has been suggested (Houben & Guillaud, 1994). For this reason, water should only be added for wet mixing precisely before the start of the moulding process. If any delay between dry mixing and moulding is anticipated, then wet mixing should be deferred.

The dry mix should be covered with a polythene sheet or similar protective cover. Delays of more than two hours due to lunch breaks or other human needs should not be allowed. The effect of hold-back time on the performance of blocks is investigated experimentally (Chapter 6).

3.4.4 Compressing the Damp Soil and Cement Mix

Compressing the damp soil and cement mix is a key stage in the production of CSBs. The effect of cement stabilisation of soil is significantly enhanced by compressing it (Ingles & Metcalf, 1972; Gooding & Thomas, 1995). Compression reduces voids by driving off air (compaction) and any excess water (consolidation) from the damp soil and cement mix. The combined expulsion of air and water, and the squeezing of the solid particles together increases the density of the mix. Uncompressed soil-cement mix of the same mass prior to moulding may have density ranging between 1000 kg/m^3 and 1400 kg/m^3 (Norton, 1997). After compression, the increase in density for the same mass of mix is between 30% and 120%, commonly ranging between 1700 kg/m^3 and 2200 kg/m^3 (Houben & Guillaud, 1994; Rigassi, 1995). Higher densities are associated with improved durability (Spence, 1975). Compression of the mix should be done as soon as it has passed the drop test. The compression stage involves five distinct steps, namely: measuring out, mould filling, moulding, demoulding, and handling of the green blocks (Rigassi, 1995). Underestimation of any of these five steps can lead to the production of inferior blocks of low compressive strength and durability.

The damp soil-cement mix has to be correctly measured out before filling the mould. Any slight variations in the amount of mix fed into the mould can result in blocks of differing density and sizes. Cases of differences in density are normally associated with fixed-volume type of compression machines while size variations with fixed-pressure ones (Lunt, 1980). The two types of errors are cumulative and should be minimised or avoided completely. To do this, the amount of damp soil-cement mix to be filled into the mould should be strictly controlled. This can be achieved by measuring out the exact amount of mix to be placed into the mould each time using either a graduated bucket, scoop, or measuring box of fixed volume. Measurement by weight, though considerably slower, can also be done. Presses equipped with adjustable measuring devices which either use sliding valves or tipping boxes are extremely rare. Whichever method is adopted, the important point is to ensure that the correct amount of mix, and of even moisture content, is fed into the mould each time. The moisture content of the mix matters a great deal, and variations should preferably be avoided. Variations can lead to changes in specific volume causing differing amounts of mix to be placed each time. During the manufacture of block samples for experiments in the course of this research, measuring out was done exclusively by weight (Chapter 5).

Filling of the mould with the measured out mix should then follow promptly. Before the actual filling of the mould box, its interior should be cleaned. Although mould types vary, they are generally designed to be completely filled with the mix. After filling the mould, the top of the last layer should be scraped off level with the sides of the mould. The filling is best done in two or three equal layers. The filling operation for each layer should be checked each time, with the fingers being used to press the mix into the corners after each layer has been placed. Pressing the corners is necessary because the bottom corners of the mould are the most difficult part of the mould to fill. In addition to this topping up, removing excess material and any lumps of soil or stones, etc., should all be done for the top layer at this stage. After the mould has been filled and checked, it can then be covered with the mould lid. The lid itself has to be correctly positioned ensuring that no mix is left entrapped between the lid and the edges of the mould. There is yet no known device to indicate that the mould has been correctly filled (Mukerji, 1988; Rigassi, 1995).

The mix can then be compressed. As machines vary widely, the operations needed to compress the block will differ according to the specified characteristics and operating manual for each press. Block making presses will vary by:

- Compression type (static compression, dynamic, or kneading)
- Moulding pressure (low < 3 MPa; moderate 4-6 MPa; high > 7 MPa)
- Compression ratio (1:1.65 to 1:2)
- Productivity (maximum daily or hourly output)
- Mould size and type (fixed, adjustable: solid, hollow, frogged, interlocking)

In most manual presses, the force applied to the compression lever will depend on how much mix has been placed in the mould. This force should neither be too high, nor too low. If the force required is too high, either the machine will gradually get damaged, or the operators will tire out quickly. If the force is too low, the block will be insufficiently compressed (Norton, 1997). Such difficulties are experienced even with motorised press units. As the compression force remains uniform, it becomes impossible to check during compression if the mould has been correctly filled. If the correct amount of mix is at its OMC is placed each time and the same moulding pressure is applied, it can be expected that blocks of constant density are produced. Such blocks will also tend to be of uniform dimensions. For the Brepack machine used to produce samples in this research, an attached pressure gauge provided the needed indication of the pressure exerted (6 MPa and 10 MPa). The transmission of energy to the mix was through an hydraulic system. The main advantages of this compression machine were that the number of operations needed were few, thickness of the block could be controlled, and laminations usually associated with other compression methods avoidable. Laminations will tend to occur if the speed of compaction is below 1-2 seconds (Houben & Guillaud, 1994). A further advantage was that the sides of the blocks were well compacted. This should be expected as the internal friction of the soil-cement mix increases, so does the pressure on the surface of the mould. The mix closer to the mould surface is more thoroughly compressed than that further from it. Which is why the least compacted soil-cement mix is likely to be found at the middle of the block which is subjected to the least shear (Houben & Guillaud, 1994). This has clear implications for the durability of a block. It explains why block surfaces should be protected at all costs and not allowed to deteriorate prematurely. If allowed to recede inwards, it will expose the core of the block which is its least compacted part. The rate of deterioration is then likely to increase significantly from then on (Chapter 2).

After moulding, the green blocks have to be ejected usually through the same piston that compressed the block (in most presses). On ejection, the block should be carefully removed and handled. Since the green block is still weak and fragile, great care should be taken during the handling operation. The surface area of contact between the block and the mechanism of removal (hands, block pincers, wooden pieces) should be as large as possible to reduce any unreasonably high pressures on the green blocks to a minimum. Special precautions should be taken while removing blocks from certain types of moulds. Removal of solid blocks is easier than removal of hollow, frogged and interlocking blocks of a similar size. Non-solid blocks will tend to have several points of vulnerability, such as protrusions, indentations and thin sections. Areas of the block such as edges and corners still remain particularly vulnerable and should not be touched. These considerations are often underrated with the result that blocks with broken edges and chipped corners are commonly produced. On removal from the mould, green blocks should undergo certain quality control checks. Between 5 and 10 blocks per batch can be selected at random for such tests (Rigassi,1995).

Details of the tests conducted at this stage and findings are presented in Chapter 5. These tests were done to identify variations in blocks produced and their possible reasons. For example, any variations in the direction of compaction (height) could easily be attributed to irregular filling, which could then be corrected. Density variations can be detected by weighing the samples and taking their dimensions. Low density for the same mix could then be attributed to insufficient mould filling. These quality control tests are useful since they contribute to reduction in wastage and early detection of poor procedures which would otherwise lead to the production of inferior quality blocks, of low compressive strength and durability (Chapter 4).

For quality output to be sustained, regular maintenance of the press should be conducted. After each day, or even on brief stoppage of work, the press should be thoroughly cleaned and left in a state ready for the next production to begin. Maintenance procedures normally included in the manual for each press should be strictly adhered to. Supervisors can assign one person the responsibility to do the daily maintenance. Each inspection and maintenance conducted should be verified and a record of what was done and when should be kept.

3.4.5 CURING OF GREEN BLOCKS

Curing of green blocks may be the last stage in the production process but remains one of the most consequential. As stated earlier, the strength of CSBs, as with almost all concrete products in which OPC is used, increases with age (ILO, 1987; Lea, 1970). The hardening of OPC takes time, and so will the development of strength in a block. For the OPC to harden normally, it requires the continued presence of moisture in a block which enables it to complete the hydration process. Insufficient w/c ratio, and low degree of hydration can result in considerably weak blocks. If the green block is not allowed to retain sufficient moisture, then the hydration process will have been interfered with. This can result in unsatisfactory blocks of low strength and poor performance (Enteiche & Augusta, 1964; Odul, 1984).

The objective of the curing stage is therefore to ensure that moisture still in the block is allowed to facilitate the hydration process and to come out gradually and evenly. The two variables during curing that can affect this objective are the duration (time) and conditions (wet, dry, temperature, relative humidity, wind). The curing duration is often dictated by the specifications for the type of binder used and is based on the time needed to achieve the maximum degree of hydration. For OPC the recommended length of time is usually 28 days (BS 12, 1971; Spence, 1980; ILO, 1987; Taylor, 1998). Curing conditions specifically refer to the microenvironment in which the green block is placed. Normally the conditions are such that wet curing is followed by dry curing. During this research, the effect of varying curing conditions and time were investigated. The results are discussed in Chapters 6 and 7.

The curing process normally consists of two phases (ILO, 1987; Neville & Brookes, 1994):

- Primary curing phase (3-5 days)
- Secondary curing phase (up to 28 days for OPC, up to 56 days for lime)

The *primary curing phase* follows immediately after the demoulding of green blocks. During this phase, emphasis is placed on ensuring the retention of moisture within the block. The green blocks should be shielded from direct sunlight and strong winds. The process usually takes three to five days with seven days being the maximum possible (ILO, 1987). If the green block is not shielded, then rapid evaporation is likely to take place, promoting the undesirable loss and uneven distribution of moisture in the block. This can result in surface shrinkage cracking. For this reason, the surface of green blocks should be well protected using light coverings such as polythene sheeting, tarpaulins, or other suitable light materials. Polythene sheets are quite useful since they allow the temperature to rise, while at the same time ensuring that approximately 100% relative humidity is achieved (Rigassi, 1995). During the curing of samples for this research, green blocks were superficially covered on the first day, then placed inside sealed polythene sheeting 24 hours later. The blocks were then laid next to one another in a designated primary curing area within the laboratory.

Current indicators of sufficient primary curing are based on colour changes of the block, and sometimes on the degree of evaporated moisture trapped beneath the covering polythene sheeting. Freshly demoulded blocks, due to the relatively high moisture content still in them, tend to be of dark complexion. As the moisture is used up for hydration, with some escaping, the complexion of the demoulded block begins to adopt a much lighter colour. When sustained light colouration is attained then primary curing can be considered complete. Generally, the moisture content of the block should not be allowed to vary by more than 1-2% during the primary curing period (Houben & Guillaud, 1994; Rigassi, 1995).

The *secondary curing phase* follows on from the previous phase, with the objective this time being to allow any moisture still in the block to evaporate out gradually and evenly. The gradual evaporation of moisture out of a block affects both the OPC hydrates and the clay minerals in the block. Secondary curing also allows the semi-cured blocks to be conveniently stacked nearer to the actual building site proper. Even then, the blocks have not yet fully developed the required compressive strength. They should therefore be stacked not more than 10 blocks high on a hard, flat and level surface (Rigassi, 1995). The stacked blocks should continue to be protected from direct sunlight, wind and rain. This can be done by dry stacking the blocks under a covered shed or shelter for 2 to 3 weeks in the case of OPC stabilised blocks. After 28 days from the date of demoulding, the blocks are deemed to have achieved sufficient strength. After this period, there will be no further noticeable significant increase in strength for the OPC hydrates that bind the blocks particles together (Fitzmaurice, 1958; PCA, 1970). For lime stabilised blocks, twice the time recommended for OPC should be provided for during both primary and secondary curing (BS 890, 1972; Bessey, 1975; Coad, 1979; Apers, 1983; Webb & Lockwood, 1987).

The fully cured blocks can then be placed on wooden pallets, or stacked in easily counted lots. Initial performance tests can then be conducted on randomly selected samples from each batch (ILO, 1987). These are then compared with local acceptable minimum standards for buildings (Houben et al, 1996). Results of initial performance tests for blocks produced during this research are presented in Chapters 6 and 7.

3.5 CONCLUSION

From the preceding sections, a number of important conclusions can be made. These are summarised below, presented in the order of coverage in Chapter 3.

Main constituent materials (cement, soil, water)

CSBs will perform well for the service life of the structure of which they form part if sufficient attention is paid to the choice of materials and their proportioning. A thorough knowledge of the nature and properties of the three main materials (cement, soil and water) is thus required.

Cement constitutes between 5 and 8% by weight of a block. It was noted in Chapter 3 that the main function of OPC is to bind the soil particles in the block together, thus forming a composite structure with increased compressive strength (both wet and dry), limited dimensional movement and improved durability. For this to be attained, the mechanism of cement hydration and the properties of the resulting cement hydrates that can influence the durability of the block, should be well minded. It was established from literature sources that present approaches in the use of the binder appear to take these factors for granted. Yet for OPC to have maximum effect in binding the soil particles together, and for the block to develop high strength, the water-cement ratio used should be low and a maximum degree of hydration has to be achieved. The former can be facilitated by use of cement replacement materials, while the latter can be achieved by proper curing. These two considerations rarely feature in current CSB manuals. The effect of these two factors on the durability of blocks are investigated experimentally in Chapters 6 and 7.

Soil constitutes the bulk of CSBs. Amounts as high as between 90 and 95% by weight of the block are normally used. Soil is composed of fine gravel, sand, silt and clay. In natural soils, the proportions of these four main soil constituents can vary infinitely, and with each variation, so do the properties of the soil. Not all soils can therefore be considered suitable as found for CSB production. To assess the suitability of a particular soil, the soil will first need to be identified and classified. It was established from literature sources that the most important basis for soil classification are through its particle size distribution and its plasticity. Current suitability criteria for soil requires that they be well graded. The soil has to contain almost every soil size fraction between the maximum (usually gravel less than 20 mm, or 6 mm), and the minimum particle size (usually clay less than 0.002 mm). In a well graded soil, the packing of the soil particles is considered to be in its most dense state. The plasticity of soils on the other hand is associated with the presence of fines, usually clay. According to literature sources the desirable plasticity index of soil suitable for stabilisation should vary between 5% and 30%.

Clay types vary immensely, though three main groups are identifiable (kaolin, illite and montmorolinite). It was widely reported in the literature that the clay type and amount is a major factor in determining the suitability of soil for stabilisation. Soils with clay content below 30% can be stabilised using OPC, while those with more than 30% using lime. Lime is known to have the capacity to fix the clay, through a pozzolanic reaction.

Water is added to the dry soil-cement mix to hydrate the cement and to lubricate the soil to attain maximum densification. Unfortunately the literature reveals that current emphasis is generally placed on the required quantity of water, but not on its quality. Due to the scarcity of water in most developing countries, all kinds of sources are likely to be used for CSB production. Water of unknown service record may contain contaminants that may adversely affect the hydration reaction of OPC. Such water may contain suspended solids and soluble substances in excess of current limits for drinking water. The effect of the use of water of unknown service record is investigated and discussed in Chapter 4.

Soil-Cement Stabilisation

Chemical stabilisation of soil using OPC as the binder of choice was the main stabilisation method described. It was noted that the effect of cement stabilisation is more long lasting than pure mechanical or physical means of stabilisation used alone. It was also reported in the literature that the combination of all the three methods is more effective. It was noted in Chapter 3 that in the mechanism of stabilisation using OPC, the binder joins the soil particles together by forming strong interlocking bonds with the fine gravel and sand fractions of the soil. The lime that is released from the hydration reaction of OPC then reacts with the clay to form a secondary binder, with similar binding effects.

The composite matrix that results contains cement hydrates, conventional mortar, calcium hydroxide, unhydrated OPC residues, unstabilised soils, and capillary pores. According to CSB literature sources the exact proportions of each of these matrices in the block fabric is still unknown. The proportions of each of these matrices is likely to influence the durability of blocks significantly. Attempts are made in this thesis to identify some of these matrices using the petrographic analysis of thin sections (Chapter 7).

Block Production Cycle

It was established from literature sources that the CSB production cycle comprises four main stages, each with several sub-processes. The main stages include soil winning and preparation, soil-cement-water mixing, moulding and curing. It was noted that the processes were so interdependent and interrelated that they require to be conducted in a proper sequence. Omission of any of the stages is likely to adversely affect the properties of the final block.

With the preceding conclusions, the objectives of Chapter 3 were met. The key issues identified in Chapter 3 are to serve as the theoretical background for the experimental investigations described in Part B of this thesis.

PART B:

MAIN INVESTIGATIONS AND FINDINGS

CHAPTER 4

EXPOSURE CONDITION SURVEY OF CSB BUILDINGS

4.1 INTRODUCTION

The performance of CSBs can be better understood through a combination of theoretical knowledge, study of precedents and assessment of the experience of its users. This chapter reports on methods and findings from a study of the last two approaches.

As part of the research, a fieldwork was undertaken in Uganda between January and March 2000. Uganda was selected for two main reasons: firstly, its geographic location within the humid tropics, and secondly due to the large stock of CSB buildings found in the country. The exposure conditions were considered to be representative of similar conditions in most of the humid tropics. Further, CSBs were first officially introduced in the country for low cost housing in high density urban areas in 1987 (Okello, 1989). Since then, several hundred CSB structures were built mostly under the auspices of donor agencies like the ILO. During this period (1987 to 1995) the author, apart from involvement in similar projects in other parts of the country, directly supervised the construction of a number of residential buildings using CSBs (Kerali & Schmetser, 1995). At the time of the fieldwork visit, the use of CSBs for low-cost housing had been extended to other large urban municipalities in the country.

The objective of Chapter 4 is to report on the main methods and key findings from the fieldwork. Four methods were used during the fieldwork, namely:

- Collection of documented data on the inventory of CSB buildings and environmental exposure conditions in Uganda.
- Conduct of exposure condition survey of CSB structures of various ages and stages of completion. This involved: random inspection of existing buildings, in-service testing, scrutiny of maintenance records and other test records. Photographic records of inspected structures were then kept.
- Observation of methods of work on current CSB production sites including the conduct of suitability tests on soils and quality test checks on cement and water used.
- Interviews and questionnaires to gauge the opinions and experiences of randomly selected respondents.

The scope of coverage of Chapter 4 therefore focuses on the discussion of findings resulting from using the above methods. The chapter is divided into six sections. After this introductory section, the rest of the chapter covers background documentation, condition survey methods and findings, block production site visits, interviews and questionnaires, and conclusion.

4.2 BACKGROUND DOCUMENTATION

In this section, the inventory of CSB structures in Uganda and the characterisation of the exposure environment are presented.

4.2.1 INVENTORY OF EXISTING CSB BUILDINGS

The purpose of seeking information on the inventory of CSB buildings in the country was to obtain an indication of the overall total number of existing CSB structures. The same exercise was also used to get information on current building programmes and future plans.

Since the introduction of CSB structures in the country in the late 1980s, over 400 buildings have been constructed. As mentioned earlier, CSB structures were introduced officially under the auspices of the International Labour Organisation (ILO). The ILO was implementing an earlier resolution of the United Nations Conference on Shelter Strategy that had been held in Vancouver, Canada in 1978 (DoH, 1992). At the time, the projected housing backlog in Uganda by the year 2006 was estimated at 3 million dwellings. CSB structures were targeted at the high density, low income urban areas (Davidson & Payne, 1983; Taylor & Cotton, 1994).

Other CSB structures were built in rural areas in the form of public buildings such as health centres, schools, community centres, etc. These were initially built in the central region districts of Kampala, Luweero, Mpigi and Kiboga. The largest single housing estate in which CSBs were used remains at Namuwongo (in Kampala)where over 100 residential buildings were erected. At the time of the fieldwork visit, the project site consisted of buildings in various stages of completion (completed, on-going, abandoned, etc.). Also at the time of the visit, another large CSB project site had been initiated at Malukhu, in Mbale Municipality. Over 80 structures had been erected, with plans to construct at least 100 buildings annually over the next few years. This latter project was being funded by the Danish Agency for International Development (DANIDA). These two sites therefore represent the largest single concentrations of CSB structures in the country. Both sites were extensively inspected by the author and in-service tests conducted on buildings as well as on green blocks being produced. Photographs of some of the main features at the two sites were taken.

The findings are discussed in Sections 4.3, 4.4 and 4.5 of this Chapter.

Even with these promising developments, the housing deficit in the country, as is the case with many other developing countries, remains acute (Hamdi, 1995). The demand for CSB structures is therefore likely to remain very high in the foreseeable future.

4.2.2 Characteristics of the Natural Exposure Conditions in Uganda

Characterisation of the exposure environment in which CSBs were being used was considered to be a crucial undertaking during the fieldwork. The objective was to identify the main naturally occurring agents whose effects were likely to remain deleterious to the block structure over its service lifetime. The approach which led to the listing of the different types and ranges of deterioration agents was based on the deterioration mechanisms discussed in Chapter 2. The highlights of the mode of occurrence of the main deterioration agents (rain, temperature, relative humidity) and the results of the visual inspection of defects were used to produce a provisional severity ranking of deterioration mechanisms (Appendix D).

The type of agent acting on a block and the severity of its actions are closely correlated to the geographic location of the CSB building structure (BS 7543, 1992; Sjostrom et al, 1996). Moreover, local topography and geographic features are known to modify climate. Before presenting the average climatic conditions in Uganda therefore, it is necessary to first of all describe some of the main geographic characteristics of the country.

Uganda is located astride the Equator, lying between latitudes 4°12N and 1°29S, and within longitudes 29°34E and 35°0E. Although the total land area is 241,000 square kilometres, about 20% of it is covered by water, and about 30% by forests (Briggs, 1994; Hood, 1996; Tetley, 1998). Located at the highest altitude in Africa, the elevation above sea level (ASL) varies between 620 metres ASL and 5110 metres ASL. About 85% of the country lies between 900-1500 metres ASL. As can be expected, these geographic features (water bodies, forest cover, elevation ASL) do have a considerable influence in modifying the climatic conditions in the country. The use of CSBs under such unique climatic conditions can therefore be expected to present special problems. The description of the average climatic conditions in the country would not have been complete without mentioning these geographic features. In terms of macro-climatic and global weather classification, Uganda falls within the Equatorial belt. This humid, tropical belt stretches between 6°N and 6°S (BRE, 1980; Webb, 1988). The climatic characteristics of interest to this research are rainfall and temperature.

The *mean annual rainfall* in Uganda is about 1500 mm per annum (Hood, 1996). The rainfall, which is seasonal, is fairly well distributed throughout the country. Two distinguishable rainfall seasons are the long rains of March to May and the short rains of September to November. In analysing the potential deleterious effects of rainfall on CSB structures, it is the mode of occurrence of the rain within the immediate proximity of the block which is critical (intensity and duration of the rain) (Ola & Mbata, 1990). The intensity of rainfall in the country, a measure of the quantity of rain falling in a given time, is reported as being greater than 7.5 mm/hr. This falls within the classification for heavy rains (> 7.5 mm/hr) as opposed to light rains (< 2.5 mm/hr) or moderate rains (2.5 – 7.5 mm/hr) (Linsey et al, 1975; Wilson, 1993). The maximum fall of rain in any 24 hours was recorded as 300 mm in Ssesse Islands. The average drop size was reported to vary between 0.5mm and 6.0 mm (Wischmeier &

Smith, 1958; Kirkby & Morgan, 1980). The duration of rainfall in the country, a measure of the period of time in which it falls, also varies a great deal. Periods of between less than one hour and six hours are reported as being typical (Newman, 1986; McIllveen, 1998). It is well documented that the higher the intensity of rainfall in the country, the shorter is the duration in which it occurs. It is this intensity-duration relationship that can considerably influence the erosive potential of rain (Blanchard, 1948; Bilham, 1962). The erosivity of rain can also be determined by the rain drop-size, its distribution, fall velocity and impact kinetic energy (Ellison, 1944). As can be expected, an erosive threshold below which no surface erosion will take place ought to exist. A similar approach has been successfully used in soil erosion sciences. It was established that the erosive threshold for loose soil in terms of rainfall intensity was about 25 mm/hr (Kirkby & Morgan, 1980). This is a theoretical cut-off point above which erosion of soil can take place. Since CSBs are much denser, stronger and more structurally stable than natural soils, the erosive threshold is likely to be several times higher than the 25 mm/hr suggested for loose and weakly bonded natural soils. Intense rainfall on a CSB surface is more likely to initially wet the surface and generate surface flow than immediately dislodge material from the block surface. The mechanism of water-related deterioration was discussed in detail in Chapter 2. The rainfall characteristics in the country suggest that water-related deterioration of exposed block surfaces is likely to take place during the service lifetime of the block. Defects associated with this mechanism of deterioration are described in Section 4.3 of this Chapter.

The *ambient temperature* in the country is quite high. The average daily ambient temperature is 25°C. The highest mean daily temperature recorded in the country was 35°C (Karamoja region in the dry north east). The lowest mean temperature recorded was -5°C (at the peak of the Rumenzori Mountains in the west of the country). The sunshine hours in the country average between 8 and 10 hours. The mean total evaporation is reported as 1950 mm (Hood, 1996; Tetley, 1998). As can be expected these temperature conditions provide the basic setting for temperature-related deterioration to occur in blocks. Mechanisms of temperature-related deterioration were discussed in Chapter 2. The presence of large, fresh water bodies in the country such as lakes and rivers and the high temperatures ensure that the level of humidity in the country is also high. Typical ranges for relative humidity are reported as lying between 30 and 90% depending on the cloud cover.

The data presented in this section was considered to be adequate enough to provide sufficient information to link the deterioration of CSB structures to the most common deterioration agents known. The condition survey that follows describes in more detail the common types of defects found on exposed CSB wall structures.

4.3 CONDITION SURVEY METHODS AND FINDINGS

The condition survey of exposed CSB structures was perhaps the most important undertaking during the research. Three methods were used for the survey, namely:

- Visual inspection (of CSB buildings)
- In-service condition measurement (of defects)
- Field indicator soil testing (at the major CSB project sites)

These are now discussed each in turn, in the following sections, 4.3.1, 4.3.2 and 4.3.3.

4.3.1 VISUAL INSPECTION OF EXPOSED CSB STRUCTURES

As with most building materials, the initial detection of their exposure performance is initially based on visual inspection (BRE, 1982; Bungay & Millard, 1996). Visual inspection is therefore the first phase of any in-service evaluation of a material such as a CSB. In this section, the following are discussed:

- Reasons for choosing visual inspection as a method for evaluating the performance of CSBs
- The number of types of CSB buildings inspected
- The type and range of defects observed

Visual inspection as a way of assessing the performance of CSBs under natural exposure conditions was selected for several reasons. They include the following:

- the CSB specimens being inspected within the exposed wall structure are at their 'full scale' during the assessment. This makes it possible to closely examine their current condition on a full scale basis. Any defects due to dimensional changes and the effects of the restraining action of adjacent blocks and mortar, can be observed directly. The effect of such restraint is very difficult to accurately simulate experimentally.
- the weathering conditions under which the defects were caused are genuine. Because of this, the full effects of the entire range and distribution of deterioration agents acting on the wall surface can be directly observed. A cause-effect link between defect and action of agent(s) can be deduced.
- through visual inspection, more severe cases of deterioration can be distinguished from less severe ones. Using the severity ranking (defects, agents), further in-service tests and measurements can be recommended based on visual observations. The selection of test types can only follow on from the visual inspection report. This is time and cost saving (BS 8210, 1986).
- it is possible to use a number of non-destructive measurement techniques and instruments. Some of the instruments used included: depth gauges, electronic

callipers, crack gauges, hand-held microscopes, rulers, set-squares, etc.

- the in-use conditions of the buildings being inspected are genuine. All user induced influences on the normal wear and tear of the CSB structure can be assessed.
- through the use of a sufficient number of samples, it is possible to reach fairly reliable results and therefore generalise. In this way the interpretation of findings from visual inspection can be considerably facilitated.

With the above reasons in mind, a systematic inspection was made of several CSB buildings in Uganda.

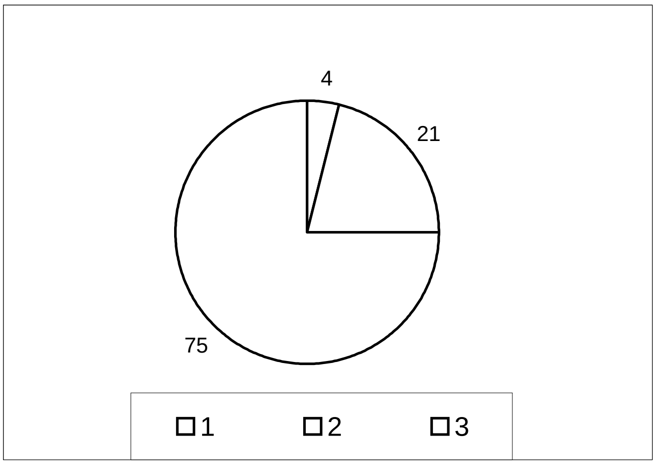
The *number and types* of CSB buildings inspected were varied, all chosen at random. Seven out of the thirty five districts where CSBs had been used for building were visited. In this way a total of 58 CSB buildings were inspected, representing a sample size of about 15% of the officially recorded number of CSB buildings in the country (above the 10% minimum normally required statistically for reliable inferences to be made). Using a checklist of all possible types of defects, the average time taken to inspect each structure was about 45 minutes. The inspected buildings were of different periods of exposure ranging from one month following substantial completion to those with over twelve years of exposure. The buildings were also in various stages of completion: completed, on-going construction and abandoned structures. Buildings found abandoned at wall-plate level and below without roofing appeared to be the most severely damaged (equitable to normal experimental exposure situations). It is from such structures that further in-service measurements (recessed volume of block, width of cracks, degree of pitting and roughening, etc.) were made. These are discussed in Section 4.3.2 that follows.

The line Ministry of Works and Housing provided background information on the period of exposure of each building, types of constituent materials used and the processing method employed to make the blocks. By compiling the list of defects and comparing the findings with the information obtained on each building, a number of useful conclusions were made.

The *type and range* of defects observed from the fifty-eight CSB buildings inspected are summarised in Appendix E. Also shown are the type of defects, façade and section of wall in which they occur, likely causes, age of structure and frequency with which the defects were observed. Comments on some of the features observed by the author, together with information from the users and co-inspectors, are also included.

From the information summarised in Appendix E, it is noted that:

- Surface erosion (resulting in mass loss, or volume reduction) and surface cracking (resulting in bond breakage and segregation) are the two most common defects observed in CSB structures left exposed to the elements. In the tally of number of buildings inspected and frequency with which a particular defect was observed, surface erosion (including roughening and pitting) occurred in 75% of all the cases. Surface and bulk cracking occurred in 21% of all cases. Other defects all counted together only occurred in 4% of the buildings observed. The above results are shown in the form of a pie chart in figure 2.



Key:

1: Others (4%)
2: Surface and bulk cracking (including crazing) (21%)
3: Surface erosion (including pitting and roughening (75%)

Figure 2: Relative frequency of observed common defects in CSB buildings in Uganda (January-March 2000)

- Surface erosion occurs more severely on the lower sections of a wall, rather than on the middle and upper sections. The combined effect of direct abrasive action of rainwater, surface run-off and splash from the ground is thought be account for this difference (Chapter 2).
- Surface cracking and crazing occur more on the east-west facades than on the north-south facades. With the country located astride the Equator, the effect of the direction and period of sustained solar radiation from the east (sunrise) and west (sunset) ought to be taken into account when explaining the difference.
- Cracking of the bulk mostly occurs within the framework of the wall rather than in the corners. The unusually thick and non-uniform mortars used (10mm to 20mm) is believed to be responsible for some of the cracking in the bulk. Mortars are designed to be weaker than the block to allow for flexibility due to dimensional changes. Where the mortar is unnecessarily thick, the restraint on movement can result in enhanced cracking (Neville & Brooks, 1994; Walton,

1995).

- The corners of walls were the worst affected. A likely explanation is that at wall corners, rain is able to strike the block from all directions. Moreover, wind velocities are highest at corners. The level of erosion is therefore likely to be higher in such parts of the wall than in others.
- Defects due to causes other than environmental factors can also occur in CSBs. These include defects due to overall foundation settlement, biological agents and impact from users. Also observed were defects related to improper material design, workmanship and processing methods (Odul, 1984).

The results of the visual inspection of exposed CSB buildings confirm that premature deterioration of CSBs can occur in humid tropical environments. In Section 4.3.2, the extent of surface erosion and cracking, being the two most common defects observed, are determined by direct measurement for the most severely affected units.

4.3.2 IN-SERVICE MEASUREMENT OF VOLUME REDUCTION, DEPTH OF PITTING AND CRACK WIDTHS

As mentioned in the previous section, the two most common defect types (surface erosion and cracking) were identified for further direct measurement. The measurements were conducted on two of the oldest exposed structures located at the Namuwongo Urban Slum Upgrading project site in Kampala City. Both CSB structures had been left abandoned at wall-plate level without roofing. A third building, also abandoned at a similar level, that had also been selected for similar assessment, was inaccessible (recently fenced off for rebuilding). The two structures were taken as being representative of the worst case of severe deterioration from long-term exposure. The walls could be equated to similar walls built on normal experimental exposure test sites (BRE, 1980). Lack of protection from environmental elements due to the absence of roof cover and external render meant that the full extent of deterioration from weathering agents could be said to have reached its maximum during the eight and twelve years of exposure respectively. Moreover, the weathering conditions (normal and severe) under which the defects were caused were all genuine.

The direct measurements involved assessment of the following:

- Volume reduction (including pitting depth) to estimate the extent of surface erosion
- Crack width measurements

The methods and results obtained for each defect type are now described.

Estimates of Surface Erosion (by volume reduction)

Surface erosion leads to irrecoverable mass loss. This in turn results in the reduction of the volume of a block. By measuring the overall depth, width and length of surface material lost due to erosion, the volume of the recessed block surface can be determined. By deducting the recessed volume of the block from the original volume (determined from original block dimensions), a volume reduction percentage for each block can be obtained.

The procedure adopted to obtain the recessed volume for blocks in each of the two abandoned buildings was the same. For each building, thirty six blocks per building were measured. This total number was arrived at as follows. For each abandoned building, the nine most severely affected blocks per façade (north, east, south, west) were identified for measurement. The nine blocks on each façade comprised three blocks each from the upper, middle and lower courses of the wall. In this way, not only would any differences in defect severity per façade be obtained, but also differences per section of the wall in which the block was embedded. Where the degree of recession was high, the determination of the recessed volume was easy to measure and calculate. Where loss of mass was spread out on the block, the block surface was divided into four sectors. In each sector, the dimensions of recession were measured, and the total recessed volume obtained by adding up. All measurements were done using an electronic calliper complete with a depth guage (Mitutoyo brand). This light, hand-held calliper displayed the depth, width and length of eroded surface zones directly on its mini-screen. From the results, the histogram shown in figure 3 was obtained for each building. They show the volume reduction percent (%) for each wall façade and sector.

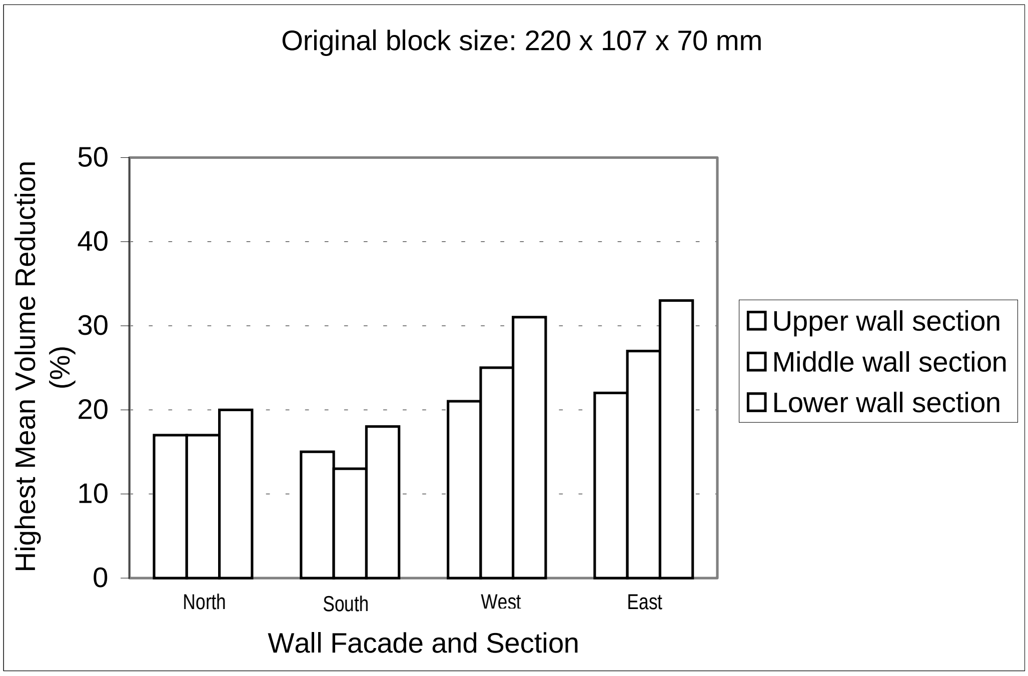


Figure 3(a): Abandoned building (NAB1: 8 years exposure)

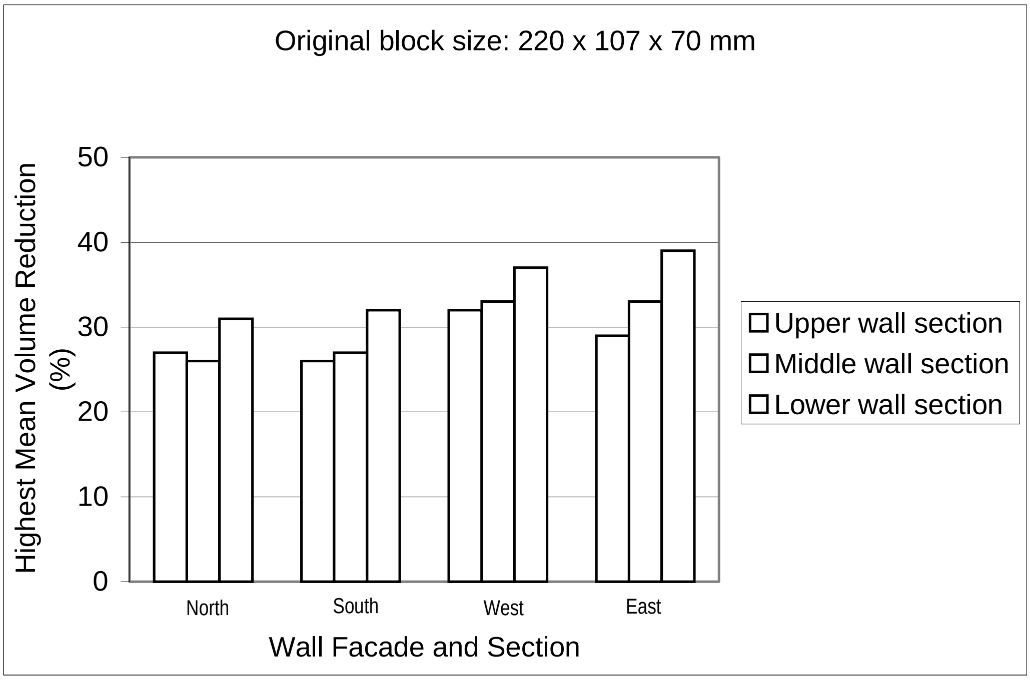

Figure 3(b): Abandoned building (NAB2: 12 years exposure)

Histograms showing the highest mean volume reduction percentage for each wall façade and sector for NAB1 and NAB2 (Uganda, January – March 2000)

From the histograms in figure 3, it can be confirmed that mass loss resulting in volume reduction does occur when CSBs are left exposed and unprotected in a humid, tropical environment. The reduction in volume is however not the same for all facades and levels in a wall. The results show that surface erosion varies according to the:

- elevation of the block within the wall (upper, middle and lower sections)
- orientation of the façade (north-south and east-west)
- age of the building (period of exposure under similar conditions)

The explanation for the above variations are likely to be several as discussed in the following sections.

The *elevation of a block* within the upper, middle or lower section of a wall can influence the rate of deterioration for several reasons. To begin with, the author was advised by the users and technical staff that most of the surface erosion appeared during the rainy seasons. Very little surface erosion if any occurred during the dry seasons. The main mechanism for surface erosion is therefore rainwater related. In each wall sector, although the amount and intensity of rain striking the wall might be about the same, the overall effect varies.

The histograms show that the reduction in volume is greater at the lower courses of a wall than at the higher ones. For the lower courses in both structures, volume reduction percentage for the most severely deteriorated blocks varied between 18% and 34% in NAB1, and between 30% and 38% in NAB2. Similar values for the upper sections were between 15% and 22% in NAB1, and between 26% and 28% in NAB2.

The amount of surface run-off created by raindrop splash from the upper section of a wall, and from the ground appear to contribute to the higher erosion at the lower wall sections. At the upper wall sector, whereas raindrops may strike the block surface, the surface might not begin to erode immediately. The raindrop striking the surface expends some of its energy in striking the wall and some in creating a splash (Chapter 2). It is the splash which then wets the block surface and may also progressively soften it. Erosion is likely to take place after a period of wetting and softening of the surface fabric. Meantime, the accumulation of rain splash transformed into surface run-off will flow downwards along the vertical profile of a wall. In the process, the middle and lower sections of the wall, in addition to being struck directly by rain drops from the same storm, will have to contend with the surface flow from the upper sections. The surface flow can increase in momentum and volume, washing away any loose soil particles from the blocks along its path. It is unfortunate that for the lower course blocks, surface erosion can be further increased by back-splash from raindrops striking the apron or ground immediately below it. The combination of direct raindrop impact, spray surface run-off and ground back splash appear to account for the increased severity of surface erosion in the lower courses of a wall than in the higher ones. As can be expected, the effect of raindrop erosion can be considerably increased in storms accompanied by strong winds (> 20 m/s). Despite these theories, the mechanism of rain erosion on CSB structures is not yet well understood. A considerable scope for reappraisal and review still remains.

Another observation made was that the lower corners of walls appeared to be more severely eroded that similar blocks at the same level. The fact that it is only at the corners that rain from all directions can strike the block is thought to account for this variation. More research is needed into this and other phenomena associated with raindrop erosion of block surfaces.

The *orientation of a wall façade* (north-south and east-west) appears to affect the extent of volume reduction. The highest average volume reduction percentage for east-west facing walls for NAB1 and NAB2 were 27% and 34% respectively. The highest average volume reduction percent for north-south facing facades were 17% and 28% for the former and latter buildings respectively. Corresponding volumes for roofed buildings can be expected to be lower. Whereas several explanations to account for the differences may exist, the most plausible one is likely to be connected to the direction of sunrise (east) and sunset (west). While all facades may experience similar amounts and intensity of rain abrasion, the east-west facades may dry up much faster on the reappearance of the sun soon after the rains stop. The duration of most storms in the humid tropics as mentioned earlier in the thesis is short (between 2-6 hours at a time). After such short periods of wetting, the reappearance of the sun can ensure that the wet block surfaces absorb considerable amounts of solar radiation. Absorption of solar radiation causes temperatures of the block surfaces to rise. This warming up effect can cause the block surface to dry up more quickly on the east-west facades than on the north-south facades. This can happen within a matter of only a few hours, causing moisture to evaporate from the wall surface, thus changing the moisture profile in the block.

The absorbed radiation can raise the temperature of the block by an amount depending on the specific heat of the block (on average between 0.65 and 1.00 kJ/kg), and on the thermal conductivity of the block (on average between 0.23 and 1.04 W/m°C) (Houben et al, 1994). As both values are positive for CSBs, thermal expansion and contraction of a block surface can therefore occur with changes in temperature. This is likely to lead to both temporary and permanent alterations in the physical and chemical properties of the block. Surfaces of blocks experiencing such cyclic changes in temperature can ultimately crack. Cracking can then expose the block surface to easy entry of moisture. Moisture within a block is likely to initiate otherwise dormant chemical activity between the constituent materials which make up the material. The range of chemical actions likely to occur were discussed in Chapter 2.

This phenomenon is also likely to occur in the reverse order of heating and cooling. Before the rainy seasons, sunlight can heat the block surfaces very fast (more on the east-west facades than on the north-south facades). Raindrops striking the already hot block surfaces can apply a severe quenching shock to it. The bonds between the soil particles and OPC hydrates can thus experience their first disruptive action (Baker et al, 1991). This can lead to weakening of the surface fabric thus exposing it to further abrasive attacks from raindrops. Surfaces which are weak can be easier to erode than those which are more intact. The combined cyclic action of wetting-and-drying can progressively lead not only to mass loss, but also to loss of strength, loss of hardness, rigidity and stiffness, as well as loss of appearance (pitting, roughening, cracking, etc.)

(ASTM D 559-55, 1975).

The *period of exposure* corresponding to the age of a CSB structure also appears to affect the amount of deterioration in the block. For the two buildings (NAB1 and NAB2) which were made from like materials and exposed under similar natural conditions in the same locality, the amount of deterioration varied according to the period of exposure. NAB1 had been left exposed for eight years, while NAB2 exposed for 12 years. The amount of deterioration in NAB1 was markedly less than that in NAB2 for each façade and at all wall levels. The highest average volume reduction percentage in NAB1 within the eight year period was 22%, while the corresponding amount for NAB2 within 12 years was 31%. Other factors being constant, the highest estimated annual volume reduction rate for NAB1 was 2.75% per annum, while that for NAB2 was 2.58% per annum. The difference in the two rates was only 0.17%. This result shows a certain degree of convergence. It can be interpreted to mean that, on the basis of the measurements taken, the highest average rate of volume reduction percent in CSB structures exposed under similar circumstances can be expected to be less than about 3% per annum.

The rate of volume reduction is likely to be influenced by the degree of resistance to surface abrasion that the block can offer. A block surface that is smooth, impermeable, non-reactive and of high inter-granular strength, is likely to offer more resistance to surface erosion than one which is not. The abrasion resistance of block surfaces can be increased in a number of ways. These include the use of surface render, surface coating and surface layering with mixes of higher inter-granular strength. These protective procedures can transform the block surface into a layer of significantly greater wearing resistance. As mentioned earlier in the thesis, protection of block surface should remain the main strategy in enhancing its durability. If the block surface is eroded, exposure of its core to similar deleterious action can prove to be more severe since the bulk is its least compacted zone (Houben & Guillaud, 1994; Gooding, 1994). Ways of improving the durability of blocks through the use of CRMs are investigated experimentally in Chapters 6 and 7.

Crack dimension measurements

Cracking on CSB surfaces, sometimes extending deep into the bulk, were commonly observed defects. Classification of the main crack patterns and direct measurement of the most extensive crack widths were done in order to link them to likely deterioration mechanisms and to assess the severity of the phenomena. It is the width of a crack, rather than its length or depth, that is commonly measured in like building materials (Neville, 1995). Moreover, maximum permissible crack dimensions are normally specified strictly according to limits based on crack widths.

The procedure adopted involved visual identification of three of the most badly affected blocks on each wall façade then measuring their crack widths. The average of the greatest crack widths from each of the three blocks were then determined. To make the measurements, two hand-held crack width measuring instruments were used, namely: an optical crack microscope and a crack comparator scale (Baker et al, 1991; Sjostrom et al, 1996). Both instruments were originally developed for measuring similar cracks in concrete structures, and the author had used them several times before. Use of the two instruments side by side did not present any difficulties. The crack microscope used was of the 'ULTRA LOMARA' Mess-Mikroskop make. The instrument powered by a battery, was held against each block surface right over the crack to be measured. The surface was then illuminated by the small internal bulb within the instrument and the magnitude of the crack width measured directly by comparing it against the internal graduated scale that was clearly visible through the eyepiece.

To complement the measurement, the simple hand-held (unmagnified) comparator scale was also used for estimating the same crack width (sometimes referred to as the crack calculator). The type used was the Colebrand/Abbot Brown crack calculator. The procedure involved is slightly different. To estimate the crack width using this instrument, the comparator was placed directly against the targeted crack on the block. By sliding it upwards or downwards until a comparable thickness was determined, the crack width could then be estimated accordingly. The range of crack widths on the comparator ranged from 0.100 mm to 2.0 mm. Crack widths wider than this maximum value had to be estimated using an electronic calliper whose double tips were inserted between the cracks and extended in opposite directions till firm contact was made. The use of these instruments was found to be necessary because, allowing for human eye variations, the minimum crack width that can be seen by the naked human eye is about 0.13 mm (Neville, 1995). As the procedure was laborious and time limited, measurements were only done on NAB2. The summary of the widest average dimensions of crack widths measured are shown in the histogram in figure 4.

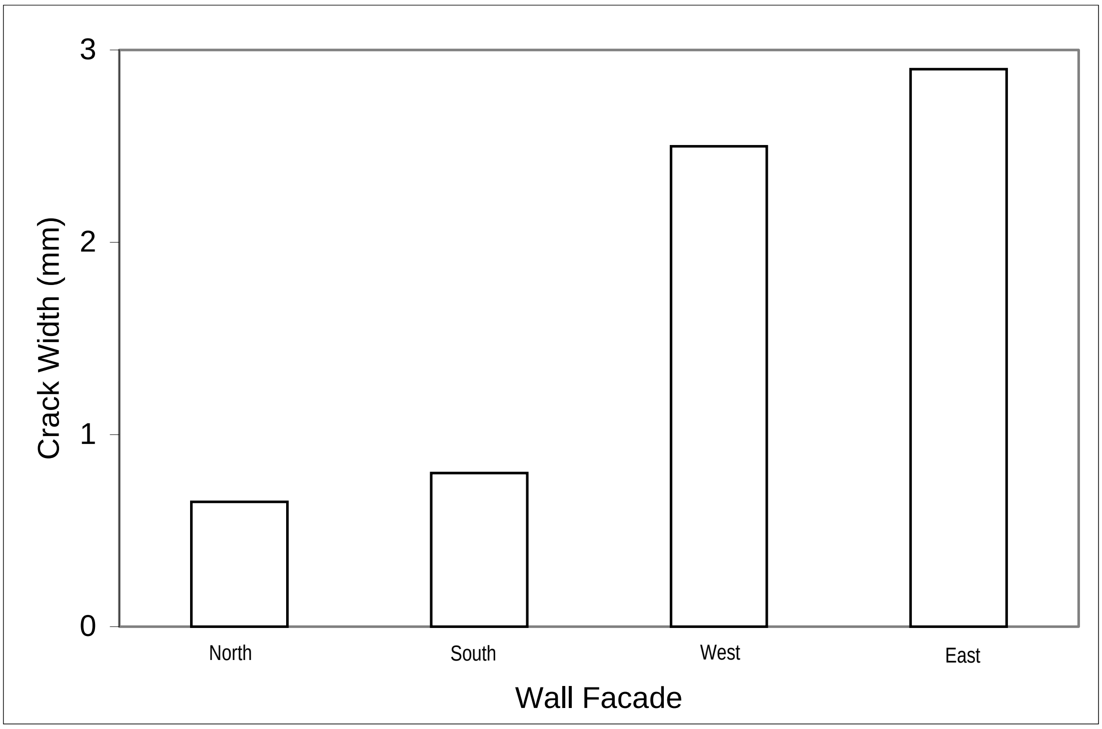

Figure 4: Histogram showing the mean crack width of three of the worst affected blocks on each wall façade for NAB2 (Uganda, January-March, 2000)

From the histogram shown in figure 4, it can be seen that the phenomenon of cracking occurs on all the wall facades of an exposed CSB structure. The highest mean maximum size crack width measured was 2.9 mm on the east façade of the building. The corresponding lowest mean crack width was 0.65 mm on the north façade. These results compare unfavourably with the maximum permissible crack width limits normally specified for concrete structures (Neville, 1995). The permissible crack width for exterior wall concrete used in normal, and under severe conditions of exposure are given as 0.25 mm and 0.15 mm respectively. The values obtained from the measurements of exposed CSB walling units (0.65 mm to 2.9 mm) are much higher than the permissible limits for concrete. The comparison will however need to take into account the presence of clay in CSBs as opposed to concret where its presence is not allowed. The presence of clay (amount and type) is likely to severely affect the magnitude of cracking in CSBs (Spence & Cook, 1983).

The results also show that cracking is more pronounced on the east-west facades than on the north-south facades. The reasons for the differences were discussed earlier. It should be mentioned here that whereas the kind of cracks measured on a block may simply be symptoms of many causes, the common feature is that they all result from the restraint made on strains. Since stress and strain are supposed to occur together, any restrain of movement can introduce a stress corresponding to the restrained strain. If these stresses and the restrained strain are allowed to develop to the extent that they exceed the strength or strain capacity of the block, then cracking can occur. The diagnosis of the exact cause of cracks in a block might therefore not always be that straightforward. Indeed, cracks can be a result of several causes such as: plastic shrinkage, drying shrinkage (clay and OPC hydrates), chemical action resulting in expanded product formation within the block fabric, settlement of the foundation, improper curing and thermal movement. Some of the mechanisms involved were discussed in Chapter 2.

In summary, whereas a particular cause within or outside the block might be responsible for initiating a crack, its subsequent development and propagation may be due to other causes. The types of cracks observed on CSB structures (star shaped, linear, interconnected) could therefore have been a result of more than just one cause. Further research is recommended to link particular crack patterns in CSBs to specific deterioration mechanisms. Limits such as have been specified for concrete should also be set for CSBs. Such limits should however take into account the presence of clay in CSBs. The limits can be specified as maximum permissible crack widths for use of CSBs under normal and severe exposure conditions.

4.3.3 *FIELD INDICATOR SOIL TEST RESULTS*

In this section, field indicator soil tests conducted during the fieldwork, together with the results obtained, are described. The results are compared with available laboratory test results for the same soils at the two major CSB project sites in the country (Namuwongo in Kampala and Malukhu in Mbale). This section covers the following:

- Need for field indicator tests
- Types of indicator soil tests available
- Results of conducted indicator soil tests

Need for field indicator tests for soils

In order to classify a particular soil, two types of tests can be done: indicator (or field tests) and laboratory tests (Webb, 1988; Norton, 1997). Only the former will be described in this section since the latter are presented in Chapter 5. The two test categories should normally be done together with the one following the other (indicator, then laboratory testing). It is normal to conduct indicator soil tests first since it is from the results obtained that justification for further laboratory testing is usually based.

Although field indicator testing might be regarded as being preliminary, it is only through such tests that the rapid evaluation of important soil properties can be made. The tests might also appear empirical but they enable the general suitability and acceptability of a soil for CSB production to be determined quickly. As can be expected, there are now many types of indicator soil tests. The common factor in all the tests remains their relative simplicity and speed of execution. These tests are also quite inexpensive to conduct given that they require little or no equipment. The only drawback (according to the experience of the author) is that these tests over-rely on the competence and judgement of the operator. The veracity of interpretation by the operator is often taken for granted despite errors likely to be caused either by human weakness or lack of competence. With better experience and training however, such problems should be easy to overcome. Soil indicator testing is likely to continue to be highly regarded as they help avoid unplanned and premature laboratory testing. At the moment, there can be no serious alternative to soil indicator testing as a precursor to laboratory testing.

Types of indicator soil tests available

There are currently several soil indicator test types to choose from. Over the years, a multitude of test types have been put forward by various authors and researchers. Despite the numbers, the common objective remains the identification of the presence and predominance of the main soil fractions (gravel, sand, silt and clay). After the various types of field indicator tests have been done, further laboratory testing may follow to determine the precise proportions of each soil fraction, and perhaps more importantly, the overall behaviour of the soil type when in contact with water.

In order to make the comprehensive review of current available field indicator test types easier, a tabulated summary listing the test methods has been drawn up. According to literature sources, up to 15 different types of soil indicator field tests are currently available for preliminary use in determining the suitability of a soil for CSB production. The different types of tests and the various authors who have reported them, are presented in Appendix F.

Not all authors managed to describe all the available tests with the exception of Houben & Guillaud (1994) and Stulz & Mukerji (1988). Although some of the authors attempted to combine some of the tests, or tried to use different names for the same test, the summary list was compiled to show separate distinct tests. Tests with similar names are shown in brackets. During the fieldwork, all the listed tests with the exception of number 10 (Dry Strength) and number 14 (Decantation), were done. The tests were done on soils taken from the sub-soil level after removal of the top soil (varying in depth between 150-300 mm). This was done to ensure that the presence of organic matter (normally found at the top-soil level), was avoided. Apart from trying to ascertain the suitability of soils used at the two largest CSB project sites, the tests were also conducted to get a feel of the operational difficulties and levels of accuracy and convergence expected. The main procedural steps involved in each test can be found in the references shown. The results are presented in Appendix G.

Summary results of soil indicator tests done in Uganda

From the summary of the results shown in Appendix G, it is noted that:

- there was no significant presence of organic matter (the soil is likely to be suitable for CSB production)
- the fines content (silt and clay) in both soils are high enough (24-35%) (the soil is likely to be suitable for CSB production)
- the coarse soil fraction content (fine gravel and sand) is above 60% in both soils (falls within the recommended limits) (Chapter 3).

With these preliminary results, the soils at the two project sites were found to be suitable for CSB production. The soil indicator test results were later compared to earlier documented laboratory test results from the Namuwongo project site which had been done in 1986 (Okello, 1989). For comparison purposes, extracts from the laboratory test results showing particle size distribution, linear shrinkage, sedimentation, natural moisture content, as well some of the test results form the initial performance testing of cured blocks, are presented in Appendix H.

The laboratory test results in Appendix H confirm that the soil used for CSB production at Namuwongo:

- was well-graded, with adequate percentage of fines and course soil fractions
- had moderate shrinkage levels, confirming a low to medium proportion of clay in the fines
- was found to contain almost similar levels of fines and coarse fractions using both the sedimentation test (soil indicator test) and the particle size distribution test (laboratory test)
- had a moderate natural moisture content.

The records from the initial performance tests done on blocks produced from the above soil showed that the blocks compared well with most minimum requirements of performance. The average wet compressive strength was above the minimum recommended values of between 1.2 MPa and 2.8 MPa (Lunt, 1980; ILO, 1987; Houben & Guillaud, 1994). The mean total water absorption capacity for the blocks were lower than the maximum permitted value of 15% (ILO, 1987). These results confirm that, in any post mortem diagnosis of possible causes of premature deterioration of exposed CSBs within the area, the inclusion of non-suitability of the soil used may not make sense. Any premature deterioration will therefore have come from factors other than soil selection and suitability.

The near convergence of field indicator test results and those obtained from laboratory records for the same soil further confirms that the former can be a very useful indicator of soil suitability. The field indicator tests should however be done following a logical order to ensure a coherent approach to testing. Use of soil indicator tests are especially recommended for CSB production sites in rural areas where no sophisticated equipment exists and where the cost of direct laboratory testing might be quite prohibitive. On very large CSB project sites, however, both field and laboratory tests should be conducted so that results from each category can be used to compliment the other. Moreover for large project sites, especially in areas known to be underlain by special soil types such as laterites, additional laboratory tests will need to be done. From Appendix H, it can be seen that this consideration was overlooked. Additional laboratory tests should have been done to provide information on the following:

- the plasticity index of the soil (using Atterberg limit tests)
- the acidity of the soil (using pH value tests)
- chemical composition of the soil minerals (using chemical analysis tests)

4.4 INSPECTION OF CSB PRODUCTION SITES

In Chapter 3, it was stated that the block production process was one of the three major influencing variables that can affect the properties and long-term performance of CSBs. The other two major variables of equally significant influence were identified as constituent material quality and action of environmental agents. In the CSB production process, any departure from widely accepted good site practice is likely to adversely affect the quality of the block produced (Guillaud et al, 1996).

In this section, results from the following investigation methods are presented and discussed:

- visits to block production sites (at two on-going CSB project locations in Uganda)
- quality checks on OPC and water used on CSB production sites.

Each of the above are discussed separately in Sections 4.4.1 and 4.4.2, that follow.

4.4.1 EVALUATION OF BLOCK PRODUCTION PROCESSES AND PRACTICE

The objective of inspecting production sites was to assess the organisational set-up of the site, and to compare individual production sub-processes against a pre-prepared checklist of good practice. Departures from the norm were carefully noted.

Two on-going project sites were visited: the large CSB building site at Malukhu (as before) and the smaller, single residential building site at Temangalo (farm in Mpigi district). While the former is an extensive project site with over 80 CSB structures built and another 200 or more planned, the latter is a single residential unit. At both locations however, the same type of machine was being used to produce blocks. The description of the machine is as below:

- Make: Hydraform block making machine (from South Africa)
- Type: Motorised diesel engine 10 kW air cooled
- Dimensions: 1000 l x 1400 w x 1300 h
- Weight: 750 kg
- Output: + 130 blocks per hour
- Mould: various (including interlocking dry stacking blocks)
- Block size: 240 x 220 x 115 mm; and 200 x 220 x 115 mm

At both locations, there was no centralised yard for mixing, proportioning, etc., as was described in Chapter 3. Details of the observations made are summarised in Appendix I.

From the summary findings shown in Appendix I, the following are deduced:

- Pre-extraction soil test records are not kept on site or nearby where they can be referred to. While manual extraction may be suitable for a small site (output about 1-3 m^3/day/man), mechanical extraction would be preferable on the larger project sites (output about 100 m^3/hour). The extracted soils are not prepared well before further use. They should be properly dried out and pulverised. Soils that have been dried out and screened ought to be stored in a protected area to preserve their moisture state and avoid changes in moisture content.

- The concept of batching is not closely followed so wastage and misuse of the stabiliser is likely. While proportioning is done by volume, checking that the gauge containers are properly levelled off each time is not strictly enforced. The stabiliser is mixed with the soil irrespective of the latter's moisture condition. As no obvious mix indicator such as the achievement of uniform colouration of mix is used, insufficient and uneven distribution of the stabiliser and water in the soil are possible. Moreover both water and stabiliser are poured down on the heaped soil instead of on a spread out soil. As no drop test is used to check the consistency of the mix, compression of blocks will take place below or way above the optimum moisture content of the soil. This will result in poor compaction of the soil, with blocks of low density being obtained. Moreover, the mixing process is also not closely supervised.
- Measuring out of the soil mix fed into the mould is not strictly done. This can result in variation in density and sizes of blocks produced. The filling of the mould is not done in layers and corners of the mix in the mould are not pressed by hand. Moreover, in motorised units as the compression force remains the same, it is important to check each time if correct filling is done.
- Demoulded green blocks are removed by hand, without use of pincers or

wooden pieces that could ensure that a large surface area is placed in contact with the yet weak block. No special attention was being given to the corners and edges of green blocks. Random quality checks normally conducted at this stage for each batch of blocks produced, were not being done as required. These shortcomings are likely to compromise the quality of blocks produced.

- Curing conditions appear not to be clearly categorised into wet and dry stages. Curing was being done under light cover under direct sunshine. Blocks were apparently being used earlier than the specified curing periods for the OPC and lime (28 and 56 days respectively). Due to high evaporation rates and pre-mature use of blocks, the likelihood of low quality blocks being used cannot be ruled out. Moreover, the blocks being cured are not separated according to batches and are poorly stockpiled at random. This could lead to the use of improperly cured blocks.

It was not possible to immediately evaluate the affects of these variables on the performance of the blocks produced. The observations do confirm that poor site practice and bad workmanship do take place (constituting significant variables likely to affect the quality and properties of a block). There is clearly a big difference between block production under strict laboratory procedures and field practice. The above problems can be attributed directly to the absence of codes of practice and checklists that should normally accompany trade standards. The findings also confirm earlier fears that variations in processing methods, especially due to inadvertent departures from the norms, could severely influence the durability of the block. Block production processes should be properly executed under close supervision if good quality and durable blocks are to be produced. It is recommended that all current impediments to the dissemination of standards and codes of practice for the production and use of CSBs be identified and resolved (Lowe, 1998; Schildermann, 1998). The above findings and their implications were brought to the attention of the supervisors found at the project sites at the time. It was clear that they had not received any prior briefing on good site practice, and could not therefore appreciate the adverse implications of their actions.

4.4.2 FINDINGS FROM QUALITY CHECKS ON OPC AND WATER

In Chapter 3, the importance of the quality of each of the three constituent materials used in the production of CSBs (soil, cement, water) were emphasised. The quality of soil used on CSB production sites has already been reported on (4.3.3). In this section, attention is focused on the basic quality checks conducted on OPC and water found being used on CSB building sites.

Although the objective of the tests at the time was to routinely ascertain the quality of OPC being used, the results obtained were rather surprising. Broadly it was found that both cement and water quality were poor, so the study was extended to cover why this was so. Although the quality of these ingredients were examined from a CSB production standpoint, the findings also have implications for all the cement-using activities in Uganda. Most of the OPC used in East Africa is expected to conform to the requirements of BS 12: 1991. It is also normally included in bills of quantities and specifications that contractors, users and consultants carry out periodic quality checks on any products in which OPC has been used. Despite the existence of this requirement, it is the normal practice in countries like Uganda to take the quality of OPC supplied (in sealed 25 kg bags) for granted. In addition, although the quality of water used for mixing of soil and cement and for wet curing of CSBs is required to be high, the normal practice on block production sites appears to disregard this consideration. It is not yet clear whether this is due to scarcity of water or other reasons such as lack of awareness of the dangers involved in using poor quality water (Chapter 3). The highlights of the procedures used for the quality checks are described next.

There are several forms of quality checks that can be done on OPC: comparing setting times, strength, or even chemical composition with standard requirements (BS 4550: Part 2, 1970; ASTM c 114-88). Tests involving the analysis of the chemical composition of OPC were considered to be beyond the scope of this research. Instead, the quality checks used were based on the comparison of the values of the wet compressive strength and tensile strength of prisms made from the OPC in question and the specified values from prevailing standards.

In the wet compressive strength test, three 50 x 50 x 50 mm cement and sand mortar prisms were cast. The prisms were made from a cement-sand mix proportion of 1 : 2.75 with a water-cement ratio of 0.49. They were cured under controlled conditions for 28 days (in water at temperatures of about 23°C). After 28 days, the cubes were tested and the value of the mean wet compressive strength of the prism made from the OPC in question, obtained. The results were compared to those specified for the type of OPC that was being used on site. The results are shown in table 2. To check the quality of water used, the same procedure was followed but this time using the water of unknown service record (found being used on the block production site) (BS 3148, 1980). The results from prisms made with clean tap water and those made from the site water were then compared. The results are also shown in table 2.

For the avoidance of doubt, an additional test was simultaneously done on both the OPC and water. In this tensile strength test, nine small prisms of dimensions 175 x 25 x 6 mm were cast (Rigassi, 1995). The sand-cement mortar prisms were cast using the ration of 1 : 3 (cement : sand) and water cement ratio of 0.49 as before. Some of the bars were wet cured for only 24 hours, while the rest were similarly cured for 28 days. For each test, three bars were tested for direct tensile strength by subjecting them to available loads of up to 100 g (24 hour cured prisms) and of up to 500 g (28 day cured prisms). To conduct the test, a simply supported prism bar of the material was loaded at the end span. The load at which the bar snapped was noted. The results are all shown in table 2.

S/N	TEST	SAMPLE AGE (days)	UNITS	COMPARISON OF RESULTS	
				Obtained Value	Recommended standard Class 32.5N OPC
	A: Cement	28	MPa	27.4	32.5
1	Mean wet compressive strength (50 x 50 x 50 prism): clean water				
2	Mean tensile load (175 x 25 x 6 mm prism) "	28	g	350	500
3	Mean tensile load (175 x 25 x 6 mm prism) "	1	g	75	100
	B: Water	28	MPa	21.2	24.76
4	Mean wet compressive strength (Same prism but site water used)				
5	Mean tensile load (Same prism but site water used)	28	g	245	500
6	Mean tensile load (same prism but site water used)	1	g	55	100

Table 2: Results of site quality checks on OPC and water (Uganda, March 2000)

OPC quality test results

The results in table 2 show that the mean wet compressive strength value of the site cement-sand prisms was 27.4 MPa. This is less than the 32.5 MPa value specified as the minimum for the same grade of OPC (class 32.5N OPC, or equivalent). The difference was even higher (15%) than the allowable difference in strength of 10% due to errors. Some variation was expected but the result obtained was rather surprising. Similar trends were shown in the results from the prisms tested for tensile load. The values obtained were between about 25% and 30% lower than the recommended load values at 1 day and 28 days respectively. Since the bags in which the OPC found on site were examined (to conform to BS 12, 1990), the only conclusion that can be reached at this stage is that the contents could have been adulterated. Recent press reports from the country confirm the widespread contamination of OPC with clay before the bags are resealed (New Vision Newspaper, June 2001).

In the experience of the author as a practising civil engineer, incidences of this nature were not uncommon even on large concrete production sites. The problem is therefore a long standing one, and is more widespread than was originally thought. As can be expected, use of low quality OPC is likely to adversely affect the properties and performance of CSBs. Due to the above findings, the author decided to find out more about use of OPC in the country. From other site visits and interactions with users, stakeholders, suppliers, contractors and consultants it was established that OPC related problems were varied. These ranged from supply problems, unsuitability, incomplete hydration and misuse.

Water quality test results

The results of water quality tests show that the sand-cement mortar prisms cast using the dirty site water were of low strength. The wet compressive strength value of 21.2 MPa was 23% lower than the equivalent value for the cube cast using clean tap water (27.4 MPa). The allowable difference should not have been more than 10%. Tensile load tests also showed that prisms cast using the site water were about 43% lower in tensile strength than similar cubes cast using clean water. As stated earlier, water quality checks had not been planned for before (had it not been for the unusual appearance of the water being used on site). These results confirm that the quality of CSBs can be compromised when water of unknown quality is used for the hydration of OPC. The quality of water being used should therefore not be taken for granted. Water is scarce in most parts of the world. Even where available, clean piped water is inaccessible to most. Use of unsuitable water for hydrating OPC can therefore not be ruled out.

4.5 FINDINGS FROM QUESTIONNAIRES AND INTERVIEWS

As part of the research, a direct survey of the personal experiences of various stakeholders with respect to the production and use of CSBs was conducted in Uganda (January-March, 2000). In this section, highlights of the methodology used and results of the main findings are presented.

Methodology

At the start of the survey, two separate contact methods were planned, namely: interviews and questionnaires. It was later decided that a combination of the two methods into one would be more cost-effective and time saving. Face-to-face interviews using pre-structured questions facilitated the process making it more systematic and relevant to the situation on the ground. Moreover in a country where telephone, postal and communication systems were all undergoing major rehabilitation, there was no alternative to direct contact with respondents. By combining the contact method, problems associated with illiteracy, need for reminders, clarifications etc., were overcome. Respondents were also able to make suggestions and to raise other simpler or more complex questions associated with the production and use of CSBs in the country.

A sample size of 35 respondents from all walks of life was used. This was considered large enough for the purposes for which the survey was intended. The respondents were chosen at random from amongst the stakeholders: users of CSBs, government officials, private contractors and consultants, potential clients and funding agency representatives. It was assumed that the contacted respondents represented an unbiased sample of the population. Other highlights of the procedure were as follows:

- Interviews were conducted at various locations. These included dwellings where CSBs had been used, work locations, block production sites, on-going CSB building sites, and on substantially completed building sites.
- All respondents were assured of future confidentiality before the start of each interview. This was done to obtain their consent and ensure that their views would be freely expressed. In this way respondents answered questions put to them while at ease, and freely shared their experiences with the author. It was made clear to all of them that the results would be used purely for research purposes only.
- Each interview took approximately 20 to 30 minutes from start to finish. With the exception of interviews conducted on block production sites and on building sites where the respondents wanted to show the author further items,

the above time frame was maintained throughout the survey process.

- The response rate was 100%. All stakeholders directly contacted as above were willing to participate freely. This led the author to conclude that the survey method adopted was the right one under the prevailing circumstances in the country. Helpful inferences could then be made from the experiences of the respondents.

Findings from the Survey

The results of the findings which were manually tallied, coded and categorised relate to the type of questions put to the respondents, namely:

(a) : current walling material of preference

(b) : reasons for making the particular materials choice

(c) : preferred block types

(d) : common defect types encountered

(e) : preferred method of protection for blocks

(f) : suggestions on ways to improve CSBs.

The results of the findings are shown in the form of pie charts in figure 5.

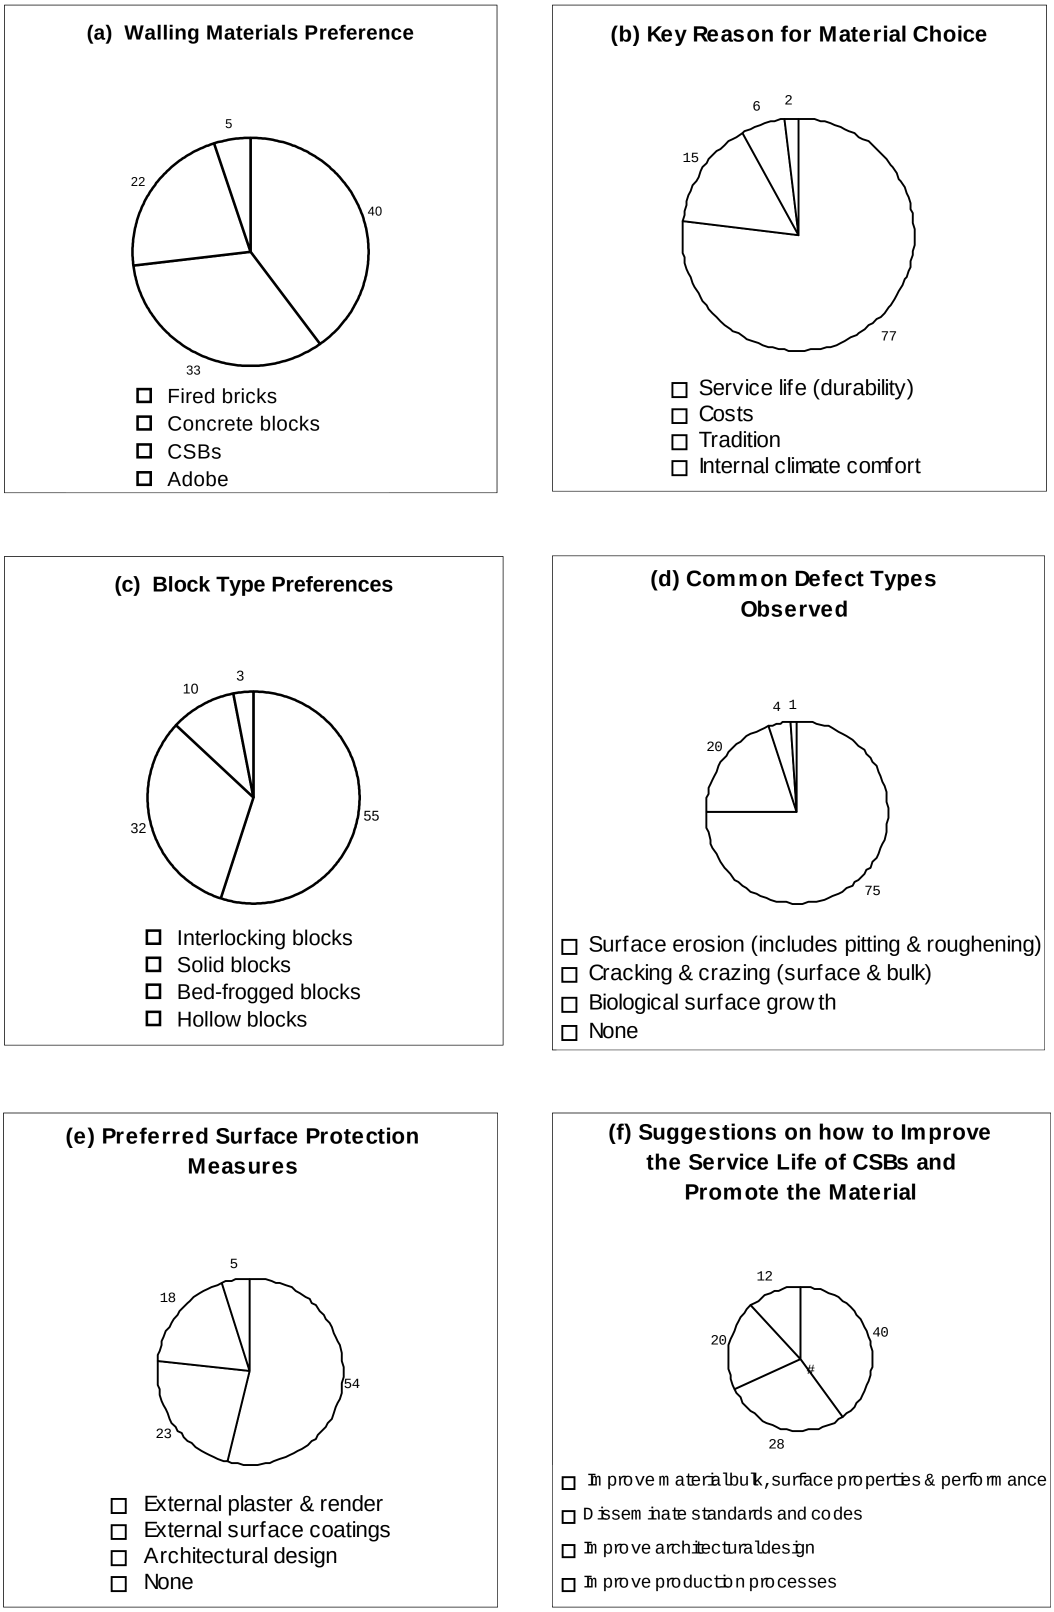

Figure 5: Results of findings from interview and questionnaire surveys conducted in Uganda (January – March, 2000)

Each of the outcomes shown in figure 5 (a) to (f) are now discussed in turn.

Preferences of walling materials to use were almost equally divided between fired bricks, concrete blocks and CSBs. However, fired bricks remain the material of first choice for most of the respondents (40%). This is followed by concrete blocks (33%). These two materials have been in use for generations and most respondents still have a high regard for them. The results for CSBs are encouraging. Having been introduced in the country only as recently as 1987, the fact that up to 22% of the respondents preferred the material over the otherwise cost free adobes (5%) represents a major sign of approval. The substantially better performance of CSBs as compared to adobes appears to account for the immediate popularity of the former over the latter (Games, 1981).

Key reasons for materials choice reveals the main basis for the selection of a particular walling unit. The key reason given by up to 77% of the respondents for choosing a particular walling unit is its in-service record (durability of the material). Only 23% of the respondents considered issues such as costs, tradition and internal climate as being more important. At the time of the survey, fired bricks were the most highly regarded walling units mainly due to their long service records requiring minimum or no maintenance. In future however, as fuel resources for firing bricks get depleted, the use of CSBs is likely to overtake that of fired bricks. According to the respondents interviewed, CSBs have gained prominence in a relatively short time because the material does not require to be fired, or burnt. Moreover, since the soil can be obtained on or near the site, where processing of the block is taking place, transportation costs are significantly reduced.

Block type preferences by respondents reveal a significant shift from solid blocks (33%) to interlocking blocks (55%). While solid blocks have been used since the introduction of CSBs in the country, interlocking blocks have only recently appeared on the scene (late 1990s). The dry-stacked-interlocking blocks have gained prominence over other types of blocks mainly because the use of mortar is not required. Other advantages mentioned are that walls from interlocking blocks are quick to build and are easy to align. Moreover, even if plaster is to be applied, the straight walls achieved require much less render than the traditional mortar bedded blocks (Van Den Branden & Hartsell, 1971). The production of interlocking blocks however, requires very sophisticated presses. At the time of the survey, these blocks were being produced by communally hired and donor subsidised motorised presses (Hydraform press, M 5 Mark I & II from South Africa). The quality of the green blocks appeared to be very high indeed (in terms of surface appearance, parallelism, edge straightness, etc.).

The *most common defects types* observed by respondents were surface erosion (75%) and cracking and crazing (20%). According to the respondents, not only were these two defect types common, but they were also clearly visible and discernible even by the casual observer. The older the building the more visible the defects became. No similar symptoms were observed in walls made from fired bricks and concrete blocks. It was therefore not surprising that 75% of the respondents had detected premature deterioration on unprotected CSB walling in the form of surface erosion (including pitting and roughening). Only 4% of the respondents had observed other, less common defect types like the peeling off of render, plant and surface growth, insect boring, etc. The majority of the respondents interviewed did not find any difficulty in linking some of the major defect types to seasonal variations. The author was informed that it was generally observed that most of the surface erosion in CSB walls occurred during the two main rainy seasons in the country (March-May and

September-November). The symptoms were reportedly similar to those that occurred on adobe walls at the same seasons of the year. The only difference was in the degree of severity. Cracking of exposed CSB walls was also a phenomena more noticeable during the long-dry seasons than during the rainy seasons. A casual link between environmental action and deterioration in blocks was therefore being strongly suggested. The author could not see any reason to disagree with the general hypothesis. When asked why they thought surface deterioration of CSBs occurred too prematurely, most of the respondents were of the view that use of low amounts of cement (4-6%) might be responsible. The reasoning was that due to the low stabiliser levels, poorly bonded soil particles at the surface of the block could easily be dislodged by the mechanical energy from rainfall impact (Laws, 1941, Herbert, 1974). The premature appearance of such defects when no similar defects could be observed in like materials of the same age serving under similar conditions was seen by many as a major cause for concern. It partly explains why fired bricks and concrete blocks, despite their higher costs, still remain preferable to most of the respondents.

Preferred surface protection measures for exterior wall faces were varied. Up to 95% of the respondents considered one form of exterior wall surface protection method or another. The most preferred option was external surface render (54%), followed by surface coating (23%) and architectural design (low roof overhang) (18%). Only 5% of the respondents were not bothered and preferred to let events take their course. Part of this latter group thought external render was expensive since it involved remedial surface repairs being done first on the walls before application of the render proper could follow. Some even considered replacing defective CSBs with equivalent sized fired bricks. Where surface render was used, incidences of plaster peeling off from the blocks were also observed. The reason for this could be attributed to inadequate curing, improper workmanship during rendering, poor choice of soils (too much clay), or even poor choice of stabilisers (high clay content, lime is preferable; low clay content, OPC is preferable). Most respondents preferred to use higher amounts of OPC to improve the overall quality and durability of the block than to have to use lower amounts and still plaster the wall in addition. They thought the former option would work out to be cheaper than the latter in terms of overall costs. The findings appear to support strategies based on enrichment of block surface layers to offer additional resistance to deleterious environmental actions. Use of enriched surface layered material is investigated experimentally in Chapters 6 and 7 of this thesis.

Proposals on *quality and durability improvement* strategies for CSBs came in many forms. The strategy that emerged as the most prominent was the improvement in the overall bulk and surface properties and performance of CSBs (40%). This was followed by the need to disseminate and comply with written standards and codes of practice on the production and use of CSBs (28%). Improved architectural design of CSB buildings and improved block production processing methods were considered by 20% and 12% respectively of the respondents as being the best ways of protecting blocks and achieving higher quality. As stated earlier in the thesis, it is the considered opinion of the author, now confirmed by these findings, that it is the durability of the block, rather than any other consideration, which will ensure its widespread demand and use in developing countries. Current research into the durability of the material therefore appears to be timely. Even where research findings may lead to the production of improved blocks, codes of practice and standards are still needed to ensure that compliance with minimum standards and better methods of work are upheld. At the time of the survey, no approved CSB standards were available in the country yet over 400 CSB structures had been built. And more CSB buildings are being planned for (DoH, 1992).

4.6 CONCLUSION

From the results and findings discussed in this Chapter, the following conclusions can be made.

CSBs are likely to remain in high demand in developing countries such as Uganda where the housing backlog is still very high. The increased use of CSBs for walling in high density, low income urban areas appears to represent the best way forward in redressing the imbalance. The current approach using community hired or centrally used motorised block presses also appears to be the best practical housing delivery method.

In humid tropical areas, rainfall and temperature variations can adversely affect the performance of a block exposed to the elements. These variations can also catalyse chemical reactions between the constituent materials forming the block. More research is needed to understand the mechanisms involved, and to explain how individual rainfall parameters such as drop size, drop size distribution, fall velocity and impact kinetic energy, etc., affect the rate of surface deterioration in blocks.

Visual inspection of a sample population of officially documented CSB structures revealed that in the absence of protective render, premature deterioration can take place. The most common defects observed included: surface erosion, surface roughening, surface pitting, surface cracking, surface crazing, bulk cracking, chipped edges and corners, and loose material residuals. Since weathering conditions were genuine and since the blocks were inspected at full scale, a direct link can be said to exist between the symptoms observed and the exposure conditions. Moreover, as a fairly sufficient number of CSB structures were inspected (more than 10% of the total number), this conclusion is likely to be fairly reliable (cause and effect link).

The amount of loose material lost from the original mass of a block was estimated by directly measuring the recessed volume of the material. The loss in volume from unroofed and unrendered blocks over a period of 12 years was about 38%. Losses were higher on the east-west facades than on the north-south facades. Lower courses of walls also experienced more losses than the middle and upper courses of the same wall (about 8-15% more). The increased amount of rainwater and splash experienced by the lower courses, and the increased amount of solar radiation absorbed by east-west facades appear to be responsible for the differences. Surface protection measures are strongly recommended for blocks that are to be used under similar conditions.

It was also found that crack patterns and dimensions followed the above trends. The widest cracks recorded (2.9 mm) were found on the east-west facades of CSB walls. These cracks are much wider than the normal permissible crack widths in concrete structures. Cracking is undesirable as it makes the block vulnerable to ingress of moisture. The crack patterns observed indicate that drying shrinkage, expanded product formation, thermal expansion and contraction and improper curing can all lead to disruption in bonding. More research is still required to explain the mechanism involved in each of these phenomena.

It was found that field indicator soil testing was a valuable tool for early identification and selection of soils for CSB production. Although at the time of the fieldwork no clear order for conducting the several available tests existed, a more planned approach is recommended. Since the results of the field indicator tests showed considerable convergence with documented laboratory test records for the soils in the same location, the former are recommended as the first step in determining the suitability of a soil for CSB production. For large CSB production sites, laboratory tests should be extended to analyse the chemical composition of the soil to be used. This should be done even after the soils have passed all basic suitability tests.

Findings from the observation of site practice at block production sites visited confirmed that the level of process management can indeed influence the quality of the block produced. Shortcomings were observed right through the production process from soil extraction and preparation to curing of green blocks. Most of the shortcomings could be corrected by better supervision and proper guidance. A balance of emphasis is therefore required between design quality of blocks and their actual quality.

Impromptu quality checks conducted on OPC and water used for production of CSBs confirmed that significant differences can exist between the required minimum standards for each material and the values obtained on site. The wet compressive strength of a sand-cement mortar cube tested at 28 days using the OPC found on site was about 15% lower than the minimum recommended value for the same brand of cement. Tensile force tests also showed similar trends. Similar cubes made and tested in exactly the same way as before but this time using the site water of unknown quality was found to be about 23% lower, well outside the allowable variation. These two findings further confirm that CSBs are likely to be adversely affected not only by variations in the processing methods or exposure to environmental agents, but also by the quality of each of the constituents used in producing them. It is therefore strongly recommended that regular quality checks, inspections, tests and certification be introduced at all key stages in the block production process.

Surveys conducted using interviews and questionnaires revealed a number of wide ranging issues. It was found that a good service record (durability) of a material would ensure its widespread use (as underlined by 77% of the respondents contacted). It was noted that interlocking blocks that do not require use of mortar were the most highly demanded block type. These blocks were considered to require less time and money to use for building than comparable solid, hollow and frog-bedded blocks. It was established that most respondents were quite familiar with causes of premature defects in CSBs, citing surface erosion and cracking as the two most common defect types. To improve the service life of CSBs, various surface protection measures were regarded as the most economic way of achieving the goal (by 90% of the respondents). Other approaches considered included improved intergranular strength (40%), dissemination of standards and codes (28%), better architectural design (20%) and better processing methods.

With the preceding conclusions, the objectives of Chapter 4 were met.

CHAPTER 5

EXPERIMENTAL DESIGN AND PREPARATION OF SAMPLES

5.1 INTRODUCTION

In this Chapter, experimental design for the main laboratory based tests are described. The preparation of CSB specimen samples for further tests are also described. Laboratory based experiments were planned for in the research methodology mainly to test ideas, theories and designs that had been formulated. The scope of this Chapter is limited to the description of the experimental design adopted and the methods used to produce CSB specimen samples. Surface and bulk property tests for which the specimens are fabricated are discussed separately in Chapters 6 and 7.

The objectives for which CSB specimen samples were produced were:

- to obtain a sufficient number of CSB samples from which statistical generalisations can be made.
- to obtain quantitative experimental results from samples with various input variables (response experiment).
- to monitor the effects of the main input variables in CSB production.
- to compare the experimental data obtained with theoretical predictions and with other available data on CSBs.
- to facilitate the explanation of discrepancies between predicted and measured performance.

The laboratory tests had to be completed within a limited period of time. For this reason, the samples produced as described in this Chapter were meant to satisfy only a limited number of tests. For all laboratory tests attempts were made to ensure that the results obtained satisfied three basic conditions: accuracy, reliability and reproducibility. Only standard methods were used in the production of CSB samples. This chapter only describes the measurements made on green blocks and just cured blocks. Measurement on block samples were limited to: dimensions, weight, shape and appearance. The specimens were then marked and labelled for further extensive tests (reported in Chapters 6 and 7).

The rest of this Chapter is presented in four sections, namely: experimental design, results of soil classification tests, preparation of CSB specimen samples, and conclusion.

5.2 EXPERIMENTAL DESIGN

Variation of any of the several production input variables can influence the quality and performance of blocks (Chapter 3). These variables include:

- Soil (type and proportions of main fractions)
- Stabiliser (type and content)
- Mix-water (amount)
- Compaction pressure
- Curing conditions

For any meaningful experiment, it is unhelpful to vary all the input variables at the same time. The experimental design was therefore based on fixing some of the variables while varying others. The control (independent) variables were taken as the composition variables (soil type, stabiliser, water) and process variables (compaction pressure, curing conditions). The main variable fixed was the soil type. All block samples were made using soil of a fixed composition. In this way the effect of varying the stabiliser type and content, compaction pressure, mix-water content and curing conditions on the properties (response) of the block could then be easily monitored. It was also considered necessary to specify the number of observations, the values of the control variables at every observation and the order of observations (Ray, 1992; Greenfield et al, 1996).

The main approach adopted was to compare the properties and performance of two categories of blocks, namely: traditional blocks (TDB) and improved blocks (IPD). While the former were made in the conventional way using OPC and/or lime as the stabiliser, the latter were made using partial replacement of OPC with condensed silica fume (microsilica). The amount used was fixed at 10% of the OPC content (Neville, 1995). The blocks were regarded as being improved because of the theoretical expectation of enhanced performance due to the inclusion of microsilica (Chapter 3).

The stabiliser type and content, rather than any other variable, was used as the main categorisation parameter for several reasons. To start with, it is the stabiliser content which is responsible for most of the improvement in CSB strength, dimensional stability and durability (Spence & Cook, 1983). Compaction pressure could have also been used as the main parameter for categorising block types. Unfortunately, although compaction pressure contributes towards reducing voids and thereby increasing density in blocks, its effects can be easily reversed in the absence of a stabiliser (Chapter 3). It is the stabiliser content alone which is responsible for binding the block particles together on a more permanent basis. It was reported in Chapter 3 that densification alone without the addition of a chemical stabiliser has no permanent effect on soils. However, the effect of varying the compaction pressure, mix water content and curing conditions were also investigated for both improved and traditional blocks. The summary of the actual input variables used in the design of the experimental samples are shown in table 3.

S/N	INPUT VARIABLE	UNITS	AMOUNT	EXPERIMENTAL DESIGN	
				FIXED	VARIED
A	SOIL 'S' (Laboratory soil)			•	
	Gravel	%	2	•

	Temperature	°C	22-24	•	

Table 3: Summary list of the main constituent materials and input variables used in the production of block specimens.

Each of the variables listed in table 3 are discussed in turn.

The *soil type* was kept fixed, with approximate composition: gravel (2%), sand (75%), silt (8%) and clay (15%). As several block types of nominal dimensions 290 x 140 x 100 mm were required for the experiments, keeping the soil type the same for all specimens would help increase reliability in the tests. It was from the full block sizes that smaller specimen samples were obtained for further experimentation. By keeping the soil type the same at all times for all specimens, better consistency, repeatability and controllability could be achieved. The selected soil composition had to comply with the suitability criteria earlier discussed for soils for CSB production. An optimum composition of soil fractions for more effective stabilisation with OPC rather than lime was chosen. The criteria used for soil classification was particle size distribution. According to literature sources, an ideal soil for effective stabilisation with OPC has the following composition: coarse fraction (gravel and sand) 75% and fines fraction (silt and clay) 25% (Fitzmaurice 1958; United Nations, 1964; Houben & Guillaud, 1994). Following from this, an artificial soil was blended in the laboratory for repeatable use.

The mock soil was made by controlled mixing of ordinary buildings sand (OBS) and ordinary potters clay. The soil was from then on referred to as soil 'S'. The clay type was of the Kaolinite group, chosen due to its known stability and non-expansive nature when in contact with water (Scot, 1963; ILO, 1987; Webb, 1988). The importation of representative soils from the humid tropics was considered not to be necessary. Even if this had been done, not much would have been achieved. This is because soil remains a highly variable material even within each country and moreover, even within regions of the same country. A further advantage in using the artificial laboratory blended soil was that soil properties such as particle size distribution, plasticity, bulk density, moisture content, etc., could all be easily controlled. These soil properties could be kept consistent for all block samples. Any variations in soil properties would not only influence the choice of stabiliser, but also the properties of the blocks produced from it. By keeping the soil type consistent, a more logical interpretation of the effects of other production variables on the performance of the block could be achieved. Further, any variations detected in the performance of blocks could be linked to the method of investigation used instead of attributing it to variations in soil composition. For the soil 'S', key soil properties such as particle size distribution, linear shrinkage, moisture content, etc., were tested using standard test methods. Test methods are described in Webb (1988) and in Webb and Lockwood (1987). The key test results are presented and discussed in Section 5.3 of this Chapter.

The *stabiliser type and amounts* were varied as discussed earlier (table 3). The predominant stabiliser type used was OPC of class 42.5N, supplied from Rugby Cement (BS 12, 1996). The other stabilisers used in combination with OPC were lime (BS 890: 1995) and condensed silica fume (Illston, 1994; Neville, 1995). OPC was selected as the main stabiliser for a number of reasons (Chapter 3). Of all the common stabilisers OPC is widely available in most parts of the world. Lime was also used in combination with OPC for a limited number of specimens. The objective of such combinations was to evaluate the effect of lime on the clay fraction of the soil (Hilt & Davidson, 1960). The lime type used belonged to the Limbux brand, a high quality hydrated lime of typical assay 96.5% calcium hydroxide. The neutralising value was 7.4% CaO. Each required amount of lime was accurately weighed in self-sealing bags on an electronic scale. Microsilica (non-combustible amorphous S_1O_2: CA_5 No. 69012-64-2) in controlled amounts of 10% of the OPC content, was added to a selected number of blocks. The microsilica used was grade 940-4 (Elkem microsilica from Norway). The objective was to assess the effect of such partial cement replacement materials on the improvement of strength and quality in blocks. The material was known to have been employed in the production of high-strength concrete (Neville, 1995). By progressively altering the stabiliser content and type, variations in the performance of blocks produced under each category were monitored. The extent and significance of changes in properties were of great interest to the research. The amounts of OPC used is shown in table 3. OPC content varied from 3% to 11% by weight in increments of 2%.

Theoretically, when OPC is partially replaced with a CRM such as microsilica, the latter acts as a nucleic centre, thus reducing the water-cement ratio (Chapter 3). With proper wet curing, a maximum degree of hydration can also be achieved. Moreover, the microsilica also reacts with the lime that is released during the hydration of OPC to create a secondary binder in the block. Under such circumstances, it can be expected that such a block would have a much higher inter-granular strength, higher density and more resistance to surface abrasion. It is for this reason that such blocks have been referred to here as 'improved blocks' (IPD).

Mix-water content was varied (from 7% to 9%) for a select number of blocks (those made with 5% OPC content). For all other blocks, the mix water content was maintained at 8.5% by weight of the soil plus stabiliser mix. Variation of mix-water content was not originally planned. After accidentally adding more water than was originally intended and obtaining a much higher value of wet compressive strength for the block, it was decided that the variable be investigated further experimentally. The effect of changing the mix-water type was also investigated: ordinary laboratory tap water and distilled water. The results from three samples showed that there was no significant difference in the performance of blocks made from either type of water. Consequently, Coventry tap water was used to produce all block specimen samples used in the experiments. The water temperature was approximately 23°C.

Compaction pressure was maintained at 6 MPa, but only varied to 10 MPa for a select number of blocks. The latter was used purely for comparison purposes only since such high values are rarely used in practice. It is common to compact CSBs at compaction pressures between 4 MPa and 8 MPa (Houben & Guillaud, 1994). The BREPAK press that was used to make all the blocks was equipped with a pressure monitoring gauge (Webb & Lockwood, 1987).

Curing conditions were maintained for all blocks according to the specifications for the binder type used. For a select number of blocks, curing conditions were varied by curing the blocks under exposed and wet conditions throughout (immersion after 24 hours of demoulding). Otherwise normal curing conditions were applied to the majority of blocks produced. Primary curing taking 3-7 days, followed by secondary curing for 28 days was the general format adopted. Where lime was included in a block, the above periods were doubled. After curing, the blocks were then cut to the required sizes (Section 5.4).

5.3 CHARACTERISATION OF SOIL 'S'

Soil classification tests were performed on soil 'S' in order to confirm its category amongst other soils. The main tests conducted included the following:

- Particle size distribution test (Vickers, 1983; BS 1377: Parts 1 and 2, 1990)
- Sedimentation test (Appendix J)
- Linear shrinkage test (Appendix K)
- Moisture content test (BS 1377: Parts 1 and 2, 1990)

The procedures involved in each of the above tests are described in the references shown while some are discussed in Appendices J and K. The soil tests were conducted before and after the manufacture of the several specimens. These showed that no significant changes in soil composition had occurred during the entire testing period. Summary of the average values obtained in the above tests are presented in table 4.

S/N	TEST	UNITS	TEST RESULTS	RECOMMENDED VALUES
1	PARTICLE SIZE DISTRIBUTION			
	Gravel	%	1.3	< 40
	Sand	%	75.4	25-80
	Silt	%	8.1	10-25
	Clay	%	15.2	8-30
2	SEDIMENTATION (JAR)			
	Gravel and sand	%	73.9	75
	Silt and clay	%	26.1	25
3	LINEAR SHRINKAGE	mm	17.6	15-30
4	MOISTURE CONTENT	%	0.9	<3
	SOIL TYPE		SANDY SOIL	

Table 4: Summary of soil classification test results for soil 'S'. (Recommended values: ILO, 1987; Houben & Guillaud, 1994; Rigassi, 1995)

The *particle size distribution* test results for soil 'S' show that the soil type is predominantly sandy (Appendix L). The proportions of the main soil fractions present fall within the recommended ranges. Soil 'S' was therefore found to be suitable for stabilisation with OPC. The soil has sufficient proportions of coarse fraction (fine gravel and sand) for the skeletal frame and body of the block, as well as an adequate proportion of fines (silt and clay). The test method used is fully described in Vickers (1983) and in BS 1377: Part 2 (1990).

The *sedimentation (jar)* test results also confirm the presence of sufficient quantities of coarse soil fraction and fines. This result also shows convergence with the previous test. According to the results, the amount of coarse soil fraction was about 73.9% and fines fraction about 26.1%. As explained in the earlier parts of the thesis, the main advantage of having a sufficient amount of fines is to make sure that the block remains intact on demoulding. On ejecting a block, the hydration reaction of OPC is still at a very early stage and the cement will require more time before it begins to set and harden. The presence of a natural binder like clay in the block is therefore advantageous. The sedimentation test is however, quite slow (over 48 hours) and of medium accuracy. The values of silt and clay can be slightly distorted due to swelling and expansion in water. It was also found difficult to differentiate the silt from the clay as both appeared to be well intertwined. The test method is described in Appendix J.

The *linear shrinkage test* (LST) result of 17.6 mm (mean value) confirmed that soil 'S' had just enough clay in its composition (Webb & Lockwood, 1997). There is therefore no need to add more clay than the amount already added (15%). The results also confirm that the use of OPC, rather than lime for stabilisation would be more effective in this case. Lime would have been required if the shrinkage value had been higher, signifying a high clay content in the soil. The LST method is described in Appendix K.

The *moisture content* value of 0.9% shows that soil 'S' is in a near dry state. The term 'dry' as used here might not be strictly accurate since there is still some water present in the soil in the form of adsorbed water which surrounds the solid soil particles (Chapter 3). The term 'dry' has been used here to indicate that soil 'S' attained constant weight on being heated to 105°C - 110°C (BS 1377: Part 2: 1990). The dry state of soil 'S' is quite important since mixing of the soil with the stabiliser has to be done with both materials in a similar state. If the soil had been wet, then its specific surface area would have varied unnecessarily. The size and density of blocks obtained would not have remained consistent (Chapter 3). By determining the dry state moisture content, it was also then possible to determine the total amount of water added to achieve the optimum moisture content of the soil. The test for the optimum moisture content in this case is done using the drop test. Soils are compacted at the optimum moisture content because it is difficult to compact them at lower moisture contents. An increase in moisture content lubricates the soil, making it more workable. Dry density increases and air voids are reduced. The optimum moisture content of the soil is however, not a parameter dependent on the soil type alone. It also depends on the type of grading and on the compaction effort used (ILO, 1987). The test method used to obtain the moisture content value for soil 'S' is based on BS 1377: Part 2: 1990.

5.4 PREPARATION OF CSB SPECIMENS

In this Section, the design and production of CSB specimen samples used for subsequent tests and experiments are described. The summary list of the total number of samples made during the experimental stages is also provided. The sample size for each test was based on earlier exploratory tests where the coefficient of variability for each test type was determined (5.4.2).

5.4.1 LABORATORY PRODUCTION OF CSBs

The planned experiments demanded a large number of specimens prepared to a high degree of accuracy, reliability and consistency. Extra care had to be taken at all stages of the block production process: soil preparation, mixing, compression, and curing of the samples. After curing, the block specimens were cut to conform with the sizes required for each test. Apart from the mix-proportioning stage that distinguished the block types by amount and type of stabiliser used (improved and traditional blocks), the rest of the procedures remained the same. Specimen design and preparation describes the procedures adopted and the precautions taken to produce the required number of block specimens for the various tests planned. The description is based on the four main stages of CSB production:

- Soil preparation
- Mixing
- Moulding
- Curing (and sizing)

Soil preparation involved the mixing and storing of soil 'S'. Before this was done however, the ordinary builders sand (OBS) was dried and screened prior to mixing with clay. The sand was supplied in 500 kg bags and placed in bins outside the laboratory. The sand had been supplied clean, i.e. after washing out the clay fraction from the sand. To dry out the material, the sand was removed from the yard bins and spread out on the hard, flat concrete laboratory floor. About 100 kg of the OBS was weighed and spread out each time. The weighing was done using the Avery Weighing Scale: type 3202/CLE No. B672521 (capable of weighing up to 50 kg at a time). The objective of drying out the sand was to ensure that a material of an almost even moisture content was obtained. The spread out sand was regularly and repeatedly raked to turn it over every four hours for about three days. When both the bottom and top layers achieved uniform light colouration, the sand was considered to be dry enough. The dry sand was then screened by pouring portions of it at a time onto a circular framed screen placed tightly over a laboratory soil storage bin. The square sieve aperture used was 5 mm (BS 410) to allow only fine gravels and sand to pass through (sieves made by Endcotts Test Sieves Limited). In this way all medium to coarse gravel present in the supplied sand was eliminated. Even then, it was still found necessary to use the hand to occasionally remove soil fraction sizes larger than 5 mm that may have accidentally gone through. The screened material was then stored in sealed bins within dry areas of the laboratory.

Mixing was then done to improve the grading of the sand. Controlled mixing was done by adding about 15% by weight pure grade E Kaolin clay. The characteristics of the clay used were: ECC International Grade E potters pure clay (quality China clay made in England); specific gravity 2.6; specific surface area 8.0 m^2/g; water soluble salts 0.15%; silica (S_iO_2) 50%; alumina (Al_2O_3) 35%; and pH 5± 0.5. The Kaolin clay was supplied in 25 kg bags. The OBS and clay were mixed mechanically using the Hobart machine mixer. Mixing was done for each batch of about 30 kg for about 4 to five minutes till a uniform colouration was achieved each time. After a homogeneous mix was obtained, soil classification tests were performed for every other five batches (Section 5.3). Soil 'S' was then stored in laboratory bins, covered and sealed. Covering of soil 'S' was done to minimise risks of contamination and to ensure that the moisture content remained uniform throughout. This procedure was repeated until enough soil to make about 60 blocks of nominal dimensions 290 x 140 x 100 mm was obtained. Each block required about 8.0 kg of soil 'S'. The amount of OBS and clay supplied was sufficient for the required number of experimental samples.

Mixing of soil 'S' with stabilisers (OPC, lime and microsilica) and water, was done in four stages for each batch. Proportions for the various stabilisers and soil 'S' used are shown in Appendix M. The key objective during the mixing stage was to ensure a good distribution of the stabiliser and water throughout the mix. Consistent proportioning out, dry mixing and wet mixing were required to obtain proper samples.

The proportioning out of soil and stabiliser was done by weight, not by volume. An electronic weighing scale capable of weighing up to 20 kg to an accuracy of 0.05 grams was used each time. All materials were weighed inside a plastic bag which was then sealed and clearly marked. The bags were carefully labelled to show the exact weight, type of material and date of weighing. By sealing the bags, variations of moisture content and contamination of the weighed out material were avoided. In all cases, dry mixing was done first before wet mixing with water. All mixing (wet and dry) was done in the Hobart Machine mixer as described earlier. Dry mixing was done for about three to four minutes. After this, water was then uniformly added to the dry soil and stabiliser mix and the process repeated. Amounts of water varied between 7.0% and 9.0%. The amount used was determined to give the soil its approximate optimum moisture content. The water was also meant to be sufficient for hydration of the stabiliser(s).

After uniform colouration was achieved, a consistency test was done for each mix (Chapter 3). Soil and stabiliser mixes which passed the drop test were immediately separated into three equal amounts sealed in polythene bags. Separation was necessary in order to ensure that mould filling could be done in three equal layers. Except where it was done deliberately, no delay between mixing and moulding was allowed.

Compression of the damp soil and stabiliser mix was done using the pre-installed BREPAK block making machine (SN BQ 038074, originating from Bristol, United Kingdom). The block making machine was designed on the quasi-static compression principle. The same machine was used for all block specimens produced. The main characteristics of the machine were: maximum nominal block size: 240 x 140 x 100 mm; maximum daily output, 300 blocks; maximum moulding pressure, 2 to 10 MPa.

Instructions contained in the operators manual for the machine were followed while making blocks (Webb & Lockwood, 1987). The compression procedures were done in three stages: mould filling, moulding, and demoulding. Mould filling was done after first cleaning the mould using release oils. This was repeated after every four to six blocks were made. Filling was done in three equal layers as described before, using the pre-weighed and separated mixes. By accurately weighing the mixes, it could then be expected that blocks of the same size and of consistent density could be produced. On placing each layer into the mould, the operation was checked by using fingers to press the mix into the corners of the mould. After the last layer was levelled, the mould cover was turned into position to cover the mix. The pressure monitoring gauge attached to the machine was used to determine the amount of force applied as required. The procedures were repeated till the required number of blocks were produced. Three blocks were produced for each specific mix type.

After the blocks were made, demoulding and handling followed, (done with great care as the blocks were still weak). Plywood sheets of about 20 mm thickness were used to remove the blocks from the elevated mould base plate. The sheets over which the green blocks were carried were each pre-weighed. The removal procedure was the same for all green blocks demoulded. While holding the pre-weighed plywood sheet level with the top of the elevated mould base plate, the green block was gently moved onto it using a second plywood sheet. The removed green block was then weighed together with the plywood sheet on which it was carried. Weighing was done using the electronic scale described earlier. External dimensions of the demoulded blocks were also taken. Dimensions were taken using a Mitutoyo shockproof dial calliper accurate to 0.05 mm. Measurements were taken at several locations on the block edges and mid-sections as specified in BS 6073: Parts 1 and 2, 1981 and BS 3921,

1985. The blocks were then carefully labelled using a soft-nib permanent marker. This was done to identify each block by date of manufacture, serial number, stabiliser content and moulding pressure used. The blocks were then covered with polythene sheets, which were also marked externally as before.

Curing of green blocks was done according to the specifications for each type of stabiliser used. A selected number of blocks were however cured under different conditions to evaluate the effect of varying this parameter on the properties of the block. For all other blocks, normal curing procedures were followed. Primary curing periods varying between three and seven days, followed by secondary curing periods lasting up to 28 days for OPC stabilised blocks, were maintained. Where lime was included in the mix, these periods were doubled. Secondary curing temperatures were maintained at the laboratory levels (22-24°C). After curing, the blocks were again marked to indicate the time and curing conditions followed for each block. The blocks were then cut down to smaller sizes as required for each test category (Section 5.4.2).

5.4.2 NUMBER OF SPECIMENS PRODUCED

A sufficient number of CSB specimens were required for all the planned laboratory experiments. Initial performance tests and accelerated tests for surface and bulk properties of blocks required specimens of different sizes. For these reasons, the CSBs that had been produced in full scale had to be cut to smaller dimensions.

Blocks were cut mechanically using a concrete lathe machine (masonry saw machine: Clipper, model EN 2-40-3). The lathe was driven electrically with a powered circular saw complete with a water sprinkler. Each block was accurately pre-demarcated with the required dimensions before the lathe was used to cut through. The machine was so effective that the cut surfaces were neat and straight. In this manner, blocks of nominal dimension 290 x 140 x 100 mm were cut down to the following major sizes: 100 x 100 x 100 mm (two per block); 100 x 100 x 40 mm (two per block); 100 x 100 x 90 mm (one per block); 100 x 90 x 40 mm (one per block). Even during the cutting, differences in the resistance of the block bulk to cutting could be felt. The blocks made using partial replacement of OPC by microsilica were the hardest to cut while blocks made with lime inclusion were the weakest to cut. Blocks compacted at 10 MPa were also harder to cut than blocks compacted at 6 MPa but consisting of the same stabiliser and soil mix.

For each test, three specimen samples made in exactly the same manner and composition were required (reasons explained later in this section). The total number of full size blocks made in this way were three per stabiliser and soil mix. The grand total number of blocks made was 51. From this grand total, over 306 smaller specimen samples of different dimensions were obtained. The specimens were then used for various bulk and surface property tests as described in Chapters 6 and 7. Appendix N shows the list of the various types of blocks produced as well as the different specimen samples obtained from them. Specimen samples for comparable materials such as concrete blocks (CBS), fired brick samples (FBS) and rock block samples (RBS) were obtained from the laboratory. These materials were used for the TWA and SDI tests only.

The reasons for testing three specimen samples for each test (then using the mean for interpretation) were based on the following considerations:

- as it is well known that all test results vary, preliminary tests using six specimen samples composed of 5% OPC and compressed at 6 MPa (cured for 28 days) showed the estimated variation from the mean in each case (properly tested) to be consistently low: WCS, 2.49 MPa (variance 0.027): BDD, 2127kg/m^3 (variance 0.023): TWA, 9.8% (variance 0.135) and SDI, 81.4% (variance 0.118). A 95% confidence interval was used in each case. There was no reason to expect that other mixes of differing OPC content would not show similar consistency and trends.

- previous findings by other researchers had arrived at the same conclusion (Webb, 1958; Fitzmaurice, 1958; Gooding, 1994)
- composition variables (soil type, stabiliser content, mix-water-content) and processing variables (moulding pressure, curing conditions) were determined using precision instruments and standard processing methods respectively. The specimens were therefore produced with a high degree of consistency. It is unlikely that the methods used in the laboratory can be repeated in field practice without major departures (Chapter 4).

Moreover, even if more specimens than the determined number of three for each case had been produced, other research constraints such as cost, time and space, had to be taken into account. Time constraints at planning, design and implementation showed that mandatory delays due to curing periods meant that the number of specimens required had to be limited. The time for the actual experimental work and for recording, computation and analysis of the results were also important considerations. Cost considerations relating to ordering of materials, delivery, wages, electricity, water, etc., were other important constraints. From the degree of accuracy, reliability and repeatability achieved in each case, it was later found that the decision made to use three specimens per test was justifiable.

5.5 CONCLUSION

From the preceding discussions in Chapter 5, a number of conclusions can be made regarding the following: experimental design, soil 'S' test results, CSB specimen production, and the total number of specimens provided.

The *experimental design* was based on identifying the main composition and processing variables involved in the production of CSBs: soil type, stabiliser type and content, mix-water content, compaction pressure, and curing conditions. In the experimental design for sample production, the soil type was fixed. Soil 'S' was composed of about 75% fine gravel and sand, and about 25% silt and clay. This was done to ensure that consistent use of the same soil would be possible throughout the testing period.

Stabiliser type and content were varied: cement content was varied from 3% in increments of 2% to 11%. Microsilica amount was fixed at 10% of the cement content. The amount of lime was fixed at 5% by weight of the soil when used in combination with cement. Blocks made using a mixture comprising microsilica and cement were designated as 'improved blocks'. Blocks where microsilica was not used were regarded as 'traditional blocks'. The categorisation was based on the stabiliser type because it is this variable that remains the single most influential factor that can affect the performance of blocks.

The mix-water content, compaction pressure and curing conditions were maintained at similar levels for the majority of blocks produced. For a select few numbers of blocks, these parameters were varied. The majority of blocks were made with a mix-water content of 8.5%, while the select few referred to were made using 7.0% and 9.0% by weight respectively. Blocks made using the 9.0% mix-water content were later found to perform better than those made using 8.5%. Compaction pressure was fixed at 6 MPa for most blocks. A few blocks were produced using a compaction pressure of 10 MPa mainly for comparison purposes only. Curing time and conditions were maintained at the specified levels required for each stabiliser type. All wet curing (100% humidity) was done for a select number of blocks to evaluate the effects of such conditions on the performance of blocks. The effects of these variables on the bulk and surface properties and performance of blocks are discussed in Chapters 6 and 7 respectively.

The *artificial experimental soil* blended in the laboratory (soil 'S') was found to meet critical requirements for suitability for stabilisation with OPC. The mean linear shrinkage value of 17.6 mm was within the range (15-30 mm) indicating the presence of a sufficient amount of clay. If the shrinkage value had been less than 15 mm, then the soil would have been regarded as having an insufficient amount of clay in it. The glass jar sedimentation test results confirmed that the coarse soil fraction (fine gravel and sand) was about 73.9%, while the fines fraction (silt and clay) was about 26.1%. Both values are within the recommended ranges for soils suitable for stabilisation with OPC. The laboratory dry moisture content value of 0.9% showed that the soil used was in a near-dry state, and of uniform moisture distribution. Most soils have moisture content well above 3% in the 'dry' natural state. The particle size distribution test results confirmed that soil 'S' was composed of all the four main soil fractions: fine gravel (1.3%), sand (75.4%), silt (8.1%), and clay (15.2%). The amount of silt was however lower than the recommended minimum of 10%. The values obtained still fall within the range for suitable soils for CSB production.

Specimen design and production of CSBs for further testing were done with the main objective of obtaining an adequate number of samples for all the planned experiments.

For each mix type, at least three blocks were obtained. From these blocks, smaller specimen sizes were cut. A total of 51 blocks of nominal dimension 290 x 140 x 100 mm were produced. Out of this number of blocks, over 306 smaller specimen sizes were obtained. This number was considered to be adequate for all the bulk and surface property tests planned for. The decision to use three specimens per test was based on earlier findings by other researchers, and the low variance calculated during preliminary tests. Careful attention was paid to the block production process: preparation, mixing, compression, and curing. The blocks produced were all found to be of high quality and fit for further testing. Each of the block samples produced and specimens obtained were carefully labelled for easy identification.

From the preceding conclusions, the objectives of Chapter 5 were fully met.

CHAPTER 6

BULK PROPERTIES AND PERFORMANCE

6.1 INTRODUCTION

As mentioned earlier in this thesis, CSB bulk properties can be influenced by the proportions of the main constituents that form the block and by the processing methods used to produce them (moulding pressure, curing conditions, etc.). The objectives of this chapter are twofold, namely: firstly, to identify the main bulk properties likely to affect the durability of a block, and secondly, to test experimentally the performance of blocks made using differing input variables (stabiliser content, mix-water content, moulding pressure, curing conditions, etc.). The bulk properties identified as likely to influence its durability include (Lunt, 1980; Baker et al, 1991; Illston, 1994; Rigassi, 1995):

- Wet compressive strength (WCS)
- Block dry density (BDD)
- Total water absorption (TWA)
- Total volume porosity (TVP)

For each of these properties, the effect of varying some of the input variables described before are investigated (Chapter 3). The results obtained from the tests are analysed with a view to identifying general trends as well as comparing the performance of traditional blocks and improved blocks. Current standards and initial performance characteristics of like materials such as fired bricks and concrete blocks are also compared. Finally, the results are used to validate or query theoretical assumptions made in the earlier chapters of the thesis. The implications of the findings on future methods of design and production are discussed.

The coverage in Chapter 6 is limited to the discussion of experimental findings related to the above properties. All experiments were conducted following standard procedures to ensure accuracy, repeatability and reproducibility. Chapter 6 is presented in six sections. After this introductory section, the others include discussions of the findings relating to compressive strength, dry density, water absorption, volume porosity, and conclusion.

6.2 THE COMPRESSIVE STRENGTH OF BLOCKS

The compressive strength of a block is perhaps one of its most important engineering properties. It was established from the literature that the durability of CSBs increases with increase in its strength (Stulz & Mukerji 1988; Houben & Guillaud, 1994). Indeed a stronger block which has been well cured is usually better resistant to deleterious environmental agents (Chapter 2 and 3).

It is on the basis of the value of the strength of a block that its mechanical and other valuable qualities are judged (Rigassi, 1995; Young, 1998). Knowledge of the compressive strength value of a block can be used in a number of ways. They include:

- to check the uniformity of block quality
- to compare a given block sample with a specified requirement
- to approximate the degree of hydration achieved by OPC (through the strength of bonding)

- to classify a block in terms of its resistance to abrasive durability

Just as is the case with concrete, CSBs are composite materials. Such materials are known to be brittle and are therefore more accommodating of compressive stresses than tensile ones. The tensile strength of a block is about 90% lower than its compressive strength (Fitzmaurice, 1958). For this reason, the discussion in this section is confined to the behaviour of a block under compression only. The discussion is presented under the following three sub-headings:

- Type of inter-particle bonding in CSBs
- Factors influencing strength in CSBs
- Test methods used to investigate the compressive strength in blocks

Type of inter-particle bonding in CSBs

As a heterogeneous mixture of fine gravel, sand, silt, clay and stabiliser, the type of bonding between the different particles in a CSB is believed to be complex (Ingles, 1962; PCA, 1971). The nature of the bond is known to greatly influence its compressive strength. Unfortunately, determination of the quality of bonding is difficult to assess as no accepted test exists at the moment. However, most of the strength of a block is said to depend on the bond between the cementitious matrix and the coarse soil fraction (fine gravel and sand) (Houben & Guillaud, 1994). Physical mechanical interlock takes place between OPC hydrates and the mainly sandy fraction of a soil, with the bond strength varying from point to point (Mitchell & El Jack, 1978). The bond strength also varies according to the type and texture of the coarse soil fraction. It is generally held that characteristics of sand which do not permit penetration of its surface by the hardened cement paste cannot be conducive to good bonding. Soft, porous and mineralogically heterogeneous sand particles are likely to result in better bonding with cement paste. This consideration is often mentioned in concrete research (Glanville & Neville, 1997; Young, 1998).

As sand particles form the bulk of a block, by preserving their own integrity through their own high internal bonds, they constitute the strongest component within the block. Such high internal strength surrounded by 'weaker' contact strength can influence the path lines of failure in a block (cracks). The compressive strength of a block cannot therefore be expected to exceed that of its constituent sand particles. This theory is easier to assume than to test experimentally.

The cement hydrates that intertwine sand particles in a block are known to be porous aggregation of interlocking fibres (Hertzog & Mitchell, 1963). Bundles of these fibres form a cross-linked anisotropic network that effectively limits and opposes movement within the block fabric. The bonds between OPC hydrates are reported to be of the van der Waal type (Weidemann et al, 1990; Young, 1998). Such bonds are known to be physical in nature arising from the large energy available at the surface of gel particles. The forces at the surface of these gels can be large in comparison with their body forces. The bonds within OPC hydrate fibres are however chemical in nature (of the ionic and covalent types) (Taylor, 1998). Such bonds are stronger than the physical ones. These bonds are strong enough to resist any unlimited thixotropic expansion that might normally occur. Lastly, the bond between clay particles in a soil and the OPC hydrates is thought to be of the chemical type (Herzog & Mitchell, 1963; Ingles & Metcalfe, 1972). Through linkage due to the presence of water, a fairly stable chemical bond occurs between the clay minerals and the freed lime from the hydration reaction of cement.

In summary therefore, the strength of a block is governed by the strength of its cement paste, the strength of bonding between the cement paste and sand particles, and the internal strength of the sand particles (Uzomaka, 1978).

Factors likely to influence the strength of CSBs

The strength of CSBs can be influenced by a number of factors (BRE, 1980; Hughes, 1983). The main ones are the:

- water-cement ratio and degree of hydration
- degree of compaction
- state of moisture in a block
- temperature of a block
- age of a block
- type of coarse fraction present

The above factors are briefly discussed each in turn.

The *water-cement ratio and the degree of hydration* are known to determine the strength of a cement matrix (Neville, 1995). It can be expected that the lower the effective water cement ratio and the higher the degree of hydration, the lower the capillary porosity and the stronger the block. This can be achieved through accurate determination of the water cement ratio (proportioning and consistency testing) and proper curing (to maximise the degree of hydration). The degree of hydration can increase as long as moisture continues to be available for hydration. Wet curing of green blocks soon after demoulding is therefore a critical factor in this respect. This phenomenon is investigated experimentally in this research. The total volume porosity of a block and its correlation to strength are also investigated experimentally in this thesis (Section 6.5).

The *degree of compaction* can also affect block strength (Chapter 3). Compression reduces the amount of voids and increases inter-particle contact within a block.

Higher density has always been associated with higher strength (Spence, 1975; Gooding, 1993). This phenomenon is also investigated experimentally in this thesis.

The *moisture state* of a block can also influence its strength. Saturated blocks are weaker than dry blocks (Fitzmaurice, 1948; Houben et al, 1996). The difference in strength can be explained in a number of ways. Firstly, the presence of moisture in a block lowers the weak van der Waals bonds between the surfaces of the cement hydrates and the surface of the sand particles in the material. Secondly, since CSBs contain clay minerals, their high affinity for water leads to absorption and subsequent dispersal of any unstabilised grains. This can have the undesirable effect of weakening the state of bonding in the block. Thirdly, in a saturated state, as a block is subjected to loading, internal pore pressures can build up within it. Such pressure build-up can lead to the type of stress relief normally associated with disruption of inter-particle and inter-phase bonding in cement-based materials (Lea, 1970; Newman, 1986). The difference between the wet and dry compressive strength of a block is likely to be a valuable indicator of the strength of bonding achieved within it. The smaller the gap between the two, the higher can the bond strength be expected to be. This difference is also investigated experimentally in this thesis (Section 6.2.2).

The *temperature* of a block can also influence its strength, and by implication its durability. The effect on strength is likely to be more pronounced during the early age of a green block. It is known that the hydration reaction between OPC and water depends on temperature (Weidemann et al, 1990; Illston, 1994; Young, 1998). The rate of hydration increases as the temperature increases. At later periods in the life of a block, higher temperatures can still be counterproductive. A higher temperature maintained during the service life of a block is likely to result in short-term strength gains but, lower long-term strengths. This phenomenon is not investigated experimentally in this thesis.

The *age* of a green block influences its strength since the degree of hydration of the OPC stabiliser is known to increase with time. During the early stages of production, the degree of hydration within a block increases with curing age, and so does its strength. This phenomenon is investigated experimentally in this thesis. It is also possible that the hydration reaction of OPC might never really become complete (Taylor, 1998). CSBs are therefore likely to continue to gain strength for many years. The rate of increase in strength is however known to decrease after some years.

The *type of the coarse-soil fraction* (fine gravel and sand particles) used to produce blocks can also influence their strength. Increased surface roughness of sand particles is thought to be beneficial in improving bonding, mainly due to improved mechanical interlock between the sand particles and the OPC hydrates. Moreover, improved grading of sand particles can also improve the degree of interlocking due to closer packing of the grains within a block (Chapter 3). Conversely, the use of larger soil grain particles is likely to be disadvantageous. This is because larger soil fractions have a lower overall surface area with a corresponding weaker transition zone. Limits on the size and proportion of the maximum soil fraction can therefore lead to improved bonding, and thus strength of blocks. During the block production stage for this research, the maximum allowable coarse fraction size was limited to 5 mm (by screening with a 5 mm aperture sieve, Chapter 5).

Compressive strength test methods and factors considered

In this sub-section, highlights of the test method and factors considered during compressive strength evaluation of CSB specimens are discussed. Block specimens were produced as discussed in Chapter 5.

The compressive strength of a block is the failure stress measured normal to its face. For all CSB specimens tested, standard methods of test were used throughout (BS 6073: Parts 1 and 2: 1981; BS 3921: 1985). For research purposes only, some similar block specimens were tested both in their wet and dry state. Current standards only recommend testing of samples in the wet state. The reason why dry state testing was also done was explained earlier in this section.

Standard procedures which were consistently followed with no departures allowed are presented in Appendix O. This was done because even with standard procedures, a slight variation in one of a number of test conditions can easily affect the outcome. The most important test factors considered included the:

- block specimen size
- sample moisture condition
- specimen curing age
- specimen end-surface preparation
- rate of application of loading
- rigidity of the testing machine

Each of the above factors are now briefly discussed in turn.

The *block specimen size* was kept uniform as 100 mm cubes for all samples tested. Although standards permit use of cylinders as well, it was found to be a lot more convenient to use cube prisms. The decision was mainly dictated by the method of manufacture used to produce full-scale block samples. Cutting out smaller specimens from the full-scale sizes had several advantages. The 100 mm cube specimens were:

- easy to cut out
- expedient to protect from damage

- cheaper to make
- convenient to test with a lower capacity machine
- economic to test as less material was wasted (the test was destructive)
- small enough to be less likely to contain elements of weak points

It is well established that the strength of a cement based specimen decreases with size (Neville & Brooks, 1994). So does the *variability* in strength of geometrically similar block specimens, because smaller specimens are more homogenous. The results obtained were satisfactory with a high degree of consistency (Section 6.2.1).

The choice of *moisture condition* in the test samples was considered an important factor. Testing in the 'wet' state is advantageous in that it is more reproducible than testing in the 'dry' state. Testing in the latter state can be unhelpful since it includes a widely fluctuating degree of dryness in a block sample used. The outcome from such a test would really not be that accurate to compare. Testing in the dry state can also lead to higher strength values being recorded (Fitzmaurice, 1958). This can be misleading when related to actual service conditions where blocks are likely to be continually subjected to moist conditions. Testing in a wet condition therefore relates better to real life applications of the block. For purely research purposes, compressive strength tests on a select few number of blocks were conducted in both states.

The choice of *specimen curing age* was based on the specifications of the stabiliser type used. As stated earlier, curing is associated with the rate of hydration of the stabiliser used. Indeed it is with age of hydration that OPC gains strength, especially at the early stages of the process (Weidemann et al, 1990). For practical purposes the hydration of OPC is generally regarded as being substantially complete at 28 days (Illston, 1994). Compressive strength test values obtained around this time ought to reflect the full strength of a cured block. No significant increase in strength is likely to be recorded after 28 days (Lea, 1970). For these reasons, all cement based block specimens were tested at 28 days. Lime based blocks were tested at 56 days (BS 890, 1972; Bessey, 1975; Coad, 1979).

The *end surface preparation* for each test specimen was considered a critical factor likely to affect the results. As during the test two dissimilar types of surfaces (block surface and testing machine platen) would be coming into intimate contact with one another a special precaution was required. While the surface of the end platen of the machine might be smooth, the surface of the CSB specimen is rougher, uneven and not really plane (ILO, 1987). Such dissimilarities can give rise to undesirable stress concentrations on the block specimen. This effect can lead to variations in test results to the extent that the outward compressive strength of a block specimen would appear to be diminished (Bungey & Millard, 1996). In order to overcome this problem, the surfaces of all block specimens tested were capped using plywood pieces of dimensions 105 x 105 x 12 mm (BS 6073: Part 1 and 2, 1981). The size was chosen to be about the same as the top of the block specimen. In this way, the influence of any surface defects in planeness that could have created significant variations in test results were removed, or at the very least minimised. The narrow scatter of test results later showed that this decision had been the correct one (Section 6.2.1).

The *rate of application of loading* (compression testing machine) was also regarded as an important factor likely to affect the seeming strength of test specimens. It is well established that the lower the rate at which the stress is increased onto the block, the lower will the eventual recorded compressive strength be (BS 6073: Parts 1 and 2, 1981). Conversely, if the load is applied rapidly, higher strength values can be recorded. The reasons behind such outcomes is based on the rate of increase in strain over time. It is widely reported in concrete studies that when the limiting strain is reached too soon, failure also takes place prematurely (Lea, 1970; Neville & Brookes, 1994; Jackson & Dhir, 1995). It is therefore important that the stress on block specimens is applied at a uniform and consistent rate for all samples tested. In this way comparable results can be obtained. The selected rate of loading applied gradually without shock for all specimens tested was 15 KN/minute (BS 6073: Parts 1 and 2, 1981; BS 3921: 1985; ILO, 1987). It was generally observed that stronger blocks (higher stabiliser content 7%-11%) exhibited lower severity to the strain rate. The required rate of loading was selected using an electronic input board attached to the testing machine. Failure in most blocks samples occurred within about 2 to 4 minutes.

The *rigidity of the testing machine* was the last factor considered. A less rigid testing machine can store up energy leading to explosive fractures occurring in the test specimen. The machine used for the tests had just been serviced and recalibrated only a few months earlier. This problem cannot therefore be a source of errors for the tests conducted during that period.

After failure was achieved, the crushing strength of each block specimen was calculated by dividing the maximum recorded load carried (in KN) by the cross-section area of the specimen (mm^2). The crushing strength was expressed to the nearest 0.05 KN/mm^2 (MPa). The results are discussed in Sections 6.2.1 to 6.2.4.

6.2.1 EFFECT OF VARYING THE STABILISER CONTENT AND MOULDING PRESSURE ON THE WCS OF CSBs

The values of the 28-day mean wet compressive strength for both traditional and improved blocks are shown in Appendix P(1) to P(5). A plot of these values against the range of cement contents used is given in figure 6. Each of the data points shown plotted in figure 6 is an average of three separate experimental results (Chapter 5). The key to the symbols used on the graph is also given. All subsequent graphs are presented following the same format.

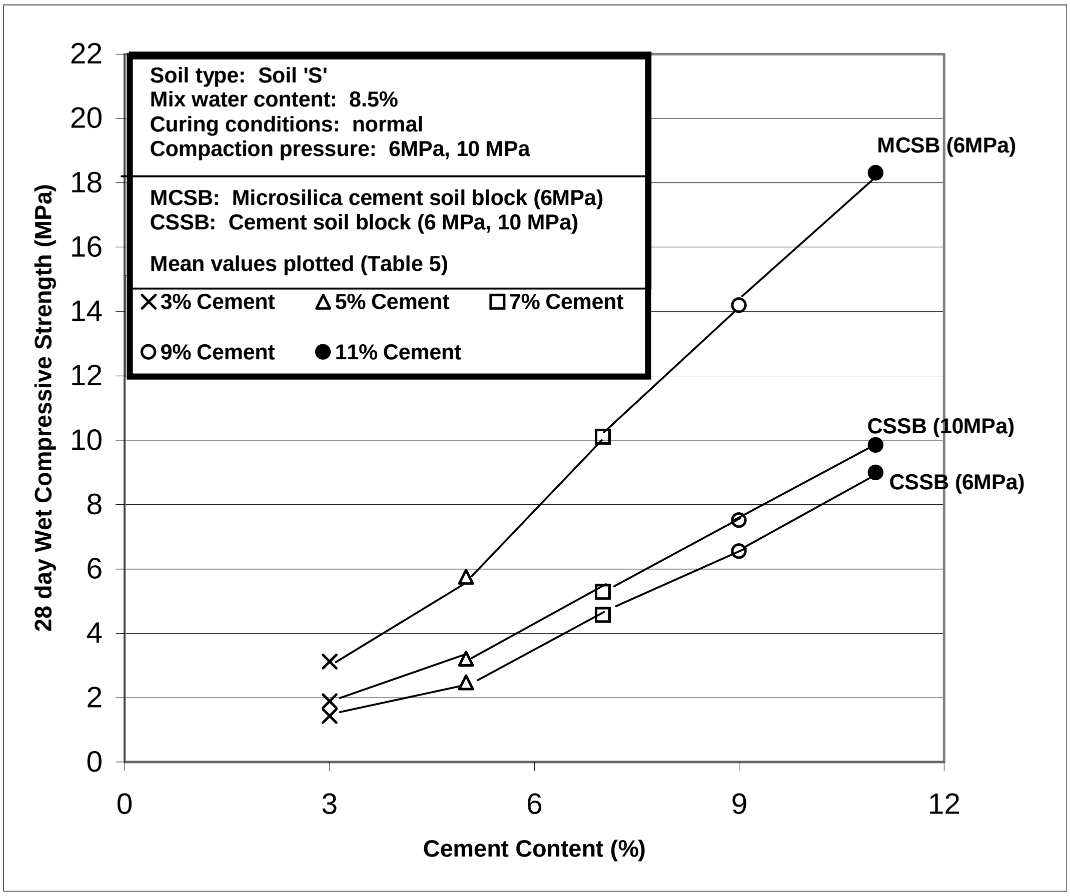

Figure 6: Effect of varying the stabiliser content and compaction pressure on the wet compressive strength of CSBs. (University of Warwick, 2000)

The discussion of figure 6 is conducted along three lines: the range of values obtained, comparison of these values to existing standards, and analysis of the trends shown by the results. This approach is used for all other subsequent results presented in this thesis.

Table 5 shows a summary of the plotted values in figure 6.

Cement content	28-day Wet Compressive Strength		
%	MPa		
	MCSB (6MPa)	CSSB (10MPa)	CSSB (6 MPa)
3	3.12	1.89	1.43
5	5.76	3.21	2.48
7	10.11	5.29	4.57
9	14.19	7.51	6.54
11	18.3	9.84	8.99

Table 5. Mean wet compressive strength values (28-day) for MCSB and CSSBs.

The values of the average 28-day wet compressive strength for both traditional (CSSB) and improved blocks (MCSB) were satisfactory. The values ranged between 1.43 MPa and 8.99 MPa in the case of the former and between 3.12 MPa and 18.3 MPa in the case of the latter. The lower values in either case correspond to the cement content of 3%, while the higher ones to 11%. As can be seen, the WCS values in improved blocks were found to be considerably higher than in traditional blocks made in exactly the same manner but without the addition of microsilica. On average the addition of microsilica resulted in the doubling of strength in blocks. Although some improvement had been expected, the magnitude of the strength gain achieved was surprising. Such high values had not been previously obtained with the corresponding amounts of OPC according to current CSB literature (Rigassi, 1995). The inclusion of a partial cement replacement materials (CRM) such as microsilica therefore appears to be an effective way of increasing the WCS of blocks. These results also confirm the earlier theoretical assumptions described in Chapter 3. This approach represents a new way forward in terms of strengthening CSB fabrics for wider engineering applications. It is also likely to be particularly useful for blocks exposed to severe environmental conditions.

According to literature sources, recommended WCS values for CSBs are quite wide-ranging, varying from country to country, and from author to author. The experimental values obtained here however, compare well with most current CSB standards. Some recommended minimum values are: 1.2 MPa (Lunt, 1980),1.4 MPa (Fitzmaurice, 1958) and 2.8 MPa (ILO, 1987). The value of 1.2 MPa is now more widely used (Houben & Guillaud, 1994). The lowest experimental value obtained for traditional blocks (1.43 MPa), is about 20% higher than this. For improved blocks the 3.12 MPa value is about 62% higher. Both values correspond to blocks stabilised with 3% OPC. The blocks made with OPC contents of 5-7% were all significantly stronger than the 1.2 MPa standard (5 to 8 fold stronger). Moreover, by interpolating the plotted values for IPD blocks below the 3% cement content point, it can be estimated that only about 1% of the binder content would be required to achieve the minimum recommended WCS value of 1.2 MPa. The approach established from these results constitutes a significant new finding.

The preceding discussions concerned variation in stabiliser content only. The results of varying compaction pressure from 6 MPa to 10 MPa over the same range of cement contents for TDB blocks are also shown in figure 6. No improved block samples were subjected to similar variations in compaction pressure. The results show that for the same stabiliser content, increase in compaction pressure leads to an increase in WCS. It was found that at lower cement contents, increase in compaction pressure from 6 MPa to 10 MPa (about 70%) resulted in increase in WCS of about 32%. A similar increase in compaction pressure resulted in a corresponding increase of only 9% at the higher cement contents (11%). Within the range of interest (5-7% cement content), the increase in WCS was between 16 and 30%.

These values are much lower than the dramatic increases witnessed by varying the stabiliser content. The findings confirm earlier work by other researchers that increase in stabiliser content is a more economic way of increasing the wet compressive strength in blocks (Lunt, 1980). Blocks stabilised at high stabiliser contents but compacted at low compaction pressures were found to perform satisfactorily. The final wet strength of a block appears to be more sensitive to changes in cement content than compaction pressure. The results also show that although improved performance can be achieved by increasing compaction pressure, the degree of improvement diminishes as this pressure is increased. Block making machines operating within the range of 4 to 8 MPa should therefore be adequate to give satisfactory results (Houben & Guillaud, 1994).

6.2.2 Comparison of the ratio between Mean dry and wet Compressive Strength

The effect of varying the stabiliser type and content on the gap between mean dry and wet compressive strength was investigated experimentally. The values obtained are plotted as shown in figure 7.

The range of the plotted values shown in figure 7 are summarised in table 6.

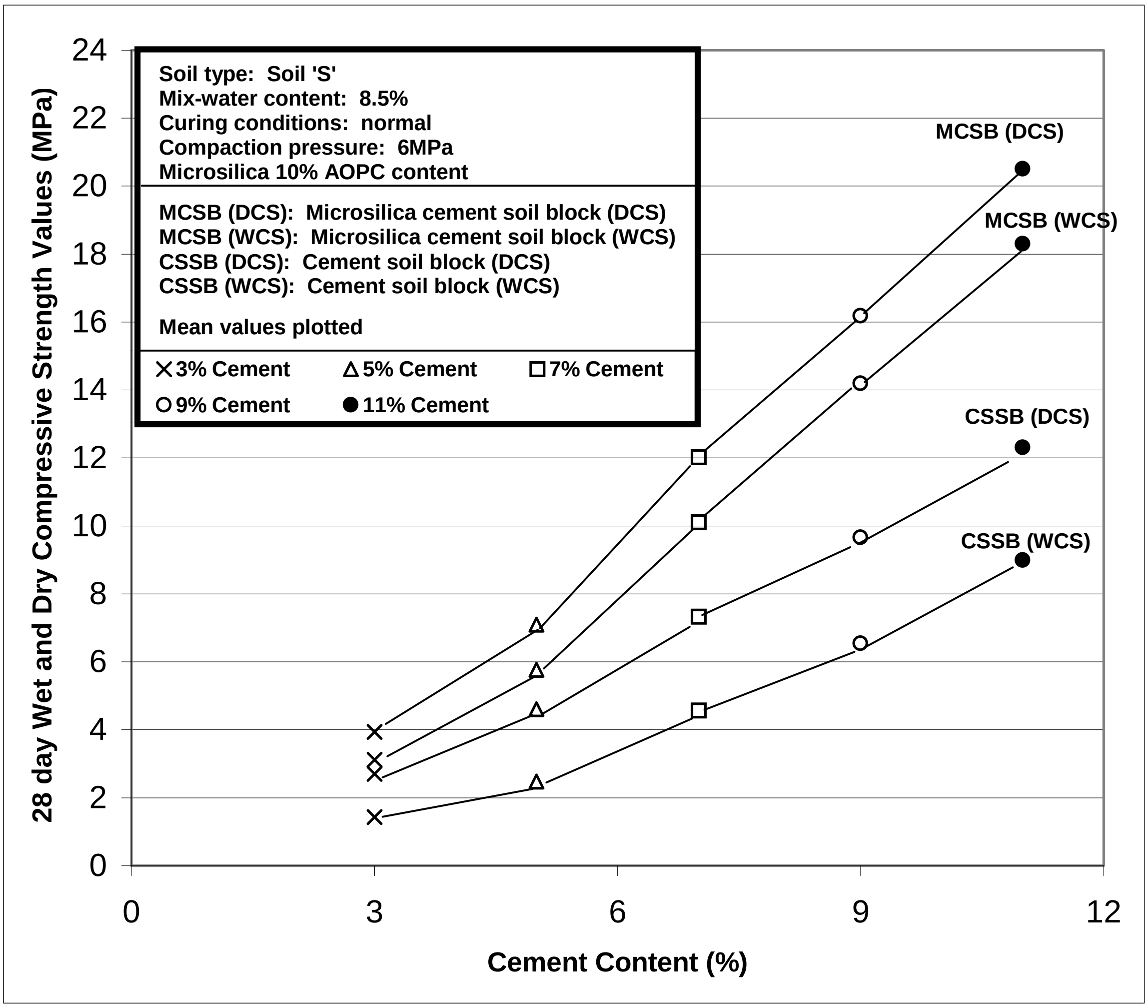

Figure 7: Comparison of the mean wet and dry compressive strengths in both traditional and improved blocks (University of Warwick, 2000).

Cement content	Mean Compressive Strengths					
%	MPa					
	MCSB			CSSB		
	WCS	DCS	Ratio	WCS	DCS	Ratio
3	3.12	3.94	1.3	1.43	2.70	1.9
5	5.76	7.09	1.2	2.48	4.61	1.9
7	10.11	12.02	1.2	4.57	7.33	1.6
9	14.19	16.18	1.1	6.54	9.66	1.5
11	18.30	20.50	1.1	8.99	12.30	1.3

Table 6. Values of the 28-day mean WCS and DCS of TDB and IPD blocks: Ratio (DCS/WCS).

The values of the mean WCS in traditional blocks ranged between 1.43 MPa and 8.99 MPa. The equivalent values of their dry compressive strengths ranged between 2.70 MPa and 12.3 MPa. The difference between mean DCS and WCS ranged between about 40% (for 11% cc) and 90% (for 3% cc). This shows that the higher the cement content, the lower the fractional difference between mean wet and dry strength in a block.

A similar trend emerged with results obtained for improved blocks. The mean WCS in these blocks ranged between 3.12 MPa and 18.3 MPa, while the matching dry strength ranged between 3.94 MPa and 20.5 MPa. Apart from the inclusion of microsilica (10% of the cement content), all other production variables remained the same. As before, the magnitude of the gap ranged between 12% and 26% only (for 11% and 3% cc blocks respectively).

The results for improved blocks compare well with values reported in concrete research where the difference between mean wet and dry compressive strength ranges between 9% and 21% (Neville, 1995). The results for traditional blocks similarly compare well with results obtained by earlier researchers. It was found that the difference between the two strength values in stabilised blocks varied between 35% and 120% (Fitzmaurice, 1958). It has also recently been recommended that the ratio of the mean dry and wet compressive strength in CSBs should not be greater than 2 (Houben et al, 1996). The experimental results obtained here for both traditional and improved blocks fall well within this limit. However, the ratio in improved blocks (1.1 to 1.3) is much lower than in corresponding traditional blocks (1.3-1.9). The variation in ratios for IPD blocks is also less wide-ranging than the case with TDB blocks. The considerable reduction in the gap between the mean dry and wet compressive strengths achieved in improved block represents a major breakthrough in

CSB development. It is well established that the higher the gap between the two, the lower can the strength of bonding between the particles and phases in a block be expected to be (Houben et al, 1996).

The marked increase in strength witnessed in improved blocks as opposed to traditional blocks can be linked to an increase in the degree of bonding within the block. In this case, the improvement can solely be attributed to the inclusion of microsilica in the mix (Chapter 3). The use of this CRM in moderate amounts (5 to 10% of the OPC content) for particular applications is recommended in preference over OPC-only mixes. The general pattern of improvement in strength and other properties of the block are undeniable. The upturn in strength is a consequence of its pozzolanic reaction with the freed lime from the hydration reaction of OPC with water, and also due to its ability to effectively 'fit in' between the OPC grains (Weidemann et al, 1990; Illston, 1994; Young, 1998; Taylor, 1998).

According to cement literature, in traditional blocks, the cement hydrates produced from the hydration reaction grow away from the OPC grains (Weidemann et al, 1990; Taylor, 1998). Even when hydration is deemed complete, the extended hydrate structure is likely to remain sparse, weak and permeable, given the low amounts of OPC used. When microsilica is added, the situation is markedly different. Being an almost pure silicon dioxide, when well dispersed in the cement/block, it can surround every OPC grain with about 100,000 microspheres (surface area 15,000 m^2/kg compared to 350 m^2/kg in OPC) (Illston, 1994). Finer and stronger hydrates can then grow from both the OPC and the 'nucleation centres' of the well dispersed CRM. As can be expected, this action can transform the relatively weak and porous structure into a far denser, more homogenous and impermeable matrix than hitherto possible. As the results in this thesis have shown, dramatic improvement in block properties are evident. Higher strength, density and hardness, as well as effective abrasion resistance and possibly longer service life, are some of the beneficial outcomes. The fact that the block attains superstrength in a matter of weeks shows that improved blocks are likely to outlast traditional blocks in whatever condition they are used in. The wear resistance of both categories of blocks are investigated experimentally in Chapter 7.

In summary, the inclusion of a CRM such as microsilica can be expected to have the following beneficial effects on CSBs:

- Rapid strength development
- Rapid surface drying (to below 75% relative humidity in one to five days)
- No bleeding or segregation at the surface
- Very low surface permeability
- Higher wear and abrasion resistance
- Extreme durability
- Reduced life cycle maintenance costs
- High strengths (compressive, tensile, flexural)
- Very low bulk permeability and sorptivity
- Lower shrinkage and creep
- Extended use of CSBs for flooring, foundations, pathways, underwater applications, etc.

It has also been reported in the literature that concrete materials achieve about 80 to 90% of their ultimate strength within 28 days of production (Neville, 1995). The comparable value attained by CSBs within the same period is lower, about 60-70% (Houben & Guillaud, 1994). The use of a rapid strength developing material such as microsilica is therefore a major advantage where early high strength is required. The problem of increased costs due to its inclusion can be overcome in either of a number of ways. These include the use of hollow blocks, thin surface layered blocks, frog-bedded blocks and interlocking blocks. All these simple measures can effectively reduce the amount of microsilica actually used and thus enable cost reduction to be achieved at no extra expense. The use of microsilica in improving block strength, dimensional stability and durability is therefore highly recommended.

6.2.3 THE EFFECT OF MIX HOLD-BACK TIME ON THE WET COMPRESSIVE STRENGTH OF BLOCKS

The ultimate cured wet strength of a block can be affected by the manner in which it is produced. At stated earlier in the thesis, despite its importance this is an area which has previously received very little attention in CSB literature. The effect of mix hold-back time was investigated experimentally to establish the extent to which WCS can be affected when this variable is introduced. The investigation was limited to traditional blocks stabilised with 5% OPC and compressed at 6 MPa. A similar effect is likely to apply in the case of improved blocks. The phenomenon was also investigated experimentally because it was found during the fieldwork (Chapter 4) that batches too large to be moulded within the hour were being widely used. Very little concern was being shown in the field regarding the potential adverse effects of this variable on the quality of blocks produced.

The mean values of the experimental results obtained are shown in table 7 and figure 8. Each point represents the average of three block specimen samples.

Time	WCS 28-day	Ratio
minutes	MPa	
5	2.53	1.0
30	2.08	1.2
60	1.73	1.5
90	1.58	1.6
120	1.49	1.7

Table 7. Wet compressive strength values (28-day) of CSSBs compacted at various hold-back times.

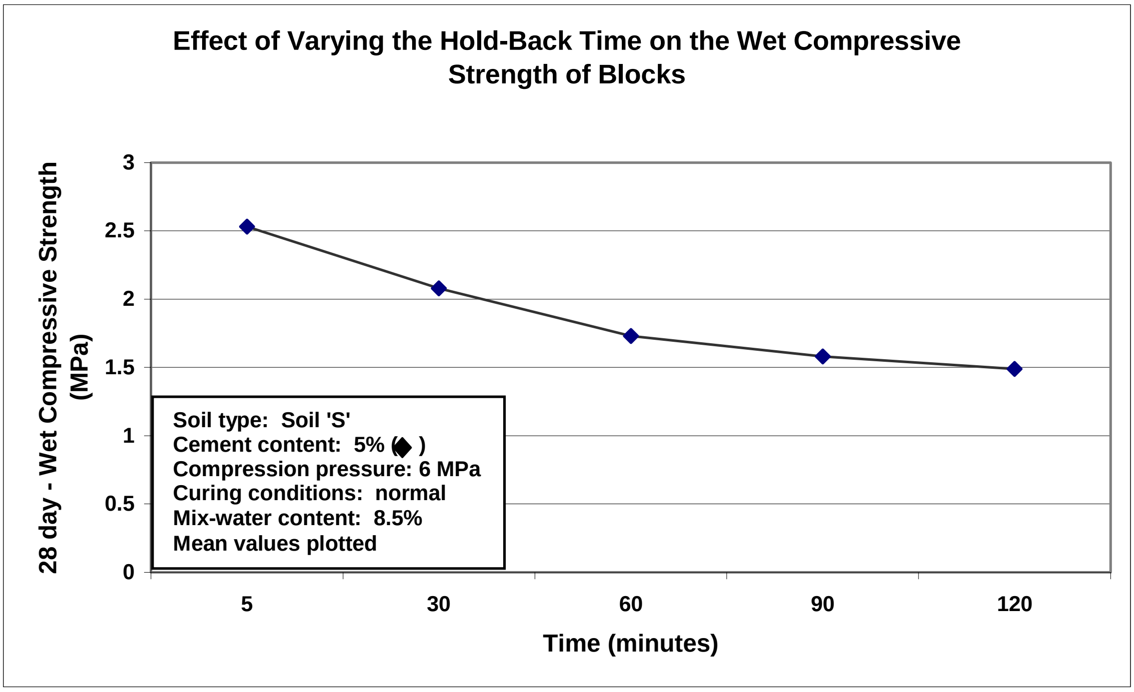

Figure 8. Effect of mix-hold back time on the 28-day WCS of CSSBs (University of Warwick, 2001)

Figure 8 and table 7 show that the average 28-day wet compressive strength fell from 2.53 MPa to 1.49 MPa as the hold-back time was increased from 5 to 120 minutes (a 41% loss).

It was found that blocks compacted within 20 minutes after damp mixing were about 27% stronger than those compacted after 45 minutes of delay. These findings confirm earlier results by other researchers. For example, it was found by Rigassi (1995) that loss of strength after two hours delay was about 50%. It was also found that blocks moulded within 20 minutes of damp mixing were between about 30 and 40% stronger than those compacted after 45 minutes (Houben & Guillaud, 1994). The time of 45 minutes is used as a yardstick because it approximates the early setting time of OPC (Weidemann et al, 1990). The findings here confirm that a general downward trend of loss of strength due to long hold-back times should be expected when OPC is used as the stabiliser. The opposite is true for lime (Bessey, 1975; Coad, 1979). OPC stabilised blocks should therefore be compacted within 20 minutes of mixing, but certainly not after 45 minutes. It is still common field practice to mix batches for hourly production which end up not being used up within the hour (Chapter 4). This discussion confirms earlier statements made in this thesis that the processing method employed during production can significantly affect the ultimate quality of a block (Chapter 3). It is therefore recommended that all CSB production stages should be treated with the same level of skill, competence and supervision.

6.2.4 The Effect of Varying Curing Conditions on the Wet Compressive Strength of Blocks

The effect of varying curing conditions on block strength was investigated experimentally for a limited range of blocks (Chapter 3). CSB specimens stabilised with 5% OPC and compacted at 6 MPa were used. As the test was meant to be indicative only, the OPC content was not varied as before. The investigation was also restricted to traditional blocks only on the assumption that similar effects would be applicable in improved blocks of matching cement content. The curing conditions were varied to approximate common practice in the field on the one hand, and to test theoretical predictions that full moist curing would be beneficial on the other. Curing time of 28 days was maintained for all blocks. The conditions were varied as follows:

Condition A: Open exposure (within a well lit area in the laboratory)

Condition B: Normal curing (7 days wet curing, 21 days dry curing)

Condition C: Complete cover (with polythene sheeting material)

Condition D: Wet curing throughout (by immersion in water 24 hours after moulding until testing time)

After 28 days, three specimen samples from each curing condition category were tested as before. The results are shown in table 8 and are also plotted in the form of a histogram (figure 9).

Condition	28-day WCS	Ratio
	MPa	-
A	1.13	1.0
B	2.54	2.3
C	3.28	2.9
D	6.85	6.1

Table 8. 28-day WCS values of CSSBs cured under varied conditions

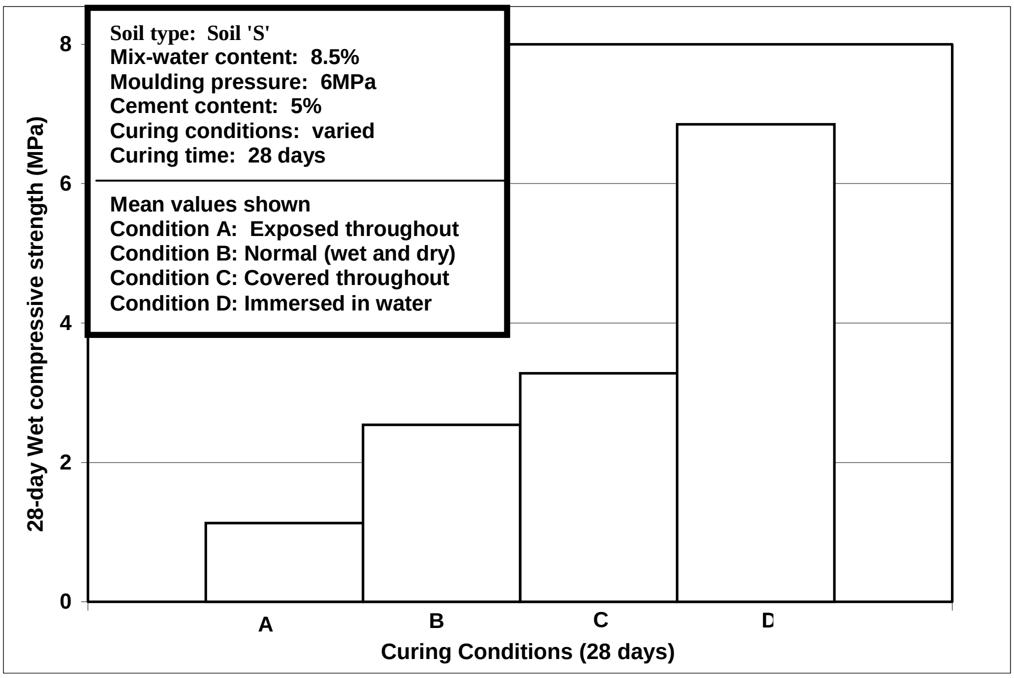

Figure 9: Histogram showing the effects of varying curing conditions on the wet compressive strength of CSBs (University of Warwick, 2001)

When condition A blocks are compared with the other blocks, the differences in strength found are considerable. Normal cured blocks were about twice stronger than exposed blocks. If these blocks had been left exposed in the sun, it is likely that the difference in strength could have been even higher. The case actually approximates actual practice on most CSB production sites (Chapter 4). The belief in such places is that the faster the loss of moisture, the stronger the block becomes and thus the faster it can be used. It is a mistaken concept since prolonged retention of moisture can be beneficial in ensuring that the hydration process continues till maximum hydration is achieved (Chapter 3). This finding partly explains the poor performance of CSBs as observed during the fieldwork.

The results also show that block samples covered throughout are about three fold stronger than those cured under exposed conditions. Blocks cured fully immersed in water for 28 days were about six fold stronger than similar ones cured exposed. The immersion in water was done 24 hours after demoulding since initial attempts to immerse them immediately proved futile. The blocks were then left in water till testing time. The difference in wet strength between the fully immersed cured blocks and the exposed blocks is about 506%. This should be a cause for concern since the latter simulates field practice in most developing countries (ILO, 1987). The recommendation here is that CSB standards covering specifications and workmanship during production should lay more emphasis on the need for proper curing. The procedures to be followed should be clear, simple and easy to understand and execute (Lowe, 1998; Schildermann, 1998). A checklist system spelling out all the necessary steps during production ought to be beneficial in this regard. The main emphasis should be on keeping green block surfaces moist for as long as possible. Exposure of green blocks to rainy conditions, direct sunlight and wind conditions should be avoided especially during the first few days of production (Chapters 3 and 4).

6.3 BLOCK DRY DENSITY (BDD)

The density of a block is a valuable indicator of its quality. It can be expressed in a number of different ways, depending on the pre-existing moisture state of the block, thus:

- Block dry density (BDD) (usually indicating the oven-dried value when desiccated to $105 \pm 5°C$ for 26 hours)
- Block bulk density (BBD) (based on the pre-existing state of moisture, e.g. soon after demoulding)
- Saturated block density (SBD) (when soaked in water for between 24 and 48 hours after oven drying as before)

It is the dry density that is commonly used in building specifications (BS 6073: Part 2, 1981) and is the one discussed in this thesis. In addition to the solid phases that exist in a block, the material also contains pore spaces filled partly with air and partly with water (Jackson & Dhir, 1996). The amount of either phase depends on the moisture state of the block (varies from block to block). When both air and water are driven out (by oven drying to constant mass), the block dry density value is obtained. Apart from the state of moisture in a block, its density also depends on the following:

- the degree of compaction used (normally between 4 and 8 MPa)
- the density of the constituent materials (especially the coarse sand fraction) Sand has a dry density value of about 2,200 kg/m^3 while that for clay is about 2000 kg/m^3 (Houben & Guillaud, 1994)
- the size and grading of the soil particles
- the form of the block (solid, hollow, frogged)

Since the structural strength of a block is the result of the friction between the constituent cement hydrates and soil grains, the closer the packing of these solids, the stronger the block can be expected to be. Densification following the stabilisation of soil with OPC can ensure that the close packing achieved is maintained through the mechanical interlock of the grains. It is this interlock which limits excessive movements more than would have been possible if the stabiliser had not been used. Without the binder, either through omission or due to progressive decay, a block is likely to become weak. In such cases, the effects of densification can be progressively reversed (Lola, 1981; Minke, 1983).

The density of a block can have implications on most of its other bulk properties (Markus, 1979). These include compressive strength, permeability, water absorption, porosity, thermal capacity, sound insulation, hardness and durability (Lunt, 1980;

BRE, 1980; Spence & Cook, 1983). The higher the density of a block, the better can its performance be expected to be. For example, density has commonly been closely associated with the strength of a block (UN, 1964; Spence, 1975). The relationship between strength and density is investigated experimentally in this thesis to determine whether density can be a surrogate for the strength of a block. The correlation between density and water absorption and porosity are also investigated experimentally. Similarly, the correlation between density and durability is discussed in Chapter 7.

Determination of the density value of a block is provided for in most standards. The test method used in this thesis is based on the one described in BS 6073: Part 2, 1981. For all block specimens, three samples were tested in each category and the mean value used for subsequent analysis (Chapter 5). The density obtained in each case was expressed to the nearest 10 kg/m^3 (BS 6073: Part 2, 1981; BS 3921, 1985). The full summary list of the results are shown in Appendix Q(1) to Q(4). The findings are discussed in Sections 6.3.1 and 6.3.2. References to the same values obtained are also made in subsequent sections of this chapter as well as in Chapter 7.

6.3.1 EFFECT OF VARYING THE STABILISER CONTENT AND COMPACTION PRESSURE ON DENSITY

The effect of changing the above variables on density were investigated experimentally. The number and type of samples tested were as before. The compaction pressure was varied from 6 MPa to 10 MPa for a limited number of traditional blocks. The plotted results are shown in figure 10.

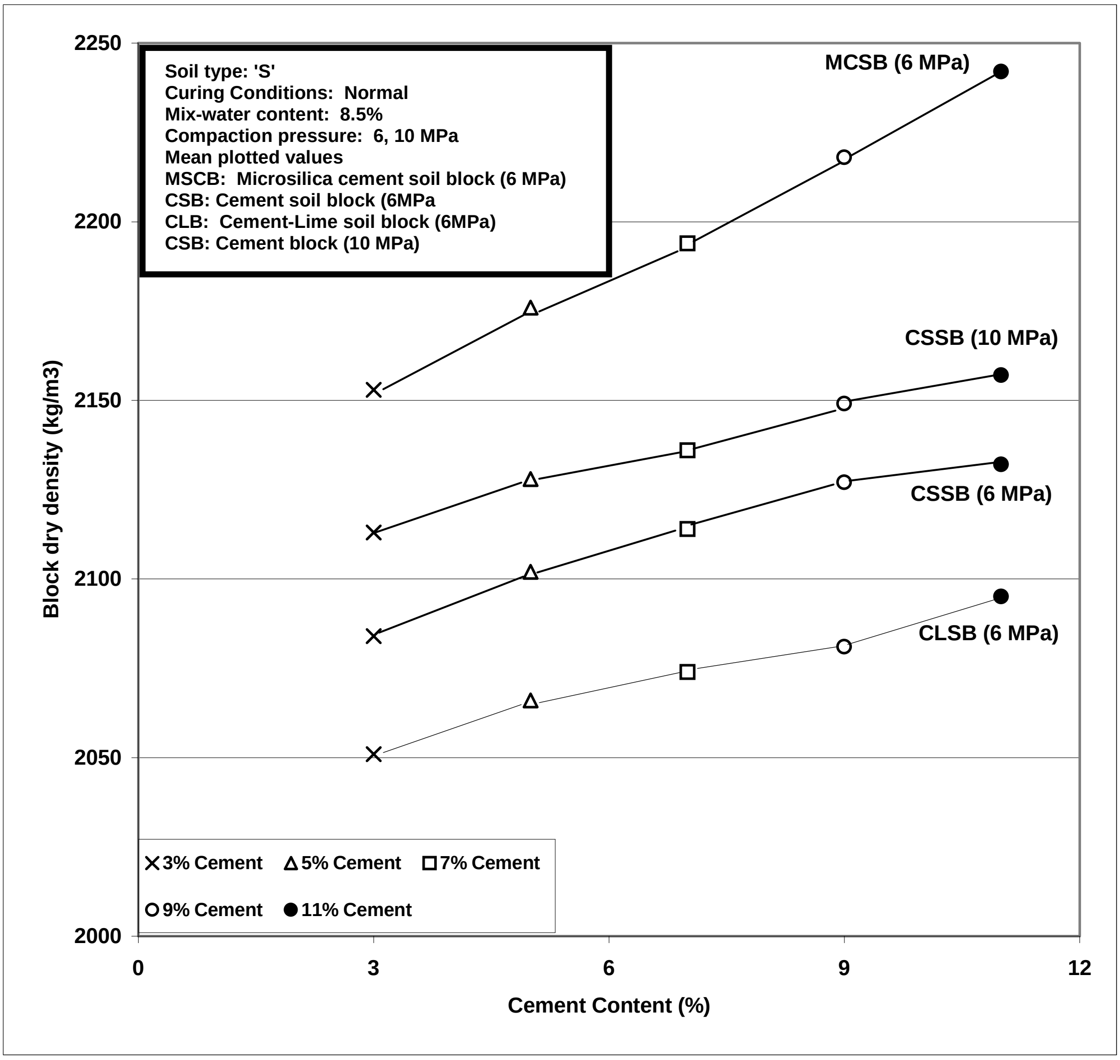

Figure 10: Effect of varying the stabiliser content and compression pressure on BDD

The range of BDD values obtained for both improved and traditional blocks are presented in table 9.

Block type / stabiliser	Compaction Pressure used	Range of BDD values	Density increase with increase in OPC from 3% to 11%
	MPa	Kg/m^3	%
Improved OPC + Microsilica	6	2153 - 2242	4.1
Traditional OPC + Lime	6	2051 – 2095	2.1
Traditional OPC only	6	2084 – 2132	2.3
Traditional OPC only	10	2113 – 2157	2.0

Table 9: Range of BDD values obtained for improved and traditional blocks

The two density values shown in table 9 correspond to blocks stabilised with 3% and 11% OPC respectively. Although the overall increase in density in improved blocks was marginally higher than in traditional blocks, the difference does not appear to be dramatic. However, for matching amounts of OPC content, improved block density was about 4% higher than in traditional blocks. The increase was directly proportional to the increase in cement contact. While the part substitution of OPC by lime resulted in less dense blocks, the partial substitution of OPC by microsilica produced the opposite effect.

Increase in density was also found to occur when compaction pressure was increased. For the OPC only stabilised blocks, increase in moulding pressure from 6 MPa to 10 MPa resulted in a corresponding increase in density of about 1.3% only. So for an increase in compaction of about 70%, increase in density of less than about 2% was achieved. This is considerably lower than the equivalent increase in density due to the inclusion of microsilica (between 3.3% and 5.2%). The addition of a partial cement replacement material appears to be an economic way of achieving higher densities in blocks. The marked increase in density witnessed in improved blocks could have been due to four factors associated with the inclusion of microsilica:

- Pore filling effects
- Increased homogeneity
- Improved bonding
- Reduced voids

The results further confirm the beneficial effects of using a partial cement replacement material such as microsilica (Chapter 3).

6.3.2 *Correlation Between Density and Wet Compressive Strength*

In this section, the correlation between density and strength is discussed. It was stated earlier that for better performance, a denser block would be required. Density was also mentioned as a valuable indicator of strength and durability in a block. The experimental results obtained for BDD are plotted against those for 28-day WCS (shown in figure 11).

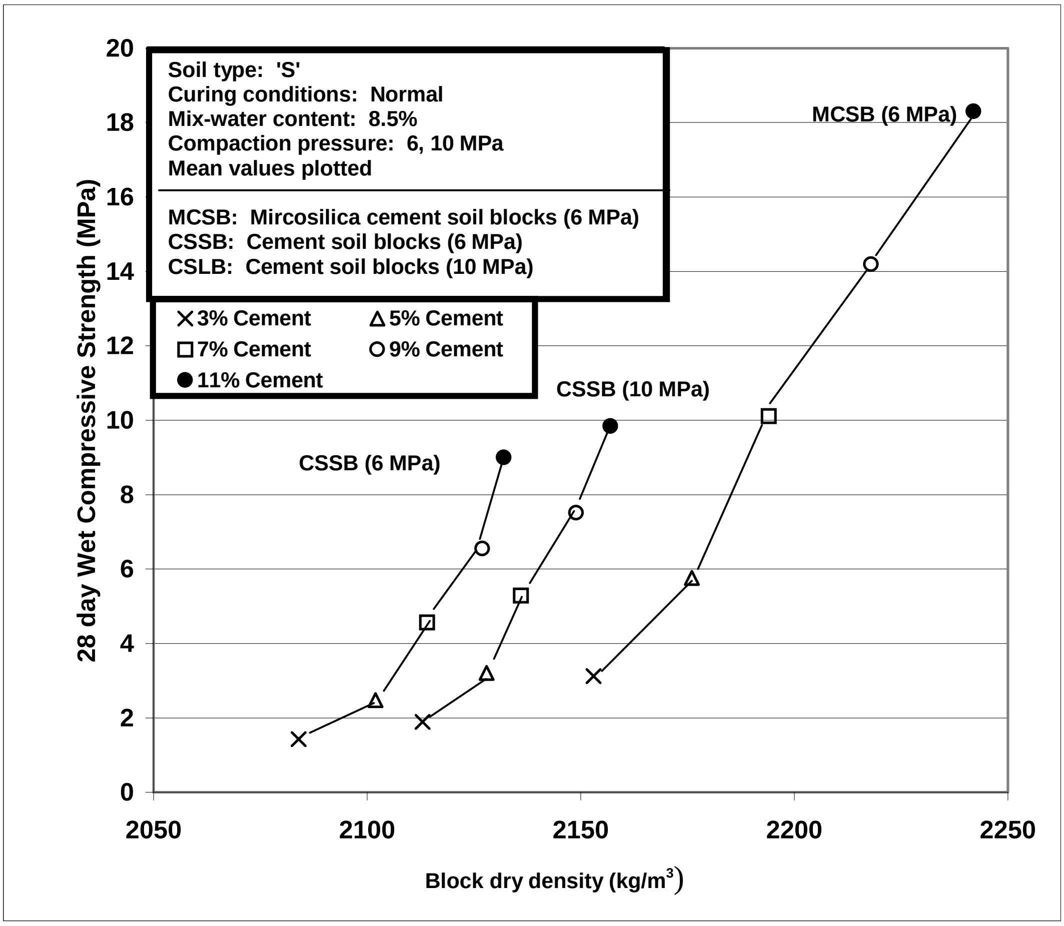

Figure 11: Correlation between BDD and 28-day WCS in CSBs (University of Warwick, 2001)

Figure 11 shows that a general positive correlation exists between BDD and WCS for all the different types of blocks tested. The graph shows that an increase in density is accompanied by a corresponding increase in strength. The coefficient of correlation and P-values are as follows: traditional block (0.971; 0.006), improved block (0.996; 0.000). A strong correlation therefore exists between BDD and WCS.

The correlation between density and strength has also been widely reported in comparable materials (Jackson & Dhir, 1996; Ruskulis, 1997). The dry density values for some like materials are:

- Fired clay bricks: 2250-2800 kg/m^3 (usually 2600 kg/m^3)
- Calcium silicate bricks: 1700-2100 kg/m^3
- Concrete blocks: 500-2100 kg/m^3

These values compare favourably with those obtained experimentally for CSBs. It is widely known that fired clay bricks are the most popular building material in most parts of the world (Parry, 1979; Agarwal, 1981; Spence & Cook, 1983). These blocks are denser, stronger and more durable than comparable materials. The average density of 2,600 kg/m^3 is probably a major contributor to the strength of fired bricks. The comparable density values also show that improved blocks were denser than concrete blocks by about 5%. The only drawbacks likely to result from higher densities are ease of handling and transportation. Blocks which are very heavy can be difficult to lay, and are normally expensive to transport (NASA, 1971; ILO, 1987).

6.4 TOTAL WATER ABSORPTION IN CSBs

Almost all bricks and blocks can absorb water by capillarity (Keddi & Cleghorn, 1980). The existence of pores of varying magnitudes in these materials confers marked capillarity in them. The total amount of water absorbed is a useful measure of bulk quality. The reason for this is that the total volume of voids (or pore space) in a block can be estimated by the amount of water it can absorb. This property is clearly distinct from the ease with which water can penetrate a block and permeate through it (Neville, 1995).

Knowledge of the value of the total water absorption (TWA) of a block is important because it can be used for:

- routine quality checks on blocks (surrogate test for quality)
- comparison purposes with set standards and values for other like materials
- the classification of blocks according to required durability and structural use
- approximation of the voids content of a block (Section 6.5)

Generally, the less water a block absorbs and retains, the better is its performance likely to be (ILO, 1987). Reducing the TWA capacity of a block has often been considered as one of the ways of improving its quality. The deleterious effects of moisture on block properties were discussed in Chapter 2. A block that readily absorbs water is likely to be vulnerable to repeated swelling and shrinkage as moisture and temperature variations take place. Repeated swelling and shrinkage is likely to progressively lead to the weakening of a block fabric (either directly or indirectly). A block that contains absorbed water is often weaker with a less hard surface than when it is dry. The presence of absorbed water can also lead to the creation of conditions suitable for the resumption and acceleration of otherwise dormant chemical activity (BSI, 1950; BS 7543, 1992). The lower the water absorption capacity of a block therefore, the more likely it is to be more durable.

Test methods used

The TWA capacity of a block can usually be measured by determining the amount of water it can take in (ILO, 1987). Since the amount absorbed is influenced by the pre-existing moisture condition of a block, it is advisable that it be first dried to constant mass before further testing (BS 3921, 1985). For this particular research, attainment of constant mass was determined using an electronic weighing scale accurate to 0.01% of the sample mass. Simple immersion of the specimen without prior evacuation can lead to incomplete absorption and saturation. Moreover, the suction exerted by a dry block is usually much higher (PCA, 1970).

Various procedures can be used to determine the TWA capacity of a block (BS 3921: 1985):

- Cold immersion in water (24 to 48 hours) after oven drying to constant mass
- Boiling test method (5 hours)
- Absorption under vacuum test

With the above methods, widely differing results can still be obtained (Bungey & Millard, 1996). It is reported that none of the three methods above can show any precise convergence (BS 3921, 1985). The results obtained from each of the three methods can be different, and neither proportional nor equivalent to one another (Neville, 1995). For this thesis, oven-drying followed by cold-immersion in water was found to be the most convenient (and easy one) to conduct. The method was also found to be fairly accurate and repeatable. It was therefore the only method used throughout for determination of the TWA capacity of both traditional and improved blocks. For comparison purposes, tests were also conducted on samples of other like materials found in the laboratory (fired clay bricks and concrete blocks). Brief details of the test method are described in Appendix R. For each test however, three specimen samples of each material under test were examined (Chapter 5). The TWA was calculated by taking the amount of water absorbed by a dried sample that had been immersed in water for a specified period of time (24 to 48 hours). Mean values obtained were taken as the total water absorption (TWA) of the sample. The result was expressed as a percentage of the original dry mass of the specimen to the nearest 0.1% of the dry mass. Details of all individual measurements recorded are presented in Appendix T(1) to T(5).

6.4.1 EFFECT OF VARYING THE STABILISER CONTENT AND COMPACTION PRESSURE ON THE TWA IN BLOCKS

Both traditional and improved blocks were examined. The mean values obtained are shown in figure 12 and in table 10. The latter shows the range of the extreme values found.

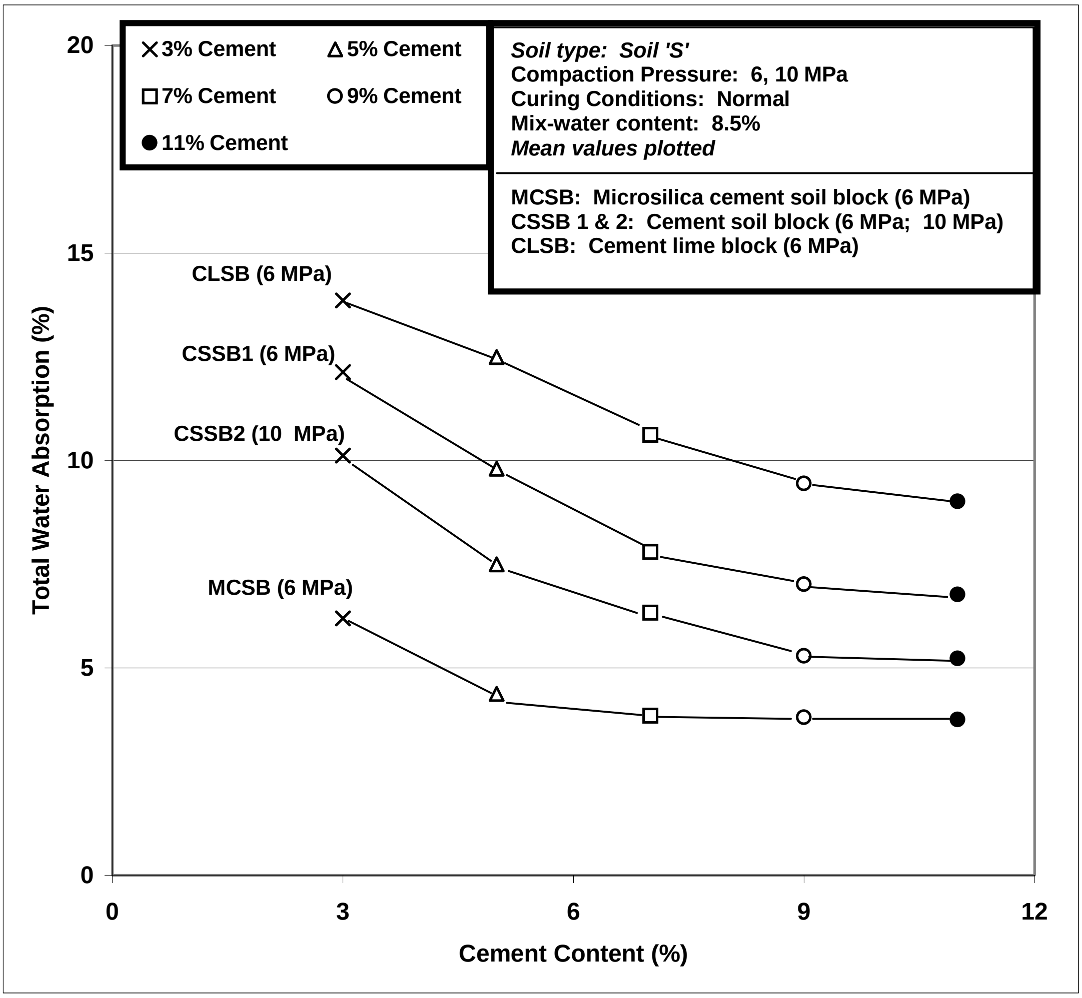

Figure 12: Effect of varying the stabiliser content and type, and compaction pressure on the TWA in CSBs. (University of Warwick, 2001)

Block Type	Compaction	Range of TWA Values		Comparison of values with those for improved blocks		Overall decrease in TWA
		OPC 3%	OPC 11%	OPC 3%	OPC 11%	
	MPa	%	%	%	%	%
Improved (OPC + microsilica)	6	6.19	3.75	-	-	40
Traditional (OPC + lime)	6	13.86	9.01	124	140	35
Traditional (OPC only)	6	12.13	6.76	96	80	44
Traditional (OPC only)	10	10.11	5.22	63	39	48

Table 10: Range of TWA values obtained

Figure 12 shows that a negative correlation exists between increase in cement content and total water absorption: coefficient of correlation values were -0.947 ($P = 0.014$) for traditional blocks, and -0.832 ($P = 0.080$) for improved blocks. From both figure 12 and table 10, improved blocks had the narrowest band of TWA results. They also absorbed considerably less water than traditional blocks. Generally, traditional blocks compacted at the same level absorbed about twice the amount of water absorbed by improved blocks.

There was a general decrease in water absorption with increase in cement content (and compaction pressure). The decrease was generally about 42% with variation in cement content from 3% to 11% (table 10). The trend was the same for all categories of blocks. Blocks of lower stabiliser contents were however found to absorb more water than those with higher ones. The reduction in absorption with increase in stabiliser content is progressive but diminishes. The absorption effectively ceases to reduce any further beyond certain cement content values in both traditional and improved blocks. These limits are 9% and 7% respectively. Beyond these limits, increase in OPC content does not result in any appreciable reduction in TWA. It is also worth noting that the limit of 9% appears to apply to all types of traditional blocks regardless of the moulding pressure used. The lowering of the limit to 7% from 9% in improved blocks can only be attributed to the inclusion of microsilica. Even beyond these points however, the block can still continue to absorb water.

The results also show that the TWA values obtained compare well with those of other like materials and with current recommended maximum values for CSBs. The recommended maximum is 15% (ILO, 1987). Although this value is neither absolute nor widely adopted by other researchers, it still serves a useful purpose. The experimental TWA values for improved blocks were on average considerably lower than this recommended value. The values obtained were favourable when compared with those of like materials (clay bricks 0 to 30%; concrete blocks 4 to 25%; calcium silicate bricks 6 to 16% (Jackson & Dhir, 1996)). According to BS 5628 Part 1, TWA values below 7% are regarded as being low, while those above 12% as high. All improved blocks tested would therefore be regarded as having low TWA values. The values for traditional blocks fall in between the two limits and would therefore be regarded as moderate.

The above results confirm that CSBs have the potential to absorb appreciable amounts of water and possibly retain it too. They also show that the use of CRMs can be a effective way of reducing water absorption. Moreover, they confirm earlier findings that improvement in the quality of a block is easily achieved by variation in stabiliser content and type. The correlation of TWA and other bulk properties are discussed in subsequent sections.

6.4.2 CORRELATION BETWEEN TOTAL WATER ABSORPTION AND DENSITY

The correlation between water absorption and dry density was examined. Figure 13 shows the plotted values from the measured points for both properties.

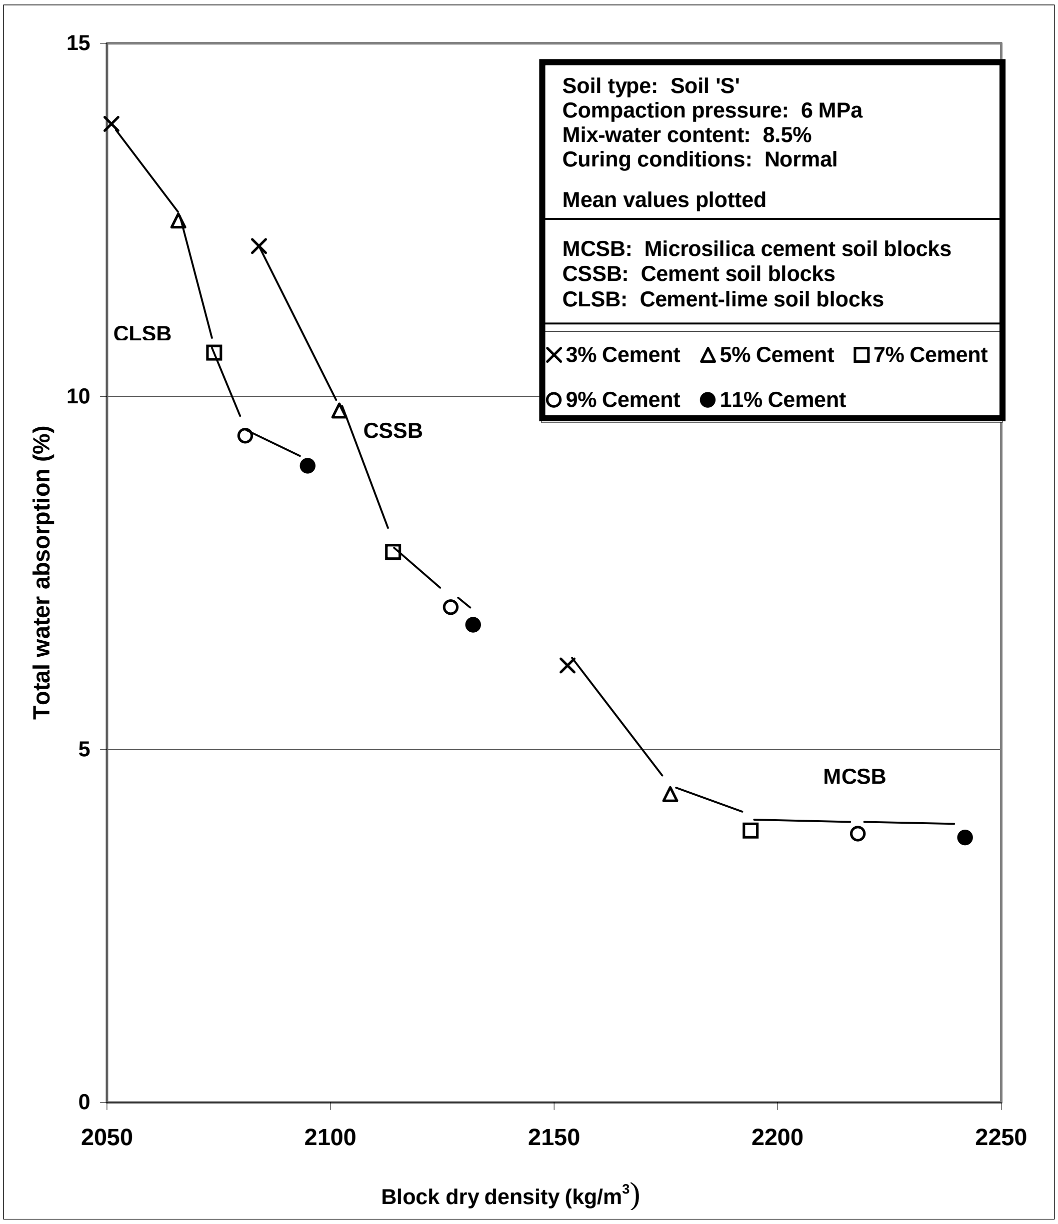

Figure 13: Correlation of TWA and BDD (University of Warwick, 2001)

As shown in figure 13, a negative correlation exists between TWA and BDD. The coefficient of correlation and P-values for both traditional and improved blocks were: -0.985 ($P = 0.002$) and –0.820 ($P = 0.089$) respectively. These values confirm that a strong negative correlation exists between the two bulk properties. Increase in the latter is likely to result in a decrease in the former. For example, in traditional OPC only stabilised blocks, increase in density from 2084 kg/m^3 to 2132 kg/m^3 (2.3% increase), resulted in an overall reduction in water absorption by 44%. Similar increase in density over the same range of cement contents in improved blocks resulted in a decrease in TWA of about 39%.

The results also show that for the samples tested, beyond a certain density value, no appreciable reduction in TWA can be found. The limiting density values correspond to matching cement contents beyond which a similar occurrence was noted in Section 6.4.1. The implication here is that no further increase in BDD would necessarily lead to continued reduction in TWA. The blocks can still be able to absorb water but at almost uniform amounts. Similar correlation was also found between WCS and TWA. Generally, the more a block was found to absorb water, the lower was its strength.

6.5 VOLUME FRACTION POROSITY

In this Section, the term porosity refers to the total amount of voids and pore structure within a block fabric (sand pores, gel pores, capillarity pores, entrapped air, entrained air, etc.) (Young, 1998). The concept of porosity has neither been well researched nor reported in CSB literature. Yet most bulk properties including strength and water absorption are believed to be a function of the total porosity of cement-based materials (Weidemann et al, 1990). The general link between porosity and quality has been widely reported in concrete literature (Neville, 1995). There is no good reason to expect that similar findings would not obtain in CSBs.

In addition to their volume, the shape and size of pores within a block can determine its bulk performance. The capillary porosity which is often the most predominant is believed to be a function of the water-cement ratio and the degree of hydration achieved (Sjostrom et al, 1996). The value of the latter can only increase as long as moisture is available to ensure the completion of hydration. Proper moist curing can therefore be a vital factor in influencing the volume fraction porosity of a block.

The total volume fraction porosity (TVP) in a CSB can be determined directly. This can be done by measuring the weight gain on saturation with water of an initially dry block after evacuation to remove air from the pore network (Jackson & Dhir, 1996). The water absorption is expressed as before in weight percent. The value of the water absorption may be converted to a volume basis porosity by using the following relationship:

$$n = \frac{(WA)\,\rho}{100\;\rho_w}$$

where n = volume fraction porosity
ρ = dry block density (kg/m^3)
ρ_w = density of water kg/m^3)
WA = water absorption (%)

A summary of the calculated total volume fraction porosity of CSB samples are shown in Appendix T. The relationship between these results and other bulk properties are discussed in the following sections.

6.5.1 *CORRELATION BETWEEN STRENGTH AND POROSITY*

The correlation between wet compressive strength and total volume porosity was examined. The mean values plotted are as shown in figure 14.

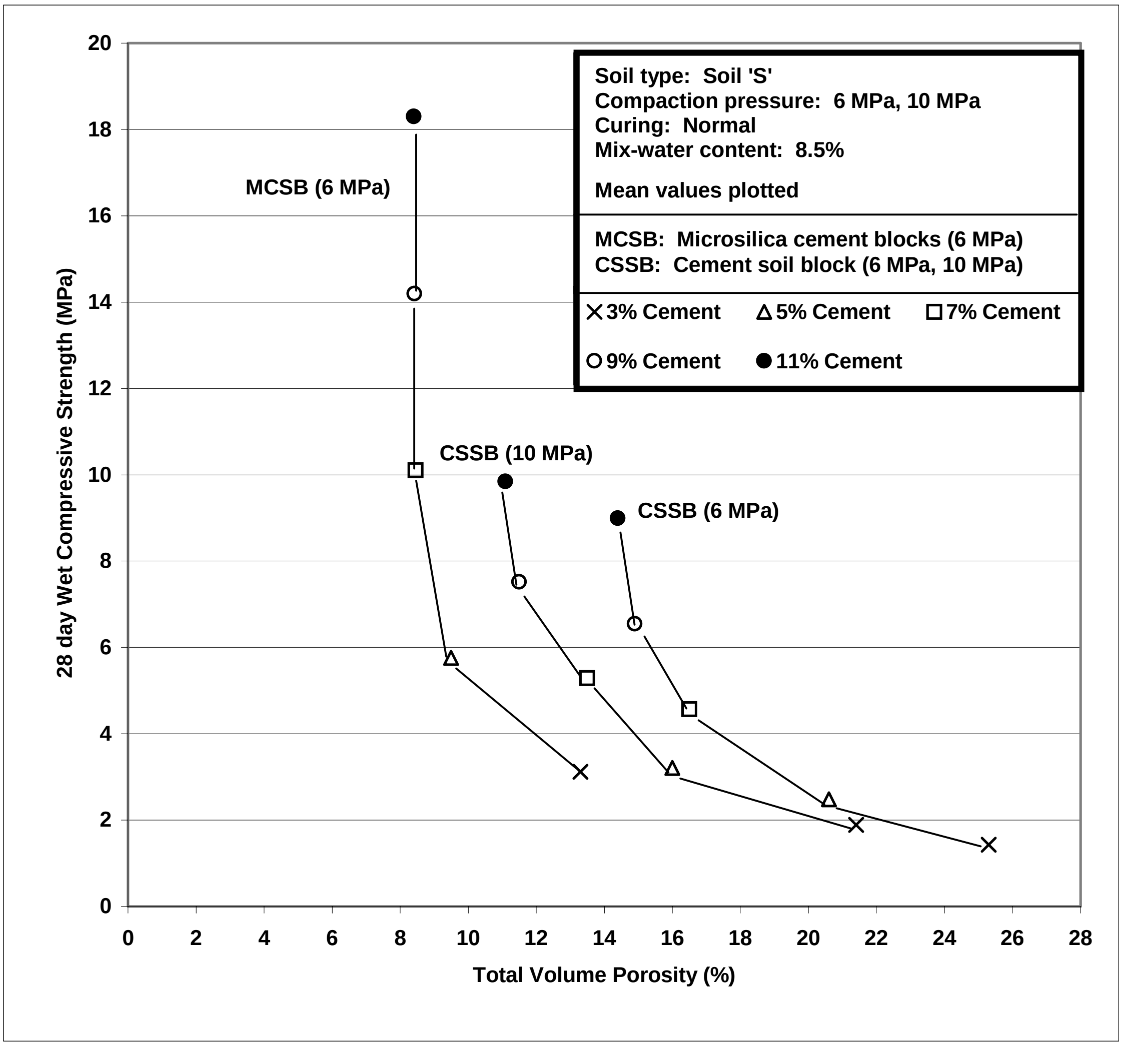

Figure 14: Correlation of WCS and TVP in CSBs (University of Warwick, 2001)

According figure 14, WCS and TVP are negatively correlated. Increase in porosity is accompanied by a decrease in strength. The coefficient of correlation and P values for traditional and improved blocks were: –0.905 (P = 0.035) and –0.771 (P = 0.127) respectively. A strong negative correlation therefore exists between the two bulk properties.

The total volume porosity values are lower in improved blocks than in their traditional counterparts (8.4% to 13.3% as compared to 14.4% to 25.3%). The pore filling effect of microsilica is likely to account for some of the difference between the two types of blocks. The lime plus OPC stabilised blocks exhibited the highest porosity (between 18.9% and 28.4%). The values for both categories of blocks however compare well with those of like materials. Materials with TVP above 30% are considered to be of high porosity (Jackson & Dhir, 1996). All the blocks examined during this research can therefore be considered to be of low porosity.

The decrease in compressive strength with increase in porosity can be partly explained as follows. The compressive strength of a block is limited by brittle fracture. It is therefore sensitive to individual flaws in the block sample under test. Discontinuities between solid phases in a block (due to the presence of voids and pore structure) constitute flaws in it. The higher the amount of voids, the weaker the block is likely to be. Large coarse soil fractions in a block can also create flaws in it. The combination of such large particles and voids in a block can make it more susceptible to brittle fracture failure.

6.5.2 CORRELATION BETWEEN DENSITY AND POROSITY

The above relationship was examined using the results obtained as before (shown plotted in figure 15).

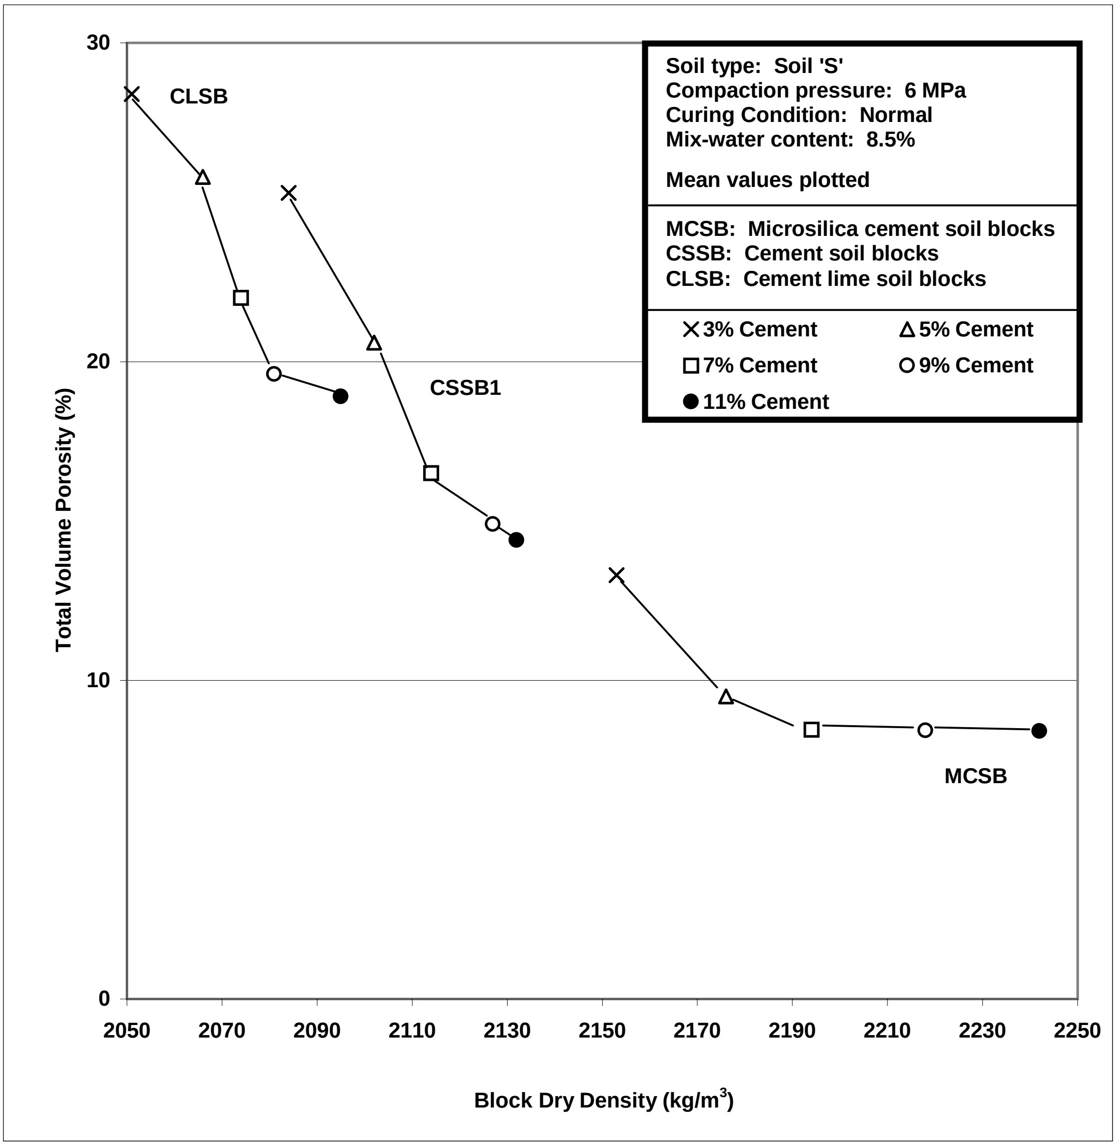

Figure 15: Correlation of BDD and TVP (University of Warwick, 2001)

Figure 15 shows the general correlation existing between the two bulk properties. The coefficient of correlation and P-values are as follows: –0.984 (P = 0.002) for traditional blocks, and –0.935 (P = 0.020) for improved blocks. These statistical values confirm that a very strong negative correlation exists between the two bulk properties. Increase in dry density is associated with a decrease in porosity for all blocks examined.

For example, in traditional cement only stabilised blocks, increase in density from 2084 kg/m^3 to 2132 kg/m^3 (3% and 11% cement contents respectively), resulted in an overall reduction in porosity of about 43%. Similar trends were shown in the improved blocks examined. Reduction in porosity by 37% was found to result from an overall increase in density of 4.1%. These blocks were generally denser than their traditional counterparts. Increased density is accompanied by closer packing of the solids in a block. The closer the packing, the less the amount of voids in a block. It was however also found that further increase in density beyond a certain value did not result in any appreciable reduction in porosity.

6.6 CONCLUSION

From the results discussed in Chapter 6, a number of conclusions can be reached.

The *wet compressive strength* of a block is one of its most valuable properties. It is influenced by the following factors: cementitious matrix (water cement ratio and degree of hydration), degree of compaction, state of moisture, temperature, age and type of coarse soil fraction present. The strength of the cement hydrates, and the bond between them and the coarse soil fraction accounts for most of the strength in CSBs.

It was found in Chapter 6 that the WCS of both traditional and improved blocks increased with increase in cement content and compaction pressure. The inclusion of microsilica in improved blocks was found to significantly improve their strength. The use of microsilica was also found to reduce the gap between the mean WCS and the DCS in blocks. The reduced gap of between 12% and 26% in IPD blocks is comparable to those obtaining in concrete products (9% to 25%). Hitherto, the same gap in CSBs was between 40% and 120%. The considerable reduction in the gap can be associated with an increase in bonding strength between the phases and particles in the block. Use of microsilica is therefore beneficial for improvement in CSB strength and by implication its durability.

It was also found that delays in compaction after wet mixing of soil and cement resulted in an appreciable reduction in the strength of a block. Delays of up to two hours resulted in loss of strength of about 41% in traditional blocks. Blocks compacted within 20 minutes of wet mixing were about 27% stronger than blocks compacted after 45 minutes of delay. Similar trends are expected to occur in improved blocks. These findings confirm earlier work by other researchers. It is therefore recommended that smaller batches of wet mixes that can be compacted within 30 minutes (instead of one hour) be planned for. Compaction of wet mixes more than 60 minutes old are not recommended.

It was also found in Chapter 6 that the WCS of a block can be affected by the method of curing used. Blocks cured under normal conditions were about twice stronger than those cured under open exposure in the laboratory. Those cured under continued moist cover were about three times stronger than exposed blocks. Moreover, blocks cured by full immersion in water (100% relative humidity) were about six fold stronger than those cured exposed. Improved curing conditions were found to be linked to higher strengths in CSBs. This can be partly due to the higher degree of hydration achieved by the OPC in the block (continued presence of moisture). Proper curing conditions are therefore critical if CSBs are to achieve high strength. It is recommended that proper curing guidelines be included in CSB production codes.

The *density* of a block is another valuable indicator of its bulk quality. Its value depends on the degree of compaction used, the form of the block, and the size, grading and density of its individual constituent materials. The higher the density of a block, the better is its overall performance expected to be. It was generally found that traditional blocks were less dense that their improved counterparts. Increase in cement content resulted into increase in density for both categories of blocks by about 3%. Increase in density due to increase in compaction pressure of about 70% only resulted in an increase in density of about 1.2%. The use of CRMs, and increase in cement content appear to be more economic ways of achieving higher densities in CSBs. The experimental density values obtained were also found to be above the recommended minimum of 2000 kg/m^3 (by about 9%). The pore filling effect, increased homogeneity, improved bonding and reduced voids due to the use of CRM was thought to be responsible for the marked increase in density of improved blocks.

The BDD was also found to be strongly correlated to other properties such as WCS, TWA and TVP. Generally, more denser blocks were found to perform better in all the complimentary tests done. Blocks which are too dense might however prove difficult to lay, and costly to transport. It is recommended that the maximum weight of a block should not exceed about 8,500 kg.

The *total water absorption* in CSBs is also an important bulk property that can be used for routine quality checks as well as for their classification. It was found that the TWA of traditional blocks ranged between 6.76% and 12.13%. Comparable figures for improved blocks were considerably lower than these values. The use of CRMs therefore results into a marked reduction in TWA. It was also found that the TWA decreases with increase in cement content and compaction pressure. However, the decrease is gradual and more pronounced at the lower cement contents than at the higher ones. Beyond a certain cement content however (7% in improved blocks and 9% in traditional blocks), increase in cement content did not result into any further appreciable decrease in TWA. All blocks made for experimental tests in the course of this thesis were found to have TWA values below the recommended maximum value of 15%. It was also found that TWA was strongly correlated with BDD, WCS and TVP.

The *total volume porosity* of a block also represents an important bulk property. It was found that porosity of block samples decreases with increase in cement content. Porosity values for traditional blocks ranged between 14.4% and 28.8%, while those for improved blocks between 8.4% and 13.3%. It was found that traditional blocks were generally more porous than their improved counterparts. Porosity was also found to be negatively correlated to strength and density, but positively correlated to water absorption. High porosity in a block is thought to reduce strength due to the presence of flaws and discontinuities in its fabric. All blocks made were found to be of low porosity, i.e. less than 30%.

From the preceding conclusions, the objectives of Chapter 6 were fully met.

CHAPTER 7

SURFACE FEATURES AND PERFORMANCE

7.1 INTRODUCTION

The surface of any building material is one of its most important features. For materials such as CSBs, the quality of their surfaces can affect their durability (Hughes, 1983). The block surface forms its first line of defence against deterioration agents likely to come into contact with the material during its service lifetime. As mentioned earlier in the thesis, the bulk of a block is its least compacted zone and is therefore in need of protection provided by a denser surface.

The deterioration mechanisms that can erode the surface of a block and expose its bulk are likely to lead to accelerated damage (Chapter 3 and 4). A good surface is therefore required if a block is to remain durable for the duration of its service lifetime. How a block surface can influence its performance depends on its surface properties. Properties thought to be affected by the quality of the outer part of a block include: surface wetting, adsorption, adhesion, abrasion, hardness and capillary effects (Young et al, 1998).

The objectives of this Chapter are to:

- identify microstructural features of block surfaces
- monitor the overall performance of the surface in conditions which simulate the main cause of surface deterioration. It was mentioned in Chapter 2 and

found in Chapter 4, that surface erosion was the most serious form of surface deterioration. The softening and abrasive action of water and the heating effects of high temperatures, are thought to combine to contribute to much of the mass loss from the surface of a block. The test method used in this Chapter is the Slake Durability Test. Its pioneering use for CSBs was found to be appropriate for laboratory testing owing to the rapid acceleration of surface erosion (ISRM, 1971).

The rest of this Chapter is presented in three sections, namely: thin-section microstructural features of block surfaces, monitoring the performance of block surfaces using the slake durability test, and conclusion.

7.2 THIN SECTION MICROSTRUCTURAL FEATURES OF CSB SURFACES

The performance of a block is closely linked to its microstructure (Houben & Guillaud, 1994). Awareness of such links has led to several recent advances being made in concrete research (Baker et al, 1991; Taylor, 1998). It was with this in mind that a similar approach was adopted for this research. After all, the two materials both develop their microstructure by solidification from solution formed as the cement particles in either material dissolve in water (Young et al, 1998). In concrete studies it has been found that the resulting microstructure controls most of its key properties, especially those associated with its durability, and it would be reasonable to expect that a similar happening would occur in CSBs.

Investigation method used

The scope of microstructural investigations were limited to the identification and description of the main surface features of blocks. Although other petrographic methods exist, two microscopic methods were considered, namely: examination of a prepared block surface specimen using reflected light and examination using light transmitted through a 'thin section' (Brandon & Kaplan 1999). The latter method was selected for use in this research. Its advantage is that it is also widely used in concrete research to identify mix components, defects types and even causes of defects (Taylor, 1998). To the knowledge of the author, this represents the first published petrological study of CSB like materials..

The CSB samples for microscopic examination were prepared as described earlier in Chapter 5. Several six month old samples, some made using 5% cement and the other using 9% cement plus 2.25% microsilica, were examined. The blocks were compacted at 6MPa and cured under normal conditions (wet followed by laboratory dry curing). Samples of dimensions 100 x 90 x 40 mm were thin-sectioned. Slices of these samples (and others not described here) were cut using diamond saws preceded by vacuum resin impregnation. The slices were then dried and again impregnated using low viscosity epoxy resins. The samples were then ground using standard petrographic procedures to a 30 μm thickness. Oil lubrication was used to avoid the dissolution of water soluble materials in the block. The thin-surface sections were then examined with a petrographic microscope. The examination was done under both plain polarised light and cross-polar light. Micrographs of the thin sections were then produced for analysis and interpretation. Appendix U shows the three sets of micrographs discussed in this thesis. Additional comments are also shown on the same Appendix.

Interpretation of the Results

The interpretation of micrographs remains a highly specialised field. What is described in this Section are key features discernible even by the casual observer. The main object was to identify the following phases and defects:

- general features
- calcium hydroxide (portlandite)
- unreacted cement residues
- cement hydrate phases
- free sand, silt and clay residues
- gross porosity
- microdefects
- possible causal links to surface properties

In terms of general features, the micrographs in Appendix U reveal the existence of an amorphous particulate composite structure of predominantly short range order. As would be expected, the spatial pattern seen throughout is not rotationally repeated symmetrically over the long range (like in concrete). The precipitates look like a collection of individual particles and phases that are fairly well agglomerated. Given the low amount of cement used (5%), it was not expected to find a continuous interlocking phase of OPC hydrates and embedded sand particles. However, such a continuity has been reported in fired bricks mainly due to the resulting mulite structure, and partly explains the marked difference in performance between such bricks and other comparable materials (Jackson & Dhir, 1996). Continuity is known to confer marked improvement in the properties of bricks. By using microsilica in improved blocks, an attempt was made to improve packing and continuity in the block microstructure. Although this does not come out quite clearly in the micrographs (only 2.25% by weight used), evidence from other tests suggest that considerable improvement in performance was achieved (Chapter 6 and Section 7.3 that follows). Nevertheless, the groundmass was far more detailed than in an OPC mortar.

CSBs contain more varied particles and phases than concrete. Distinguishable features observed in the micrographs were: fine gravel, sandy fraction, clay agglomerations, and cement hydrates phases (Appendix U(1) and U(2)). The amorphous but homogenous areas seen in the micrograph resemble C-S-H gels. However, with so little (5%) OPC present, one would indeed be hard pushed to find any technique that could detect the individual cement hydrate products. The micrographs also reveal evidence of portlandite in the sample (Appendix U(3)). Fewer than expected platelets of portlandite, characteristic of hydrated cement paste were present. Appendix U(3) shows a relatively large portlandite crystal, approximately 30μm across, embedded in the matrix. Modification of CBSs using microsilica is therefore justifiable to encourage pozzolanicity.

Normally, it should have been easy to detect unhydrated cement residues. These were however conspicuous by their absence. Despite this surprising finding, conglomerations of unreacted cement-like collections were evident during processing even though the block materials had undergone careful mechanical damp mixing. Similar collections were also observed on new surfaces of blocks that had been subjected to the slake durability test (Section 7.3).

Microdefects which should normally have been detectable at the cement hydrate and sand interface zone were not discernible in the micrographs. Instead, the micrographs show that the cement hydrates and coarse soil fractions are satisfactorily intertwined. Gross porosity was lower than expected, suggesting good compaction. It is unlikely that CSB surfaces obtained from field production sites would have had similar quality finish (Chapter 4). Instead, inclusions, cracks, point defects and production defects would have been more prominent. Overall the findings are encouraging as they indicate no fundamental defects in the material.

From the above findings it can be expected that the microstructure of a block can mediate some of its properties. Block properties likely to be sensitive to the nature of their microstructure can be referred to as being 'structure sensitive'. They are structure sensitive because of their dependence on gross porosity, grain size and level of bonding of the composite structure. Properties such as strength, dimensional stability, water absorption, permeability and durability are likely to be structure-sensitive (Young et al, 1998). Future research should be able to reveal causal links between a particular microstructural feature and a particular block property. Conversely, block properties such as thermal expansion, elastic moduli, specific gravity, etc., are likely to be structure-insensitive. This is because such properties vary only slowly with structural composition, particle sizes and microstructural variations.

The desirable qualities at the surface of a block are impermeability, non-reactivity and high-intergranular strength. These features are likely to be linked to the microstructure of the block surface, which is in turn determined by the processing methods used. By reducing voids in the fabric (microstructure) for example, pores can be reduced. By improving bonding (microsilica, high degree of hydration), contact can be improved. Such procedures could result in considerable surface resistance being offered by the block. An attempt to achieve such a surface is investigated experimentally in the next Section.

7.3 MONITORING THE PERFORMANCE OF CSB SURFACES USING THE SLAKE DURABILITY TEST

In this Section, the need for a new accelerated surface test for CSBs and the main features of the proposed test are discussed. The proposed test is the slake durability test (SDT) which was originally developed for evaluating the resistance of clay-bearing rocks to slaking, abrasion and heating (Eigenbrod, 1969; Chandra, 1970; Franklin et al, 1971; Gamble, 1971; ISRM, 1971; Franklin et al, 1971; Goodman, 1980). In the subsequent sections that follow (Section 7.3.1 to 7.3.5), the results of the application of the test to block samples made as described in Chapter 5 are presented.

Need for a new accelerated surface test for CSBs

Surface erosion has been identified as a major problem for CSBs (Chapter 2 and 4). Yet it has always been difficult to monitor the performance of CSB surfaces when they are subjected to wetting and the abrasive action of water (Ola & Mbata, 1990). Selection of experimental methods to evaluate the integrity of cured block surfaces have proved difficult in the past (Webb, 1988; Gooding, 1994). Of the current surface monitoring test methods documented (drip test, water spray test, brushing test, abrasion test, wet-and-dry cycling test, etc.), none has been without criticism (Houben & Guillaud, 1994). Further, none has gained universal acceptance and application. Current tests have been found to be simplistic, misleading, of no relevance to the main mode of surface erosion, or over-dependant on the competence of the operator. These tests have failed to be predictive enough, with the unfortunate result that substandard blocks were passed. Moreover, after the full curing period is reached, the tests become largely inappropriate. A method of test is required that can monitor the performance of a block irrespective of its pre-cured and post-cured age. An accelerated durability test that can be conducted from a few weeks of production to several weeks or years after production would be quite helpful (Baker et al, 1991).

CSBs like most other building materials are characterised by a wide variation in their surface and bulk properties. The most important surface property of a block is its ability to resist short and long-term deterioration due to wetting, abrasion and drying (Chapter 2). For example it was found in Chapter 4 that CSB surfaces that were satisfactorily protected survived the deleterious effects of rains, humidity and high temperatures. Where similar surfaces were left unprotected in similar conditions, premature defects in the form of surface roughening, pitting, cracking and erosion were found to occur. The defects were more excessive than those observed on the surfaces of comparable materials used under similar conditions. It was further found that the clearly distinguishable surface defects had negatively influenced the attitudes of many users (Chapter 4). CSBs were therefore regarded as being sub-grade and of lower durability than comparable materials.

Under normal conditions, a durable block would be required for walling for the service lifetime of a building. While some surface deterioration might be expected, the deterioration should not be so excessive that the functional requirements of the wall are adversely affected (normal load bearing, resistance to weathering, etc.). Where such phenomenon are expected, the block surface ought to be protected. Surface protection is unfortunately considered to be expensive since more costs are incurred. The erosion of block surfaces should therefore be more accurately and reliably forecasted early enough. This can only be done by using more appropriate and suitable accelerated tests than was hitherto possible. The key specification is that the required test should simulate more accurately the main mechanism of surface erosion as identified in Chapter 2 and Chapter 4. Such a test would be an invaluable asset for site and laboratory use. The author describes in this thesis one such pioneering test which was successfully used to monitor the surface performance of block samples made as described in Chapter 5. The surface monitoring test described is the slake durability test (SDT). Since both clay-bearing rocks and CSBs contain clay and rocky residues (sand, silt, fine gravel), use of the test for the latter was found to be quite appropriate. As will be discussed in subsequent Sections, use of the test was further extended to evaluate the performance of like materials such as fired bricks, concrete blocks and rock samples.

The Slake Durability Test

In this subsection, the main features of the test, the factors likely to influence the results, merits of the test and classification systems for evaluating the test results are discussed.

The *main features* of the SDT are briefly described here (full details are provided in Appendix V). The main test equipment used consists of a standard cylindrical drum 140 mm in diameter and 100 mm long (ISRM, 1971). The drum frame is enclosed by a standard 2 mm aperture sieve mesh which forms its wall. Four to five oven-dried prism block samples (about 30 x 30 x 30 mm) with a combined total weight of between 450 and 550 grams, are loaded into the drum. The drum is closed and the whole system rotated using an electrically operated motor at 20 revolutions per minute. The rotation is continued for 10 minutes through a bath filled to an assigned mark with ordinary tap water at 20°C. In the apparatus used, four drums all attached to the same motor were rotated simultaneously. Due to internal contact between the samples within the block, mixing and softening in water, attrition and abrasion from the mesh sieve walls, the surfaces of the block samples are continuously eroded. After 10 minutes of the generally slow rotation, the eroded block sample materials can be seen partly suspended in water, and partly settled at the bottom of each bath. The state of the slaking water, owing to the presence of suspended material, is clearly distinguishable by the amount and degree of discoloration observed. The partially eroded block samples are then removed from the drum, then re-weighed. The drying, wetting, abrasion and redrying cycles attempts to simulate the most severe environmental conditions that a block sample can be expected to endure in real service life.

The slake durability index is then defined as the percentage ratio of final to initial dry mass of the block samples (ISRM, 1971). The SDI for each sample to the nearest 0.1% was calculated using the formula:

$$SDI = \frac{M_f \times 100}{M_i}$$

where: SDI or (I_d) = slake durability index (%)
M_f = final mass (g)
M_i = initial mass (g)

The SDI value can be used to assess the degree of resistance offered by each block surface. Samples of traditional and improved blocks, concrete blocks, fired bricks and various rock samples were all tested in the same manner. Comprehensive results for all samples tested are shown in Appendix W(1) to W(7). The results are discussed in Sections 7.3.1 to 7.3.5.

The *factors considered likely to influence the results* were noted as: the equipment; sample dimensions; sample pre-treatment; duration of slaking; and chemistry of the slaking fluid. These are briefly discussed below.

- The *equipment or apparatus* used was the standard one. Its sieve mesh size (2 mm), drum size (140 x 100 mm) and speed of rotation (20 revolutions per minute) remained the same for all categories of blocks and other materials tested. If any of these had been varied, then comparison of the results would have been misleading.
- The *sample dimensions* selected were such that they would be approximately the same for all samples tested. The sample dimensions used were about 30 x 30 x 30 mm with a combined weight of between 450g and 550g. About four to five pieces of the same material were placed in the drum each time.
- *Sample pre-treatment* was kept uniform for all samples. They were all pre-oven dried, cooled under cover, and stored under cover. A similar procedure was followed after each test. In this way, a controlled and reproducible condition of moisture was ensured for all categories of samples tested. In a way, this could be equated to the intense drying of a block by the sun in the humid tropics. Drying has been though to accelerate the suction rate of blocks (Jackson & Dhir, 1996). In this test therefore, the very worst scenario has been applied to block samples since drying accentuates the deterioration process. Since SDI is based on the comparison of weights, before and after the test, oven drying was found to be essential for accuracy and repeatability. No similar durability test has been able to achieve this level of reproducibility (variance 0.118). Clearly, comparison of dry weights is more meaningful than comparison of wet weights. The latter would give varying inaccuracies since there is no known way of controlling initial and final water contents in the samples. Moreover, by drying, the moisture history of a block sample can be rendered useless so that previous storage conditions do not become an issue.

All samples can then be reduced to nearly the same level of zero moisture content at the start and finish of the test regime. Weighing of all cooled oven-dried samples were done using an electronic weighing scale with a display.

- *Duration of slaking* was maintained for all samples at 10 minutes (± 1%) without exception. A stop clock was used in addition to an electronic wrist alarm watch. The duration used is also the standard recommended period. If shorter durations had been opted for, the potential for errors was likely to be high. It would have for example been difficult to discriminate between any two highly durable blocks within a much shorter time. Even in actual service conditions, deterioration requires a period of initiation, followed by progression. Errors associated with timing of the test would have also contributed to poor results. Longer durations on the other hand, would have caused weaker or less durable blocks to show a 100% mass loss (or zero durability). This would have defeated the primary purpose for the test which was simply comparative and predictive.
- *Chemistry and nature* of the slaking fluid were also considered. It was found that use of distilled water and Coventry laboratory tap water at 20°C did not produce significantly dissimilar results. The use of cold tap water was therefore adopted for all test samples. Use of fluids other than water would most likely affect the results. Since it is the effects of rainwater that were being simulated, it was found not to be necessary to pursue this factor any further.

All the above factors were kept the same for all samples tested. These specifications are recommended for future similar tests.

The *merits* of using the SDT are associated with its extreme severity on the one hand,

and its simplicity on the other. The slake durability test aims at accelerating weathering to a maximum by combining the processes of slaking, abrasion and drying. During the test, as block surfaces are eroded, the new surfaces which emerge are exposed to further similar treatment. The test can therefore be said to be a very severe accelerated surface test. The more severe the test, the better even if such a test might appear to exceed the worst possible weathering conditions which a block is likely to get exposed to in actual practice. The SDT is likely to give a reasonable indication of future service behaviour of a block over time. The test measures within a much shorter time the durability behaviour of a block sample by attempting to reproduce outdoor conditions. This enables the durability of a block to be assessed within a much shorter time than would have been possible under actual conditions of use. Some short term significance can be derived from the ensuing results.

The SDT was also adopted as the main surface test due to its other several attractions over existing methods (rain erosion test, abrasion test, wet and dry cycling test, brushing test, etc.). In any case all these current tests, as mentioned earlier, still remain non-standardised and fragmented. The strong points in favour of the SDT over other durability evaluation methods can be summarised as follows:

- Simplicity
- Controllability
- Reproducibility
- Accuracy
- Reliability
- High speed and practicality
- Timeless capacity (blocks of any age)

Moreover, the SDT was found to be capable of causing significant mass loss from block surfaces of any age. All other current test methods are valid only for blocks of a certain pre-cured age. Through the SDT it was also possible to deduce the degree of alterability of a block surface. This was found to be linked to a quantitative index. As an index test, the method was found to be helpful in comparing not only one block with another, but also CSBs with other like materials. A test similar to this was not available in the past for use with CSBs. While the SDT test might not yet be able predict the rate of surface deterioration, it is nevertheless more indicative than other existing methods. In any case, the prediction of the rate of surface deterioration has to take into account all factors other than slaking, abrasion and drying that the test attempts to simulate. Further, as an index test, the SDT represents a compromise between simplicity and precision (Gamble, 1971). Most current durability tests are so complicated and delinked from the main surface deterioration mechanism that the interpretation of results is difficult. For each mechanism or group of similar mechanisms, other durability tests should be devised. Use of the test to compare the performance of traditional and improved blocks are discussed in subsequent Sections of this Chapter. It is recommended at the end of the this Chapter that a modified hand operated version of the SDT apparatus be devised for field use.

The *classification and grading* of SDT results is based on existing standards for rocks. In the present classification system, six classes of durability are provided for. These, together with the proposed recommended classes and grades for CSBs, are shown in table 11. Unequal subdivisions have been used. This might be more useful particularly for the more durable blocks. Most well made blocks might have 'extremely high' SDI (i.e. they slake to a negligible extent). In such cases, smaller subdivisions are more helpful in reflecting the slight differences in resistance to breakdown.

S/N	Author (Year)				Proposed Classification for CSBs		
	Gamble (1971)		Franklin & Chandra (1972)				
	Classification	SDI(%)	Classification	SDI(%)	Classification	SDI(%)	Grade
1	Very high durability	> 99	Extremely high	95-100	Extremely high	95-100	A
2	High durability	98-99	Very high	90-95	Very high	90-94	B
3	Medium high durability	95-98	High	75-90	High	75-89	C
4	Medium durability	85-95	Medium	50-75	Medium	50-74	D
5	Low durability	60-85	Low	25-50	Low	25-49	E
6	Very low durability	60 <	Very low	0-25	Very low	0-24	F

Table 11: Current classification systems for slake durability index in clay-bearing rocks and proposed standards for CSBs
(Adapted from Gamble, 1971; Franklin & Chandra, 1972)

The test results for all samples tested are shown in Appendix W(1) to W(7). The results when compared to the range of classes shown in table 11 represent a valuable indication of their resistance to surface erosion. Blocks giving low durability index should be investigated further to determine whether adequate processing safeguards were followed. The test results can be used in several ways:

- as an aid to block classification
- for selection of blocks for particular applications
- for quality control during production
- for prediction of the surface performance of a block

- for selecting suitable production equipment

The SDT therefore offers a new possible quantitative method of discriminating between various types of blocks. The proposed boundaries shown in table 11 are tentative and can be reviewed on the basis of results from future research or from those based on service record and experience. The use of the SDT is likely to ensure that block durability is no longer neglected in favour of other properties such as strength, whose values can be determined quantitatively (Lunt, 1980; ILO, 1987; Rigassi, 1995).

7.3.1 Effect of Varying the Stabiliser Type on the Slake Durability Index of CSBs

The effect of varying the cement content on the slake durability index of CSBs were investigated experimentally. All CSB samples were prepared in accordance with the descriptions given in Chapter 5. The mean values of the test results for blocks compacted at 6 MPa are shown in figure 16.

The mean values used for plotting the graph shown in figure 16 are tabulated for comparison purposes and for durability classification (table 12).

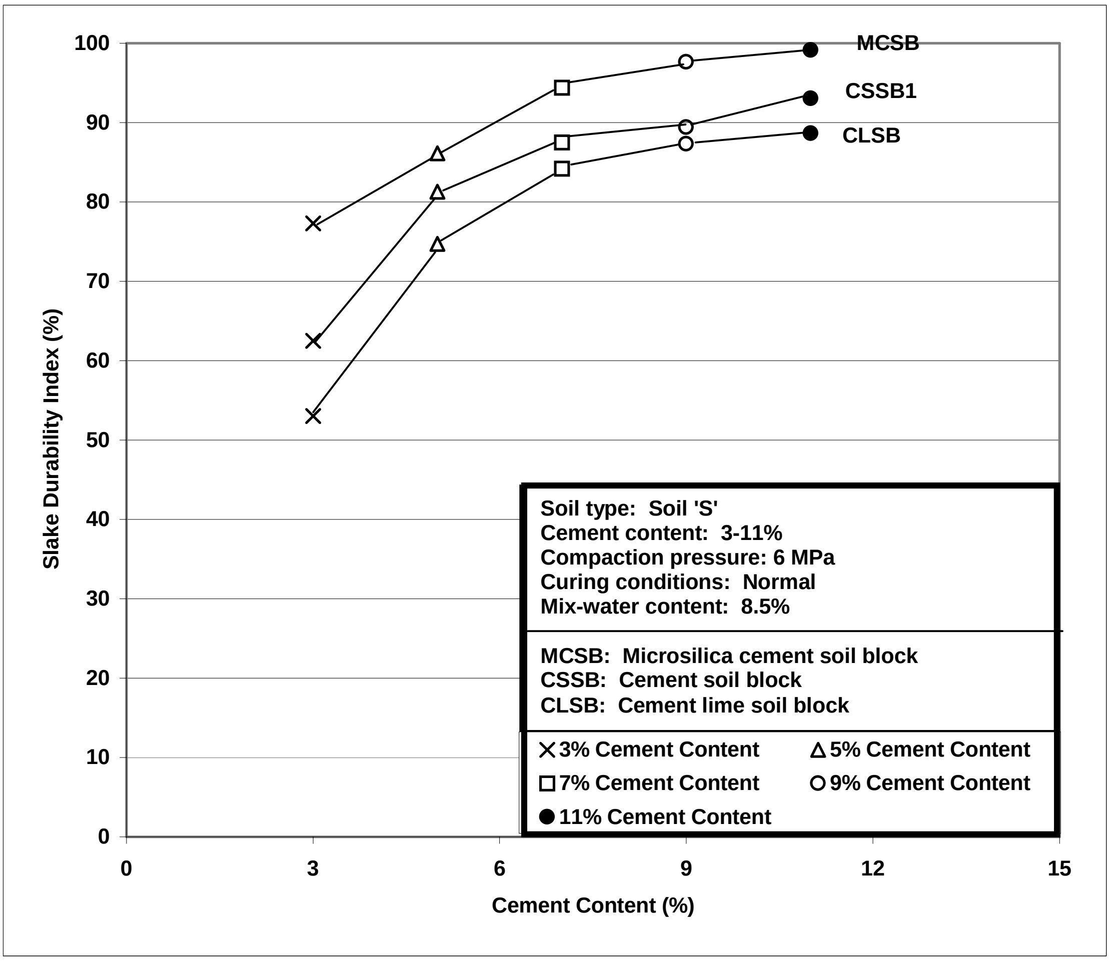

Figure 16: Effect of varying the cement content on the SDI values of improved and traditional blocks (University of Warwick, 2001)

SN	Material	cc (%)	Mass Loss (%)	SDI (%)	Durability Classification		
					Existing (Franklin & Chandra, 1972)	Proposed	Grading
1	MCSB	11	0.9	99.1	Extremely high	Extremely high	A
2	MCSB	9	2.4	97.6	Extremely high	Extremely high	A
3	MSCS	7	5.6	94.4	Very high	Very high	B
4	MCSB	5	13.9	86.1	High	High	C
5	MCSB	3	22.7	77.3	High	High	C
6	CSSB	11	7.0	93.0	Very high	Very high	B
7	CSSB	9	10.6	89.4	High	High	C
8	CSSB	7	12.5	87.5	High	High	C
9	CSSB	5	18.7	81.3	High	High	C
10	CSSB	3	37.5	62.5	High	High	D
11	CLSB	11	11.4	88.6	High	High	C
12	CLSB	9	12.7	87.3	High	High	C
13	CLSB	7	15.8	84.2	High	High	C
14	CLSB	5	25.3	74.7	Medium	Medium	D
15	CLSB	3	47.0	53.0	Medium	Medium	D
16	FBS	-	0.2	99.8	Extremely high	Extremely high	A
17	RBS	-	1.7	98.3	Extremely high	Extremely high	A
18	CBS	12-18	3.4	96.6	Extremely high	Extremely high	A

Table 12: SDI results for various samples tested and their durability classifications (University of Warwick, 2001). Abbreviations as before.

The results confirm that mass losses occur in CSBs when they are subjected to continued wetting, abrasion and drying. It was found that loss in mass in traditional blocks were higher than those in improved blocks. Table 12 shows the SDI values of the various materials tested and the range of values obtained. As can be seen, improved blocks with 7% and more cement content performed almost as well as FBS, RBS and CBS (all grade A). At the 9% cement level and above, improved blocks performed better than concrete blocks. During the test, it was found that one of the three test results from both fired brick samples and improved block with 11% cement content achieved 100% SDI values (Appendix W(1) – (7)).

According to the tentative classification system shown in Table 12, traditional blocks with cement content 5% and above can be regarded as having high durability (grade C and better). Improved blocks of similar cement content can be regarded as having high durability, although the SDI value was tending towards the very high durability classification levels. Even the 3% cement content improved blocks were found to be of high durability (grade C). This SDI surface test has been successful in grading blocks according to their degree of resistance to weakening. The findings clearly confirm that the test can be used for classification of blocks, irrespective of their storage and production history.

The graph in Figure 16 also shows that a strong correlation exists between increase in cement content and the slake durability index of blocks. For all block samples tested, it was found that increase in SDI due to increase in cement content was more pronounced at the lower stabiliser content levels than at higher ones. For example, in the traditional (OPC only) blocks, increase in cement content from 3% to 7% was accompanied by a matching increase in SDI of about 40%. Further increase in cement content from 7% to 11% resulted into a lower increase in SDI of about 6%. A similar trend was found with improved blocks where the corresponding increases over the same ranges of cement contents were 22% and 4.9% respectively. In both cases a further increase in cement content beyond the 7% level did not result in any appreciable increase in SDI.

The test results also show that most improved blocks were comparable to rocks. Rocks are known to be almost impermeable and are of high inter-granular strength. The fact that improved blocks were found to be comparable to rocks confirms that the use of microsilica can considerably improve bonding in blocks. The loss in mass as evidenced in all blocks implies that under certain environmental conditions, surface protection measures should be considered. As mentioned earlier, this could take the form of external render, low-roof overhangs, skirting plaster, thin-surface coating and thin-surface enriched layering of blocks. Where enriched surface layering is considered, costs could be saved by either using interlocking blocks, frog-bedded blocks, or hollow blocks.

7.3.2 EVOLUTION OF DURABILITY WITH CURING AGE

The SDT was also used to monitor the development of surface resistance with curing age in CSBs. The samples tested were all stabilised with 5% cement and compacted at 6 MPa. They were tested at 7, 14, 21, 28 and 56 days. The mean values of the results obtained are shown in Figure 17.

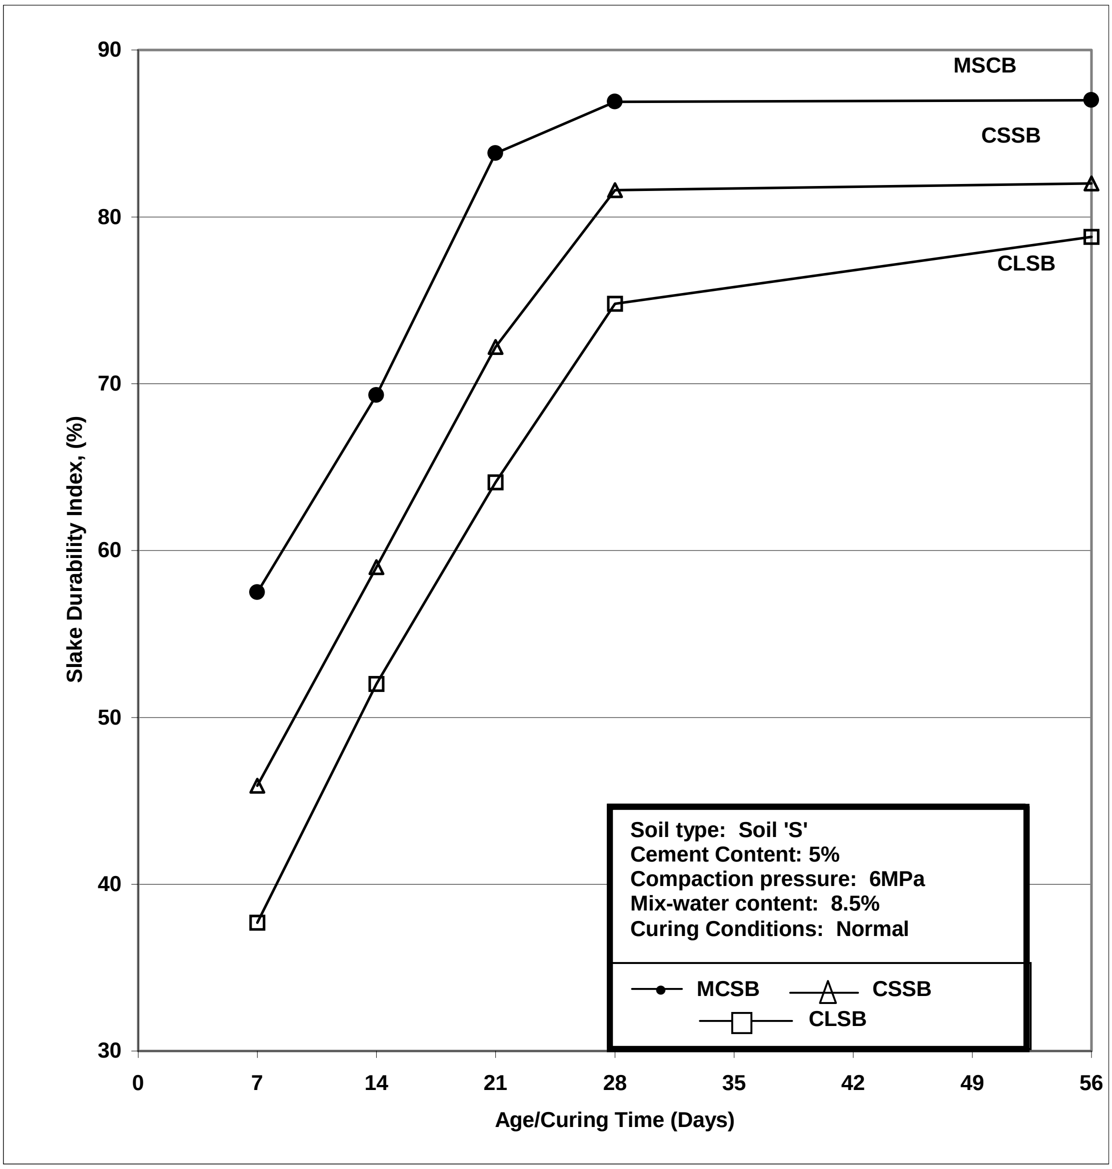

Figure 17: Evolution of SDI with curing age in traditional and improved blocks. (University of Warwick, 2001)

As expected, the results in figure 17 show that for both categories of blocks, increase in curing age is accompanied by an increase in the SDI value of a block. The increase in all cases is more pronounced before the 28th day after production than later. Except for blocks stabilised with both cement and lime, the increase in SDI value after 28 days was not appreciable. Table 13 shows a summary of the values obtained.

Age/Time	Slake Durability Index					
days	%					
	MCSB	R	CSSB	R	CLSB	R
7	57.5	1.0	45.9	1.0	39.7	1.0
14	69.3	1.2	59.0	1.3	52.0	1.3
21	83.8	1.4	72.2	1.6	64.1	1.6
28	86.9	1.5	81.6	1.8	74.8	1.9
56	87.0	1.5	82.0	1.8	78.8	2.0

Key: R = ratio (Age (SDI/7 days value)

Table 13: SDI values for various CSBs at different curing periods (all 5% cc, compacted at 6MPa).

The SDI values at 28 days for traditional blocks were about 1.8 times those at 7 days. The comparable ratio for improved blocks was only 1.5. Improved blocks were found to have gained strength more rapidly than traditional counterparts. Other ratios are also shown in table 13. These results show that SDI can also be used as a quick predictive test for gain in strength over time during curing. This can be a very useful surrogate test to identify quality problems in blocks at a very early age after production. To the knowledge of the author, this is the first published finding of such results.

7.3.3 *CORRELATION OF SLAKE DURABILITY INDEX AND WET COMPRESSIVE STRENGTH IN CSBs*

The above relationship was investigated from the results discussed earlier (Chapter 6). The mean values for SDI and WCS are shown in Figure 18.

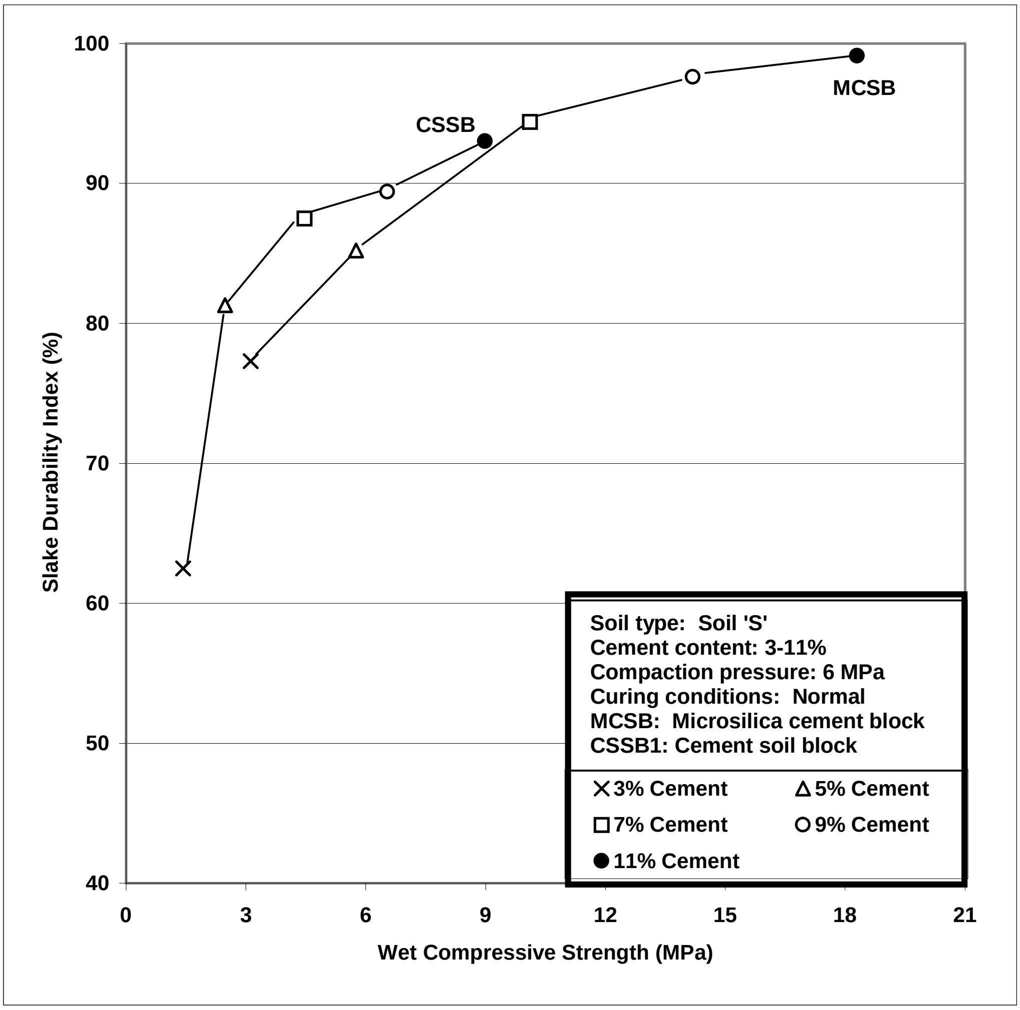

Figure 18: Correlation of slake durability index and wet compressive strength in CSBs (University of Warwick)

The graph in figure 18 shows a general positive correlation existing between SDI and WCS in both categories of blocks. The correlation coefficient for traditional blocks is

0.846 (with a two tailed significance of 0.71). The equivalent correlation coefficient for improved blocks is 0.938 (significant at the 0.05 level (2-tailed)). These non-parametric correlation coefficient values are all above 0.5 and approaching 1. They confirm that a very strong correlation exists between SDI and WCS (28-day) in stabilised blocks. The correlation is stronger in improved blocks than in traditional ones. If all points were to lie on the same curve, then WCS and SDI are surrogates for each other. The correlation is likely to remain valid only for homogenous blocks and not (for example) surface enhanced blocks. The SDT is a better test since it is more related to the surface resistance of a block, and is much easier to perform than the WCS test.

7.3.4 *Correlation of Slake Durability Index and Total Water Absorption*

The association between SDI and TWA in both categories of blocks were examined. The mean values are shown plotted in figure 19.

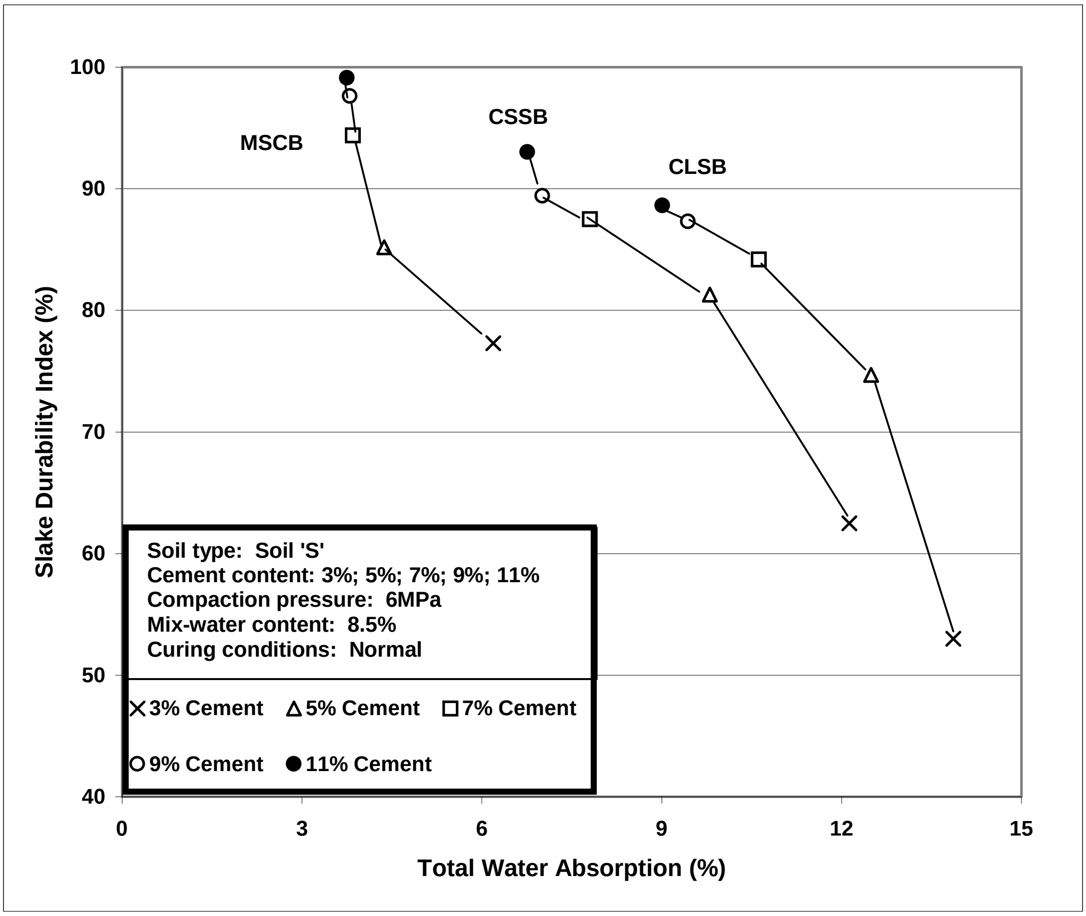

Figure 19: Correlation of Total Water Absorption and Slake Durability Index in CSBs (University of Warwick, 2001)

The results in figure 19 show that a general negative correlation exists between SDI and TWA in the blocks tested. The correlation coefficient for traditional blocks is -0.975 (with a two-tailed significance of 0.005). The correlation between SDI and TWA is significant at the 0.01 level (2-tailed). Similarly, the matching correlation coefficients for improved blocks is –0.939 (with a two tailed significance of 0.018).

Again the correlation is significant at the 0.01 level (2-tailed). These confirm a strong negative correlation between SDI and TWA. The finding implies that the higher the surface resistance, the lower the water absorption. This is a very desirable relationship in CSBs. The results show that both SDI and TWA can valuable indicators of the durability of a block.

7.3.5 CORRELATION OF SLAKE DURABILITY INDEX AND DENSITY

A plot of the mean values of SDI and BDD for the two categories of blocks are shown in figure 20.

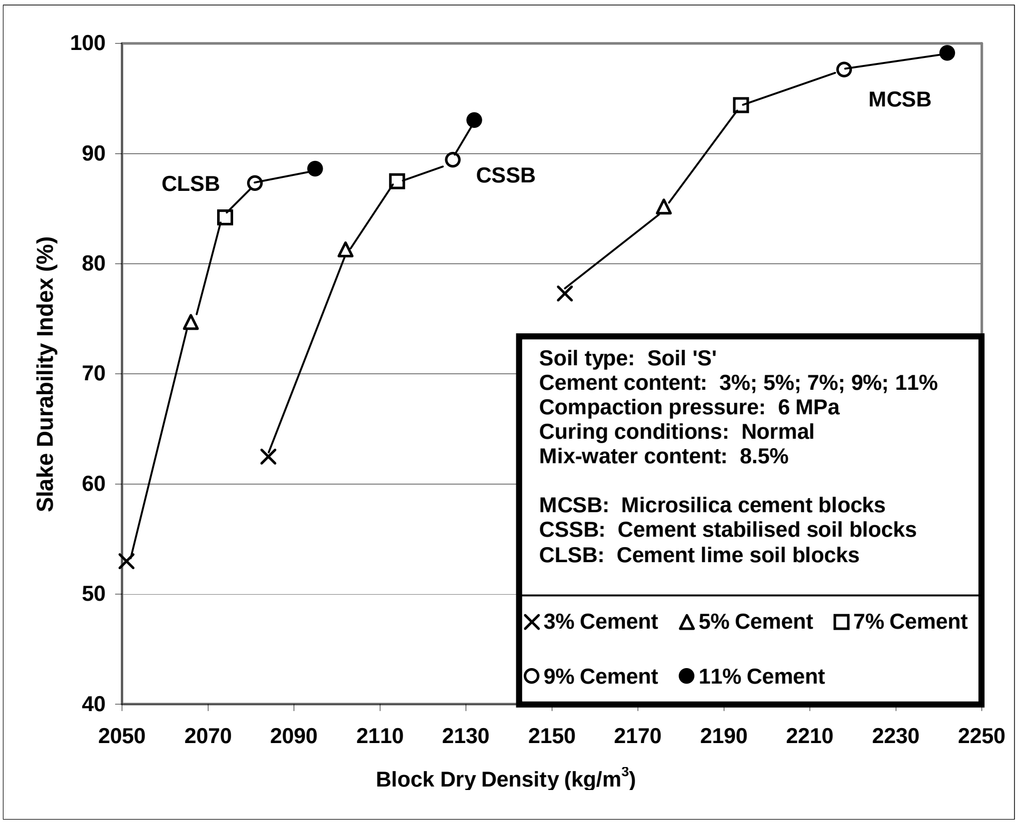

Figure 20: Correlation of Slake Durability Index and Block Dry Density (University of Warwick, 2001)

The graph in figure 20 shows a general positive correlation existing between SDI and

BDD. The correlation coefficients for traditional blocks is 0.953 with a (2-tailed significance value of 0.005). The correlation between the two properties is significant at the 0.05 level (2-tailed). The equivalent correlation coefficient for improved blocks is 0.944 (with a two-tailed significance of 0.016). The correlation is significant at the 0.05 level (2 tailed). Both values confirm a strong correlation between SDI and BDD. An increase in density can be expected to be accompanied by an increase in the durability of a block. The denser the packing of particles and phases in a block, the stronger and therefore more durable it is likely to be. Density is therefore a valuable indicator not only of strength but also of durability in blocks.

Increase in SDI with increase in density appears to be greater in traditional blocks than in the improved ones. Increase in density of about 2.3% is accompanied by an increase in SDI of about 49%. While increase in density of 4% over the same range of increase in cement content in improved blocks results into an increase in SDI of only 28%. So the denser the block, the less is the increase in SDI, but the higher is its resistance to surface abrasion.

7.4 CONCLUSION

From the discussions in the preceding Sections of Chapter 7, a number of general conclusions regarding the following key areas can be made .

The *surface microstructural features* of block samples as observed confirm the existence of an amorphous particulate composite, of predominantly short range order. The matrix shows sand and silt in a highly textured groundmass. The porosity was lower than expected indicating good packing possibly due to the compaction used. The groundmass was homogeneous, with some clayey inclusions seen in the 100 μm range. There was hardly any difference between the microstructure of the surface and bulk. Fewer than expected platelets of calcium hydroxide were present, with no CH precipitation in voids. Their presence justifies use of microsilica to promote pozzolanicity, and thus development of a secondary binding product. Generally no fundamental defects were observed in the material. It can be concluded that the method used is promising, and should be extended to examine samples from CSB production sites in future.

The *slake durability test* was found to have great potential in evaluating surface performance of various block samples. The test procedure was found to be more simple, controllable, reproducible, accurate, reliable and speedy. Moreover, it can be applicable to blocks of any age or stage of curing. The SDI values obtained could be satisfactorily compared with values from other like materials (rocks, concrete, fired bricks, etc.).

From the discussions in Chapter 7, a tentative classification and grading system for potential use in discriminating CSB samples is recommended. The classification is based on six levels of slake durability index SDI, namely: A = extremely high (95-100%); B = very high (90-94%); C = high (75-89%); D = medium (50-74%); E = low (25-49%); and very low (0-24%). While grade A represents blocks of extremely high durability, grade F represents blocks of very low durability (equivalent to unstabilised blocks). Blocks of low and medium durability can be investigated further to identify any production inadequacies.

While all previous tests relied on the veracity of an operative, and were clearly delinked from simulating the main mechanism of surface deterioration in CSBs, the SDI test is independent, and accurately approximates surface deterioration by wetting, abrasion and drying. The test is therefore strongly recommended for adoption and use in testing CSB samples of all backgrounds and ages. Its modification for manual use on block production sites is highly recommended.

It was found in Chapter 7 that increase in cement content resulted into a similar increase in the SDI value of all block categories. It was also found that all stabilised blocks and most comparable materials, were vulnerable to mass loss when subjected to continued wetting, abrasion and drying. Traditional blocks were found to be less resistant than matching improved blocks. The former lost between 12% and 45% more mass than the latter when both were tested under similar conditions.

At the range of interest (5% cement content), traditional blocks were found to have SDI values above 75%, and can therefore be classified as having high durability (grade C). Improved blocks of the same category were found to have very high durability (SDI above 90%). Unstabilised blocks were found to be of very low durability classification (0-24%). These are not recommended for use in building. The results also showed that the majority of improved blocks were comparable to rocks, concrete blocks and fired bricks (SDI > 90%). It can be concluded that the inclusion of microsilica in these blocks effectively increased the bond strength between the particles in the block. The approach therefore offers great potential for strengthening block surfaces and increasing their resistance against rain erosion.

It was also found that SDI values were positively correlated to compressive strength and density, but negatively correlated to water absorption in blocks. The SDI value is therefore a valuable indicator and surrogate measure of strength, density and water absorption in blocks. Use of the index can be favourably extended to compare the performance of other like materials.

Lastly, it was also found in Chapter 7 that with increase in curing age, a corresponding increase in SDI value of the block was recorded. The increase was uniform but more pronounced before the 28th day than after. The SDI value at 28 days was higher than that at 7 days by 51% in improved blocks, and by 88% in traditional blocks. Similar levels of change in strength with curing age have been reported in the literature. The SDI can therefore be used as a quick predictive test for gain in strength over time during and after curing.

With the preceding conclusions, the objectives of Chapter 7 were fully met.

CHAPTER 8

CONCLUSION

The principal objective of this thesis was to investigate the durability of CSBs, especially when used in conditions similar to those found in the humid tropics. Interest in the durability of CSBs is likely to remain a major concern for the foreseeable future given the potential the material has for reducing the enormous shelter backlog in developing countries (1.1). The figure in brackets relates to the section where the issue was discussed in this thesis. The adequate performance of a CSB throughout its service lifetime depends primarily on the interplay between three factors: choosing the right constituent materials, using the correct processing methods, and properly counteracting the effects of the exposure environment (1.2).

At the time of commencing this research, there was hardly any documented record of previous research in the same field. For this reason, a multi-pronged methodology was adopted involving: literature review (Part A of the thesis), laboratory experimentation, and an exposure condition survey (Part B of the thesis) (1.3). In this final Chapter, summary recommendations and conclusions are presented in three separate sections covering Part A, Part B and the highlights of the implications of the findings on further areas of research.

8.1 RECOMMENDATIONS AND CONCLUSIONS: PART A

The aim of the literature review conducted as part of the research was to provide the intellectual context for the work and to determine how far other researchers had reached. It was also meant to determine whether the literature on durability and stabilisation were accessible.

Chapter 2 explored the concept of durability and deterioration in CSBs (2.2). It was found that CSB literature on the subject was scarce and inaccessible. Since both concrete and CSBs develop their microstructure from the precipitation of solids from solution following the hydration of cement, documented findings on the former were used to try to understand related phenomenon in the latter. It is recommended that this approach be pursued further.

From the literature survey conducted, it was found that no uniformly accepted expression for durability existed. It is therefore recommended that the durability of a CSB be regarded as "a measure of its ability to sustain its distinctive characteristics of strength, dimensional stability and resistance to weathering under conditions of use for the duration of the service lifetime of the wall of which it forms part". This concept of durability is based on three important parameters: intended function of the block (for walling); conditions of exposure (weathering elements); and age of exposure (time in years). Due to the effects of exposure conditions, the properties of a block can be altered over time, and so their durability will not remain constant. Durability is therefore more dependent on exposure conditions than just time.

According to the literature surveyed, the time-related loss of quality of a block is its deterioration (2.2). It implies that the durability of a block can be regarded as its ability to resist deterioration. Due to deterioration however, the durability of a block can fall with time. The more a block deteriorates, the less durable it is, and will become over time. An assumed progressive deterioration model characterised by a gradual loss of performance (typified by a deterioration gradient) would be more applicable to the durability-time relationship. The service life of a block can be regarded as the actual period of time during which no excessive expenditure is required on its maintenance or repair in actual use (2.2.). The design life of a block is the period set by the designer of the building of which the block forms part. A gap exists in CSB literature on the concepts of service and design life. Further research is recommended with a view to reducing the gap between the two.

Chapter 2 also discussed various deterioration agents and their likely mechanisms (2.3). Three categories of deterioration modes were identified: water, temperature, and chemical related actions. Water-related deterioration was categorised as occurring in four different forms: abrasive action, solvent action, swelling action, and catalytic action (2.3.1). The most prominent of these was the direct abrasive action of rain on the surface of blocks leading to surface erosion. The exact mechanism and rate of surface deterioration is not yet well understood. Further research is recommended in this area.

Temperature-related deterioration was reported to cause both reversible and irreversible changes in block properties, occurring in three main ways: expansion and contraction, shrinkage and drying, and catalytic action. The main defect types associated with this mechanism of deterioration were surface and bulk cracking and crazing (2.3.2).

It was found through the literature survey that chemically-related deterioration was the least covered in CSB literature (2.3.3). Yet both soil and cement contain sources of potentially reactive minerals. Three categories of chemically related deterioration were identified: leaching-out effect (of clay and calcium hydroxide), expanded product formation (due to action of sulfates, soluble salts crystallisation and alkali-aggregate reactions leading to internal stress generation), and direct decomposition of the OPC hydrate binder (from acidic conditions). Leaching out effect and expanded product formation were regarded as being the most common. It is recommended that use of lime and pozolans in combination with OPC be considered in vulnerable materials. The two help in stabilising both clay and the freed calcium hydroxide from the reaction of OPC and water. It is further recommended that careful soil selection that avoids use of soils with an excess of clay (> 30%), and proper curing that ensures a maximum degree of hydration, be considered as ways of minimising some of the effects of chemically related deterioration. Limits should also be set on the amounts of sulfates (< 2.5%), active silica and carbonates, soluble salts (< 6%) and organic matter (< 3%) found in soils to be used for CSB production. At the moment, there are no such limits. The limits shown in brackets are from recommendations found in concrete literature. Despite these findings, the objectives of Chapter 2 were fully met.

Chapter 3 reviewed from literature sources current methods used to select the main constituent materials in CSBs, the mechanisms of cement-soil stabilisation, and processing methods for blocks (3.1).

The main constituent materials in CSB production were identified as: cement, soil and water (3.2). Coverage of these three materials varied a great deal in the literature reviewed, with quality of cement and water being the least documented. The function of OPC in a CSB is to bind and hold the soil particles together in a dimensionally stable unit (3.2.1). Coverage of OPC in CSB literature was very scant. No mention was made of the main desirable OPC physical properties such as specific surface area (300-350 $m^2\ kg^{-1}$) and particle size distribution (90% more than 5 μ : 1% < 90 μm). These two properties govern the manner in which OPC effectively stabilises soil. Moreover, the implications of the different rates of reaction and influence of the several OPC constituents on the stabilisation mechanism were not covered in CSB literature. Neither were the effects of the various hydrates formed following the reaction of OPC and water covered. These hydrates have implications on the durability of CSBs. By discussing issues such as these in Chapter 3, an attempt was made to fill the existing CSB gap in literature. Capillary porosity for example is closely associated with strength, and is controlled by the water cement ratio and the degree of hydration. While the former can be reduced by the use of very fine pozzolans (e.g. microsilica), the latter can be attained by ensuring that a high degree of hydration is achieved (by proper wet curing). It was this finding from the literature on cement chemistry that led to the successful manufacture for the first time of improved blocks of superior strength and durability than comparable conventional blocks (Chapters 6 and 7). The approach used is strongly recommended for CSBs meant for use in severe climatic conditions such as the humid tropics.

Chapter 3 also discussed findings from the literature review conducted on the characterisation and selection of soil for CSB production (3.2.2). It was found that soil classification and selection criteria were generally well covered in most CSB literature. Classification by particle size distribution is the most commonly used method. It is recommended that other methods based on plasticity, compactability, cohesion and chemical content also be investigated further for future use. The current soil selection criteria recommends the use of a well graded soil containing adequate proportions of coarse soil fraction (fine gravel and sand) and sufficient fines (silt and clay) for cohesion. The soil should ideally have about 75% coarse fraction and about 25% fines content (of which at least 25% is clay). As soils are highly variable and complex materials even in nature, it is recommended that even where soils on site do not conform to the above specifications, they be not rejected but modified. A dense, well graded soil requires less cement to bind its particles together due to the increase in specific surface area. The effect is even greater when a limit is set for maximum size fraction (< 6 mm). At the time of the research, it was established that various authors recommended different maximum size fraction sizes (5 mm, 6 mm, 15 mm, 20 mm). A limit of 6 mm is recommended.

The quality of water for mixing and curing is poorly covered in CSB literature (3.2.3). Due to the scarcity of water in most developing countries, the sources are varied and so is the quality. It was noted that the use of untreated water of no known service record cannot be ruled out.

Chapter 3 also reviewed current cement-soil stabilisation principles (3.3). The conclusion that emerges from the review is that, despite the recent scientific advances made, cement-soil stabilisation still remains an inexact science. Soil properties can be modified by mechanisms that vary the soil-water-air interphase through minimising the volume of interstitial voids and improvement of cohesion and bonding between its particles (3.3.1). The literature documents three theoretical and practical methods of achieving this: mechanical (compaction), physical (improvement of soil grading), and chemical (using a stabiliser such as OPC). The effect of chemical stabilisation mechanisms are widely documented as being more permanent. It is therefore recommended that chemical stabilisation of soil be done even when the other two methods have been used (3.3.3).

Further research is required to determine the proportions of the final CSB matrix known to comprise the following: cement hydrates, conventional cement-sand mortar, calcium hydroxide, unstabilised clay and sand, and unhydrated cement residues. According to literature sources, the predominance of any one of these products in a CSB fabric can influence its durability.

In Chapter 3, the block production process was described as being a major input variable that can affect the properties and behaviour of a block (3.4.1). The main processing stages identified from the literature were: soil preparation, mixing, moulding, and curing. The sequencing is so dependent that one stage must be completed before the next one can begin. The importance of each of the sub-stages in the block production process has often been underrated. Underestimation of the above steps can lead to the production of blocks of low strength and durability (3.4.1, 3.4.2, 3.4.3, 3.4.5). Generally, as the findings described in this section show, the objectives of Part A of the thesis were fully met.

8.2 RECOMMENDATIONS AND CONCLUSIONS: PART B

Part B of the thesis was devoted to direct investigations incorporating an exposure condition survey in a humid tropical environment and laboratory experimental work. The findings were reported in Chapters 4, 5, 6 and 7.

Chapter 4 described methods and findings from the exposure condition survey conducted in Uganda where CSBs have been in use since the late 1980s (4.1). Uganda is a humid tropical country, where deterioration agents occur naturally. The exposure conditions were considered to be sufficiently representative of similar conditions in most of the humid tropics. Four methods were used during the fieldwork: (i) collection of data on the inventory of CSB structures and the exposure condition, (ii) condition survey of existing buildings (random inspection, in-service testing, maintenance records), (iii) observation of methods of work at CSB production sites, including field indicator testing for soils and quality test checks of OPC and water, and (iv) interviews and questionnaires (4.1).

From the provisional inventory of CSB buildings in the country, it was found that a large stock of over 400 buildings had been built since 1987 (4.2.1). This however represents a very small fraction of the total number of buildings constructed over the

13 year period. The buildings were constructed in an attempt to reduce the enormous housing backlog (estimated at 3 million by the year 2006). Up to 90% of the CSB buildings were found in high density, low income urban areas (Namuwongo in Kampala, and Malukku in Mbale). The general conclusion made was that the rate of construction was not yet able to meet the enormous demand for low cost housing. The demand for CSB buildings is therefore likely to remain high for the foreseeable future.

Chapter 4 also described the characteristics of the natural exposure environment in Uganda (4.2.2). This was done to identify the main naturally occurring agents whose effects were likely to prove deleterious to CSB structures during their service lifetime. The main agents identified were rain, temperature and relative humidity. It was found from records that the average rainfall intensity was above 7.5 mm/hr (i.e. heavy rainfall), with drop sizes varying from 0.5 mm to 6 mm. The duration of rains varied between one and six hours. With a frequency of two rainy seasons lasting about 6 months, it can be concluded that water-related deterioration of CSBs is likely to occur during the service lifetime of such buildings. It is recommended that more research be done on erositivity of rain including the contribution of the interactions of rain drop size, drop size distribution, fall velocity and impact kinetic energy to the deterioration process.

It was also found from records that ambient temperatures averaged about 25°C, with surface temperatures in the shade reaching about 100°C. It can be concluded that under such conditions, temperature related deterioration will occur within the service lifetime of a block. Moreover, with the presence of large water bodies (lakes, rivers, swamps) throughout the country, high temperatures ensure that there is a high relative humidity (30-90%). These conditions can serve as catalysts to chemical and biologically related deterioration mechanisms. The conclusion made was that as characterised, the exposure conditions in the country provide an ideal setting for most deterioration mechanisms discussed in Chapter 2.

Chapter 4 described several reasons why visual inspection as a way of evaluating defect types and their severity on exposed block surfaces had been selected (4.3.1). All 58 buildings inspected (representing about 15% of the total CSB building stock) were all chosen at random. Their ages ranged from one month to 12 years. It was found that defect types were wide ranging: surface erosion, spaling, pitting and roughening (due to rain); surface and bulk cracking and crazing (due to temperature variations); surface and plant growth (due to biological action); disintegrated loose material residues (due to chemical action); and interblock and mortar cracks (due to settlement). The predominant defect types were surface erosion (75%) and cracking (25%). These findings confirmed that premature deterioration of CSBs can occur in the humid tropics. It was also found that like materials used under similar conditions for the same period of exposure did not show similar defects.

Chapter 4 also described findings from in-service measurements done to determine the amount of volume reduction that had occurred due to mass loss, and the dimensions of cracks (4.3.2). It was established that surface erosion can lead to irrecoverable loss of volume in a block. It was found that the reduction in volume varied with the elevation of a block within a wall, the orientation of the wall façade, and the age of exposure. For the 12-year old building, volume reduction at the higher and lower levels of its walls averaged about 28% and 35% respectively. The mean volume reduction for the east-west façade was about 34%, while that for the north-south one was about 28%. The mean volume reduction for all facades in the 8-year old structure was about 22%, while that for the 12-year old building was 31%. The average estimated rate of annual mass loss for both structures was below 3%. The rate of mass loss can be influenced by the degree of resistance offered by a block surface. It is recommended that CSB surfaces used under similar exposure conditions be made more denser, smoother and of higher intergranular strength. Other surface protection measures should also be considered, such as: rendering, surface coating and layering with higher intergranular strength mixes at the surface. Adequate surface protection is likely to remain the most economic way of increasing the durability and thus extending the service life of a block.

The severity of cracking on CSB surfaces was found to follow the same trend as surface erosion (4.3.2). It was established that while cracks occurred on all wall facades, their widths on the east-west facades (2.5 mm to 2.9 mm) were markedly greater than on the north-south facades (0.65 mm to 0.80 mm). The measured values were found to exceed the maximum permissible crack widths specified for concrete (0.25 mm for severe exposure, and 0.15 mm for normal exposure conditions). Such comparisons do not take into account the fact that CSBs contain clay, while concrete does not. It is recommended that similar permissible maximum crack widths, higher than those given for concrete, be set for CSBs. It was also found that exceptionally thick mortar was widely used for bedding blocks (15-20 mm thickness). Such mortar thickness can prevent flexible movement on expansion of blocks encouraging cracking and is therefore not recommended. It can be concluded that while a particular cause within or outside a block might initiate cracking, its subsequent development can be due to other causes. The different types of cracks observed (star shaped, linear, interconnected and penetrating) indicated that there were more than just one cause of cracking in CSBs. The linking of particular crack patterns to likely causes is recommended for further research.

Findings from preliminary field indicator tests showed that the test methods used can be valuable indicators of soil properties and behaviour (4.3.3). The conclusion made was that although the tests were largely empirical, they could still enable the general suitability and acceptability of a soil to be determined rapidly and at lower costs. It is recommended that of the 15 different indicator soil tests described, the linear shrinkage test and the sedimentation test be made compulsory. This is because they are less vulnerable to operator errors than all the other tests. The tests should also be done in the order in which they were presented in this thesis. It is further recommended that the outright rejection of soils as being unsuitable as advocated for by previous authors be avoided. It should only be done when laboratory tests show that it will prove too costly to modify the soil by improving its grading (removal of the excess fraction or inclusion of the missing fraction through controlled mixing).

It was found from visits to block production sites that no proper processing procedures were being followed (4.4.1). Yet the production process represents a major input variable that can influence the properties and performance of a block. The observations of shortcomings noted during soil extraction and preparation, mixing, moulding and curing confirmed fears that poor site practice, bad workmanship, lack of supervision and codes of practice can affect the final quality of a block. It is recommended that appropriate codes of practice, preferably based on a checklist system of good practice, be made available on block production sites. It can be concluded that without proper standards and codes, even skilled supervisors and foremen might not be able to appreciate the consequences of bad methods of work.

The results of quality checks on OPC and water used on sites showed that variations from standard specifications can significantly affect the properties and performance of a block (4.4.2). Quality checks on prisms made using the cement on site showed that the wet compressive strength (28-day) was about 15% lower than the specified minimum of 32.5 MPa for the class of OPC used (class 32 N OPC; BS 12, 1990). The prisms tested for tensile load were between about 25% and 30% lower in capacity than the recommended load values at one day and at 28 days respectively. The conclusion here is that the OPC found being used on site was not of the same quality as the specified one. It must have been contaminated at some stage (purchase, storage, mixing). Press reports seen more than one year later confirmed that malpractices involving the adulteration of OPC with clay was rampant. It can be concluded that use of low grade OPC will affect the properties and thus performance of a block. It is recommended that regular quality checks be conducted on OPC found on CSB production sites.

It was also established that use of water of unknown service record can result in blocks of lower wet compressive strength (4.4.2). The difference in strength from the specified minimum was about 23%. Tensile load tests using the same mix water source showed that the prisms were about 43% lower in wet compressive strength than the specified minimum. The conclusion here is that use of water of unknown service record can affect the strength and by implication, other properties of a block. However, since water is scarce in developing countries, the continued use of such water sources cannot be ruled out. It is therefore recommended that simple water purification and quality improvement methods be adopted (3.2.3). It was also noted that use of pre-treated tap water was taken for granted by most CSB authors.

Results of interviews and questionnaires conducted revealed a number of wide ranging issues (4.5). The number of respondents contacted was 35 (stakeholders including users, professionals, government officials, project managers, etc., all chosen at random), and the response rate was 100%. A number of conclusions can be drawn from the results.

It was found that the walling materials of choice based on previous experience and tradition were fired bricks (40%), followed by concrete blocks (33%) and CSBs (22%). Adobes were the least preferred, being considered materials of the last resort. The main reason given for preferences was the durability of the material as evidenced by its service life record (77%), followed by costs (15%) and tradition (2%). Preferred block types were found to be dry stacked interlocking blocks (55%), followed by solid blocks (32%), and bed frogged blocks (10%). Hollow blocks, despite their cost saving potential, were the least preferred (3%). The most common defect types observed by respondents over the years were surface erosion (including pitting and roughening) (75%), followed by surface and bulk cracking and crazing (20%). These findings are in agreement with earlier findings reported after the visual inspection was done. Preferred surface protection methods were external plaster and render (54%), followed by surface coatings (23%), and architectural design that incorporated a low roof overhang (18%).

According to these respondents, suggested ways of improving the service life of blocks and thus promoting their image amongst potential users include improvement of bulk strength and bonding (40%), dissemination of standards and codes (28%) and improved architectural design (20%). It can be assumed that the views of the stakeholders interviewed as summarised here represents the broad opinion and experiences of other users in developing countries. The above findings show that the objectives of Chapter 4 were fully met.

In the experimental design described in *Chapter 5*, all the input variables that can influence the quality and performance of a block were identified (5.2). They include constituent materials and processing methods (5.2 to 5.4). The soil type was fixed for all blocks, while the stabiliser type and amount, moulding pressure and curing conditions were varied. The main objective was to compare the properties and performance of improved blocks (with 10% of the cement content comprising microsilica) and traditional blocks (OPC only stabilised and OPC plus lime stabilised). Bulk and surface properties of both categories of blocks were extensively tested. The number of specimens produced for each test was three. The decision to use three specimens was based on earlier preliminary tests which concluded that the variability for the major tests were quite low (5.4.2). With the above findings, the objectives of Chapter 5 were fully met.

Chapter 6 described findings from bulk property tests which included wet compressive strength, block dry density, total water absorption and volume fraction porosity The mean WCS of improved blocks were found to be more than double those for matching traditional blocks (6.2.1). Although some improvement in strength had been expected, the order of magnitude achieved was surprisingly greater than predicted. The conclusion here is that the use of a partial cement replacement material (such as microsilica) can be an effective way of increasing strength, and by implication the durability of a block.

It was also found in the case of improved blocks, that the WCS value at the 5% cement content level (range of interest) was about five times greater than the recommended minimum value of 1.2 MPa (6.2.1). Even at the lower cement content of 3% (generally not used), the WCS value attained was surprisingly about three times higher than the minimum recommended value. The trend of the graph showed that where microsilica is used, only 1% of OPC would be required to achieve the minimum wet compressive strength of 1.2 MPa. There is no previous record prior to this thesis to show that similar spectacular gains in strength have ever been achieved in CSBs. The use of microsilica in enhancing strength in blocks is therefore strongly recommended.

The effect of increase in cement content with strength in blocks was found to closely correspond in all cases (6.2.1). Overall increase in strength in both traditional and improved blocks with increase in cement content from 3% to 11% was about six-fold. It was generally found that the increase in WCS was higher at the lower cement content levels than at the higher ones (220% compared to 97% respectively). It can therefore be concluded that use of cement contents beyond 7% is not an economic way of achieving further strength in CSBs.

It was also established that increase in compaction pressure resulted in an increase in WCS. A 70% increase in compaction pressure resulted in a 32% increase in WCS (6.2.1). The increase in WCS is however considerably lower than that achieved through a similar increase in cement content. It can be concluded that increase in cement content is a more effective way of increasing the WCS in blocks. Even where blocks of high cement content were compacted at lower moulding pressures, they were found to perform satisfactorily. The opposite was not found to be the case. This confirms earlier conclusions that the ultimate cured wet strength of a block is more sensitive to changes in cement content than compaction pressure. Moreover, it was also found that the degree of increase in WCS with increase in compaction pressure diminishes as the pressure increased. It can therefore be concluded that block presses operating within the range 2 MPa to 8MPa can be adequate to produce blocks of sufficient WCS.

It was also found in Chapter 6 that the ratio between mean dry and wet compressive strength was much lower in improved blocks than in the traditional ones (6.2.2). The ratio ranged between 1.4 and 1.9 in traditional blocks, but only between 1.1 and 1.3 in improved blocks. The ratios for the improved blocks were found to compare well with those for concrete blocks (between 1.09 and 1.21). The findings show that the higher and broader the ratio between mean DCS and WCS, the lower can the degree of intergranular bonding be expected to be. It can be concluded that the reduction in ratio for improved blocks is directly attributed to the inclusion of microsilica. This must have transformed the weaker and more porous CSB fabric into a far denser, more homogeneous and more impermeable matrix, than was hitherto possible. The use of CRMs in improving CSB properties such as strength is therefore strongly recommended. It is further recommended that use of the value of the ratio between the mean DCS and WCS be adopted as a tool for assessing the quality of bonding achieved in CSBs. Where CRMs are used, it is recommended that various cost reduction measures be considered: use of thin surface layered blocks, hollow blocks, frog-bedded blocks, and interlocking blocks.

It was shown in Chapter 6 that the effects of processing variables such as hold-back time on the WCS of blocks can be adverse (6.2.3). A progressive loss of quality was found to occur on delay in compaction of a damp soil cement mix. It was established that blocks compacted within 20 minutes of delay after damp mixing were about 27% stronger than those compacted after 45 minutes. Blocks compacted within two hours of delay were about 41% weaker. These findings compare well with those of earlier researchers. Similar effects can be expected to occur in improved blocks. It is therefore recommended that only batches that can be compacted within 30 minutes, instead of the currently used one hour, be mixed and used up in that time. The findings also confirm earlier ones which noted that poor site practice can result in the production of low quality grade blocks. It is strongly recommended that all CSB production processes be treated with the same high level of skill, competence and supervision. This should be reinforced through standards, codes, checklist systems and certification requirements.

The effect of varying curing conditions on the performance of was blocks was investigated in Chapter 6 (6.2.4). Blocks cured under exposed conditions were found to be about two-fold weaker than blocks cured under standard conditions. Had they been left exposed directly under the sun (as is commonly the practice on block production sites), the loss in WCS would have been even higher (4.4). Blocks cured by prolonged covering throughout were found to be about 29% stronger than their standard cured counterparts. Blocks cured fully immersed in water were about three times stronger than standard cured blocks, and about six-fold stronger than those cured in open exposure in the laboratory. Variation in curing conditions affects the state of moisture in a green block. It can be concluded that the fully immersed blocks emerged strongest because hydration was allowed to continue until a maximum degree of hydration was achieved. It is therefore recommended that the curing of blocks be done in such a manner as to allow the continued presence of moisture to complete the hydration reaction of OPC. Wet curing should be extended to longer periods than currently allowed for. These results also confirm the urgent need for proper codes of practice to be observed during the manufacture of blocks.

From investigation into the effects of varying the stabiliser type and content on the block dry density, it was found that the latter varied markedly with changes in the former (6.3). For matching OPC content, it was found that the density in improved blocks was between 3.3% and 5.2% higher than in corresponding traditional blocks (6.3.1). The conclusion here is that inclusion of microsilica in improved blocks had a pore filling effect, and resulted in increased homogeneity, improved bonding and reduced voids content in the block. Dry density can be a valuable indicator of quality in a block. Density however also depends on the degree of compaction used, the density of the constituent materials, the size and grading of soil particles and on the form of a block (solid, hollow, etc.). It was also established that no uniform standard exists for the determination of dry density in CSBs. It is recommended that the method requiring oven pre-drying to constant mass be adopted.

It was found in Chapter 6 that a strong positive correlation exists between density and the 28 day WCS in both categories of blocks (coefficient of correlation was 0.971 for traditional blocks and 0.996 for improved blocks) (6.3.2). It can be concluded that increase in density can result into an increase in WCS. The increase was however found not to be uniform throughout, being more pronounced at the lower cement contents than at higher ones. However, very high densities could prove disadvantageous during block laying and transportation. It is recommended that production of blocks heavier than 8.5 kg be avoided.

It was also found in Chapter 6 that due to the existence of pores within their fabric, all categories of blocks absorbed water (6.4). Increase in stabiliser content resulted into a decrease in TWA (6.4.1). Traditional blocks absorbed more water than their improved counterparts (more by 120%). The overall decrease in TWA with increase in cement content from 3% to 11% was around 40%. Generally, the less water a block absorbs, the better is its performance expected to be. It can be concluded that TWA is a valuable indicator of quality of a block as it can be used to estimate the total volume of pore space (voids).

The results showed that beyond a certain stabiliser content, water absorption by a block ceases to decrease any further, becoming almost uniform instead. The limiting value was found to be 9% in traditional blocks, but only 7% in improved blocks. It can be seen that lowering of the limit to 7% in improved blocks must have been due to the pore filling effect of microsilica.

It was also established from the results that the TWA values obtained were much lower than the recommended maximum value of 15%. Values for improved blocks were the lowest (3% to 6%). The conclusion here is that use of microsilica in improved blocks was an effective way of lowering TWA (than increase in compaction pressure). It is recommended that TWA values in blocks be used for routine quality checks, for comparison with set standards, for approximation of the voids content, and for classification of blocks according to required durability, and structural use. It is also further recommended that existing TWA test methods be standardised. Current tests do not take into account the need to oven pre-dry blocks to constant mass in order to expel air and water from the pores before immersion in water.

In Chapter 6 a strong correlation was found to exist between TWA and density (correlation coefficients were –0.985 and –0.820 for traditional and improved blocks respectively). It can therefore be inferred that increase in BDD will result in a decrease in TWA (6.4.2). For example, increase in density of 2.3% resulted into a decrease in TWA of 44% in traditional blocks (39% in improved blocks). The results also showed that beyond a certain density value (corresponding to the limiting OPC contents described earlier), no further appreciable reduction in TWA could be expected.

A general link between TVP and the performance of blocks was established in Chapter 6 (6.5). It was shown that a very strong negative correlation exists between TVP and WCS (coefficients –0.905 for traditional blocks, and –0.771 for improved blocks) (6.5.1). The conclusion here is that the greater the pores, the higher the number of flaws and localised faults within a block fabric, and so the weaker it is. The TVP was lower in improved blocks (8.4% to 13.3%) than in corresponding traditional blocks (14.4% to 25.3%). This can be attributed to the pore filling effect of microsilica. It is recommended that use of microsilica be considered in future as an economic way of reducing the TVP in CSBs.

It was also found in Chapter 6 that the correlation between BDD and TVP was strong and negative (correlation coefficients –0.984 in traditional blocks, and –0.935 in improved blocks) (6.5.2). Increase in density of about 4.1% was found to result in the lowering of the TVP by about 37% in improved blocks. It can be concluded that increased densification can be an effective way of reducing the TVP in blocks. The TVP is however also a function of water-cement ratio and of the degree of hydration achieved. The value of the latter can be increased only when moisture is available to complete the hydration process. It is therefore recommended that proper moist curing be used as a way of reducing the TVP in CSBs. The general link established between TVP and other block bulk properties are similar to those reported in concrete literature. The TVP approach has not been used before in quality evaluation of CSBs. It is recommended that TVP be included as a quality check parameter for CSBs. With the preceding findings in Chapter 6, it can be concluded that improved blocks performed significantly better than their traditional counterparts in terms of all properties for which they were tested (WCS, DCS, BDD, TWA, TVP). The objectives of Chapter 6 were fully met.

Chapter 7 described findings from petrographic analysis and surface performance monitoring tests done on improved and traditional block samples. It was noted that as the outermost boundary of a block, the surface represents its first line of defence against deterioration agents and is therefore an important feature for a block (7.1). It was also noted that any erosion of the block surface that exposes the bulk would most likely lead to an accelerated rate of deterioration.

From the thin-section micrographs of block surfaces examined it was found that the general features revealed the existence of an amorphous particulate composite structure of predominantly short range order (7.2). This was expected since particulate regularity in such a composite material is difficult to attain. Moreover since CSBs like concrete are formed from the rapid precipitation of solids from solution, random packing such as was observed should be expected. This contrasts with the distinctly continuous interlocking phases reported in fired bricks (due to mulite formed from firing). No previous publication of similar petrographic analysis exists for CSBs.

The most distinguishable features noted were coarse soil grains (fine gravel, sand), gross porosity, calcium hydroxide, clay inclusions and aggregations of OPC hydrates in the groundmass. At the resolution used, the micrographs could not resolve sub-micron phases such as individual clay or microsilica grains. The presence of calcium hydroxide justifies the use of microsilica to promote pozzolanicity in CSBs. It was however difficult to detect any micro-defects in these particular samples. It is very unlikely that similar micrographs of samples made in the field would have yielded the same results. The conclusion here is that the samples were well mixed. The micrographs confirm the release of calcium hydroxide which when left in a block fabric can be detrimental to its durability (Chapter 2). The surprisingly low gross porosity detected in improved blocks also vindicates the use of microsilica in CSBs.

The conclusion here is that by reducing voids through densification or inclusion of CRMs, pores can be reduced, hence lowering water absorption and permeability properties of a block. Further, by improving bonding through the use of CRMs and proper wet curing, closer and more rigid contacts can be attained, hence improving the surface resistance of a block. Use of microsilica in CSBs is therefore strongly recommended. Use of petrographic examination of CSBs should be extended to examine samples from various production sites.

It was discussed in Chapter 7 that no proper accelerated surface test is currently available for monitoring the performance of CSBs (7.3). Existing methods (the water drip test, water spray test, brushing test, hardness test, absorption test and the wet-dry-cycling test) all lack reliability, repeatability and accuracy. These tests were found to be operator dependent and difficult to conduct. This explains why blocks were in the past passed as durable only to prematurely succumb to normal or severe exposure conditions. The slake durability test (SDT) was therefore proposed and used as a quick predictive accelerated test for monitoring the performance of CSB surfaces of various categories (7.3). It is recommended that the standard procedures used for the test be maintained for all future tests on CSBs. It is also recommended that further research be undertaken to modify the test apparatus to make it convenient to use on a block production site (e.g. manual operation instead of mechanical).

Using the SDT, the effect of varying the stabiliser type and content on the quality of block surfaces were monitored (7.3.1). It can be concluded that more rapid mass loss will occur from the surfaces of traditional CSB samples, than from those of like materials such as fired bricks, concrete blocks and rocks. It was found that mass loss was markedly higher in traditional blocks than in improved blocks of matching cement contents.

Improved blocks of cement content above 9% were found to have mean SDI value of about 99.1%, performing as well as fired bricks and concrete block samples (mean SDI values of 99.8% and 96.6% respectively). According to current and proposed SDI classification system, improved blocks of 5% cement content and above could be categorised as being of "very high durability" or grade B and better blocks. Comparable traditional blocks of the same cement content if carefully made would be classified as being of "high durability". It can be concluded that the use of microsilica reduces the loss in mass in blocks, by considerably increasing its surface resistance to cyclic wetting, abrasion and drying. Use of microsilica (or other similar CRM) is therefore highly recommended as a way of improving the surface resistance of a block.

A strong correlation was found to exist between increase in cement content and the SDI value of all categories of blocks tested (7.3.1). It was established that increase in SDI with increase in cement content was higher at the lower cement content levels (less than 7%) than at higher ones (40% compared to 6% in traditional blocks and 22% compared to 4.9% in improved blocks). In both cases, increase in OPC content beyond 7% did not result into any further appreciable increase in SDI values. This phenomenon of diminished increase in performance with increase in OPC content beyond about 7% has featured in almost all the properties evaluated. It can be concluded that at 7% cement content, CSBs will perform better in most respects than at the current lower recommended level of 5%. The elevation of the minimum amount of OPC used (5% to 7%) is strongly recommended for CSBs meant to be used in the humid tropics. Ways of reducing costs such as bed-frogging of blocks or use of interlocking blocks that do not require use of mortar or render could be investigated. Since rapid loss in mass was detected in most block samples, it is recommended that surface protection measures be used for CSBs as described earlier (especially blocks with 5% cement content and below).

It was also found in Chapter 7 that the SDI value was strongly correlated with the evolution of strength in blocks during curing (7.3.2). Increase in curing age was found to correspond to increase in SDI values. The increase was more phenomenal before the 28th day (for OPC stabilised blocks) and on the 56th day (for OPC plus lime stabilised blocks). No appreciable increase in SDI with curing age was recorded after these periods. The SDI value for improved blocks at 28 days was about 85% higher than at seven days. The comparable figures for traditional blocks was about 51%. It can be concluded that improved blocks gained strength, and thus surface resistance, more rapidly than their traditional counterparts. The results further indicate that SDI values can be used as a surrogate test for quality in CSBs irrespective of the pre- and post-curing periods. The pattern was similar to that found with increase in strength over time during curing. Moreover, the SDT test was found to be applicable even six months and after the prescribed curing periods. The conclusion is that a new test that can reliably test the evolution of strength similar to wet compressive strength has been found for CSBs. A further conclusion is that the SDT can be used to evaluate and classify blocks irrespective of their curing age and storage history. This was not possible prior to these findings.

The correlation between SDI and WCS was found to be very strong and positive, thus confirming the preceding conclusions (7.3.3). The conclusion here is that the higher the value of the 28 day WCS, the greater is the resistance offered to surface erosion due to wetting, abrasion and drying. It was however also established that there was a diminished increase in SDI with increase in WCS. The SDI is therefore a valuable indicator of both strength and surface resistance in CSBs.

A strong correlation was also found to exist between SDI and TWA (coefficients were –0.975 and –0.939 for traditional and improved blocks respectively) (7.3.4). The higher the SDI value, the lower the TWA. The inference here is that higher surface resistance corresponds to lower water absorption. Both properties are therefore valuable indicators of surface and bulk quality respectively.

It was also established in Chapter 7 that a strong positive correlation exists between

SDI and the BDD (7.4.4) (correlation coefficients were 0.944 and 0.953 for improved blocks and traditional blocks respectively). Both were significant at the 95% confidence level using the 2-tailed test. The conclusion made is that increase in density can be associated with increase in the SDI value of a block. The denser the packing of particles and phases within a block (i.e. lesser voids), the stronger and therefore more durable it can be expected to be. Increase in SDI with increase in density was higher in traditional blocks than in the improved ones (2.3% increase in density resulting into a 49% increase in SDI, as compared to 4% increase in density resulting into a 28% increase in SDI in improved blocks). The conclusion here is that the denser the block, the less is the increase in SDI value, but the higher is the resistance to surface erosion. Increase in density is therefore an economic way of increasing the SDI value in blocks.

As the preceding findings have shown, use of the SDT as a new surface quality test is strongly recommended. Use of the procedure was found to be simple, controllable, fast, practical, accurate and of timeless value. The test method was also found to be an excellent accelerated test procedure since loss in mass occurred with significant short term value for research. The test also simulated the main deterioration mechanisms on block surfaces (erosion due to repeated wetting, abrasion and drying). Further research is recommended into the test method with a view to having the results calibrated with those obtained from natural exposure condition surveys. It is possible that the test results could one day be used to estimate the rate of surface erosion due to this particular mode of deterioration.

It is further recommended that the proposed SDI classification system be adopted for use with CSBs. The SDI test results can be used in several ways: as an aid to block classification, for selection of blocks for particular applications, for quality control during production (and delivery to site), for prediction of the rate of surface material loss, and for selection of suitable presses. The use of the SDT is likely to ensure that the durability of CSBs can for once be quantitatively determined in a more uniform and independent manner than before. Minimum required values can be specified and included amongst initial performance characteristics of CSBs. This is likely to bring an end to widespread attempts to characterise CSBs qualitatively as being of low or high durability without any standardised method of quantitative determination. From the preceding findings and conclusions, the objectives of Chapter 7 and Part B of this thesis were fully met.

8.3 RECOMMENDATIONS FOR FURTHER RESEARCH

The main objectives of this thesis have been fully met (8.1, 8.2). The findings have however flagged up a number of new questions for further future research. It was not possible to undertake the identified new research areas within the current study. The areas for further research include the following:

- Durability concepts should be developed further so that a proper expression for the term (that extends what was described in this thesis) can be documented in CSB literature. This should be based on the intended function of a block, its conditions of use, and time in years.
- Deterioration agents should be ranked according to their severity as attempted in this thesis, and the mechanisms of their action investigated further with a view to understanding them better (surface versus bulk phenomenon).
- Surface protection methods should be researched into with a view to reducing costs. The cost and applicability of high durability blocks which are not rendered could be compared with those of low durability blocks which are

rendered. The use of surface enriched thin layers, hollow blocks, interlocking blocks and bed frogged blocks should be investigated as ways of reducing costs while maintaining adequate surface properties.

- The role of the various OPC hydrates in determining the durability of blocks requires further research. Ways of lowering the water-cement ratio and increasing the degree of hydration also require further work.
- In-service performance data of CSBs should continue to be collected and documented. Data banks could be established where such information can be centrally collected and sourced. Of particular interest to further research should be information on volume reduction due to mass loss, and crack formation in CSBs.
- Accelerated test methods for block surface evaluation and monitoring require further research. The SDT or similar tests that are not operator dependent, easy to conduct, and to interpret results, should be researched into. The test method should simulate the main modes of deterioration for the particular type of surface resistance required and should be convenient to use on site.

Finally, the use of CSBs as a cheaper alternative walling material is likely to increase in the foreseeable future. It is the improved durability of a block, rather than of any other property, that is likely to ensure its widespread acceptance in developing countries.

APPENDIX A

BASIC CHEMICAL CONSTITUENTS OF OPC

S/N	Compound Name	Shorthand Nomenclature	Mineral Name	Density Kg/m^3	Typical Quantity by Weight %	Role
1	Tricalcium silicate	C_3S	Alite	3150	55	The major constituent in OPC; involved in the initial gel formation contributing to setting; hydration products are C-S-H fibres and $Ca(OH)_2$ crystals; contribute to strength in the early stages of hardening.
2	Dicalcium silicate	C_2S	Belite	3280	20	Same hydration products as above; contributes to increase in strength at later stages of hardening due to its slower rate of hydration.
3	Tricalcium aluminate	C_3A	Aluminate	3030	12	Contributes to setting through gel and ettringite formation due to its fast rate of hydration, but little to hardening.
4	Tretracalcium alumino ferrite	C_4AF	Ferrite	3770	8	Contributes to colour of cement, but plays little part in setting and hardening
5	Hydrated calcium sulfate	$C\bar{S}H_2$	Gypsum	2320	3.5	Controls hydration rate of C_3A; own rate of hydration very fast
6	Alkali oxides, other impurities	K_2O, Na_2O, CaO	-	-	1.5	May affect the crystal structure and reactivity or both of 1-5 above; Na_2O and K_2O may react with soils containing silica to cause ASR

(Adapted from: Weidemann et al, 1990; Young et al, 1998; Lea, 1976; Taylor, 1998)

APPENDIX B

PROPERTIES OF HYDRATION PRODUCTS OF OPC AND THEIR POTENTIAL INFLUENCES ON THE DURABILITY OF CSBs

S/N	Product		Volume Fraction	Density	Particle Size Across	Particle Size Thick	Specific Surface Area	Morphology and Crystallinity	Strength	Impact on durability of CSBs
	Symbol	**Name**	**%**	**Kg/m^3**	**μm**	**μm**	**m^{2}g^{-1}**			
1	C-S-H	Calcium sulphate hydrate	65	2000	<1	0.01	400	Irregular foils Amorphous Microporous	Provides major cohesive force but is weak due to its microporosity. This is why dry blocks will be stronger than wet blocks (stronger van der Waal forces)	Very insoluble. Water loss from its micropores will cause shrinkage or drying and creep on loading even at room temperature. Responsible for drying shrinkage in CSBs and creep respectively.
2	$Ca(OH)_2$	Calcium hydroxide	20	2250	100	10	~ 0.5	Thick hexagonal plates which cleave easily and are crystalline	Contributes to strength in CSBs reducing porosity. Cleavage tends to limit levels of high strength pastes. Is dimensionally stable and will restrain C-S-H deformations.	Blocks capillary pores hence lowering permeability in blocks. Very soluble in water, especially in presence of CO_2. It is slowly leached out by water causing increase in porosity, permeability and reduction in strength.
3	$C_4A\bar{S}H_{12}$	Monosulpho-aluminate	10	1950	~ 2	~ 0.1	~ 2	Thin irregular plates and farily crystalline	Reduces porosity but not significantly. Has minimum effect on deformation	Responsible for causing sulphate attack by reforming ettringite and causing expansion.
4	UCR	Unhydrated cement residues	5	3150	~ 1	-	~ 0.1	Remnants of original cement grains	Not very significant but may restrain C-S-H deformation	Renewed hydration may cause autogeneous healing of internal micropores
5	CP GP	Capillary pores; Gel pores	-	-	-	-	-	Openings	Total porosity is the major factor influencing strength. Fine pores contribute to shrinkage and creep	Porosity influences permeability. Large interconnected pores facilitate circulation of moisture in blocks. These can catalyse chemical reactions.

(Adapted from: Young et al, 1998)

APPENDIX C

COMPARISON OF EXISTING SOIL SUITABILITY CRITERIA

S/N	Author	Year	Basis of Criteria	Details
1	Fitzmaurice	1958	Particle size distribution Plasticity Compactability Simplified particle size distribution test	Recommendation: 33-40% sand (min.) 20-30% clay (max.) Limit: not ≮ 5% clay OPC: 5-10% Liquid limit: 40-50% Plasticity index: Less than 22% and more than 2.5% Optimum moisture content: 10-14% (urban) 7-16% (rural) Limits: not >30% silt and clay not < 70% gravel and sand
2	United Nations	1964	Particle size distribution	Optimum: 75% sand 25% silt and clay clay not < 10% Limits: 45% sand (min.) 55% silt and clay (min.) 80% sand (max.) 20% silt and clay (max.) OPC: 4-12% by volume
3	Spence and Cook	1983	Particle size distribution Plasticity	Range: Sand 60-90% Silt 10-40% Clay 0-30% Range: Liquid limit 7-40% Plasticity index 0-20%
4	Webb and Lockwood	1987	Linear Shrinkage (Alcocks Mould)	Shrinkage limits: < 15 mm not recommended 15-30 mm recommended (use 1:20/C:S) 30-45 mm recommended (use 1:15 C:S or 1:7 L.S) 45-60 mm recommended (use 1:12 C:S or 1:6 L:S) > 60 mm not recommended. Insufficient sand Advantage: • Various soil combinations can be tested for shrinkage • Guidelines for stabiliser content given
5	ILO	1987	Particle size distribution	Limits: None specificed Recommendation: Well graded soil of max. size < 6 mm

6	Stulz and Mukerji	1988	Particle size distribution	Optimum: Gravel 7% Sand 53% Silt 20% Clay 20%
			Plasticity	Plasticity index 7-29% Liquid limit 25-50% Caution: Lateritic soils may not conform to these limits
7	Houben and Guillaud	1994	Particle size distribution Plasticity Compactability Cohesion	Range: Clay 5-20% Silt 5-40% Sand 40-90% Limits: Plasticity index 3-30% Liquid limit 24-37% Dry density 1700-2400 kg/m^3 Corresponding moulding moisture content: 4-10% Maximum acceptable load 0.3-0.6 MPa Cohesion 15,000-36,000 Pa
8	Rigassi	1995	Particle size distribution Plasticity	Recommended: Gravel 0-40% Sand 25-80% Silt 10-25% Clay 8-30% Stabiliser: OPC 4-8% not < 3% For clay content 30-70% use lime Plasticity index 15-20%
9	Houben et al	1996	Particle size distribution	Range: Gravel 0-40% Sand 25-80% Silt 10-25% Clay 8-30% Recommended: Other tests be done as well OPC: Optimum 5-6% Maximum 8% Minimum 2% Caution: Clay not > 30%
10	Norton	1997	Particle size distribution Plasticity	Recommended: Gravel/sand 45-70% Silt 15-30% Clay 10-30% OPC: 5-10% not > 10% Plasticity index 10-25% Liquid limit 25-42%

APPENDIX D

DETERIORATION AGENTS AND THEIR SEVERITY RANKING (UGANDA)

S/N	Category	No	Agent	Severity Ranking	Source	Type of Action	Effect	Affected Property		Speed	Common Defect Type
								Surface	Bulk

FIELD AND LABORATORY TESTING

SEDIMENTATION TEST (BOTTLE)

TEST TITLE:	**Sedimentation (jar or bottle) Test**
Standard:	Stulz and Mukerji (1988), Houben and Guillaud (1994).
Objective:	To determine quantitatively the approximate relative proportions of the main fractions in a soil sample.
Precision:	Low to medium accuracy.
Limitations:	It is difficult to precisely discriminate the boundaries of the grain layers, which may not always be linear. The resettling movement of sand, but more especially silt and clay can affect the results if they are taken too early. The volume of the silt and clay is slightly increased due to swelling and expansion of the particles in water. They will therefore appear to be larger than they really are.
Duration:	3 to 24 hours

APPARATUS

1. Transparent cylindrical glass jar (65 mm diameter, of flat bottom with the top sealable by the palm of the hand).
2. Clock or stopwatch.
3. Centimetre scale.
4. Clean drinking water.

TEST PROCEDURE

(i) Take a representative sample of the soil and place it into the glass jar until it is about one quarter full. Fill some of the remaining three-quarters of the jar with clean drinking water, leaving just enough space at the top to allow agitation.

(ii) Leave the bottle and its soil and water content standing undisturbed so that the soil can soak in the water for about 60 minutes.

(iii) After 60 minutes have elapsed, firmly cover the top opening of the jar and shake vigorously for between 1 and 3 minutes, then replace the bottle and its contents on a flat horizontal surface. Repeat the process again an hour later, then leave the jar standing undisturbed for at least 45 minutes. After this time, the soil fractions should begin to segregate with the heavier fraction (fine gravel and sand) settling at the bottom of the bottle. The silt, clay and organic matter fractions will settle at the top of each other in that order of lightness. Organic matter will float at the surface of the water, while the finer colloids will remain in suspension in the water.

(iv) Allow up to 8 hours before measuring the precipitated height of the segregated layers using an accurate centimetre scale. First measure the overall depth of the sediments (100%) without including the depth of the clear water covering them. Then measure the height of each fraction layer separately and record it as a percentage of the total depth. Take three measurements for each layer and record the average for the sand, silt and clay.

Results are discussed in Chapter 4 and 5.

INTERPRETATION AND RECOMMENDATIONS

The depth of each separated layer provides an indication of the relative proportions of each of the main soil constituents in the sample tested. If the results show an even distribution of sand, silt and clay, then the soil is suitable for CSB production. If the results reveal an excess or absence of either sand, silt or clay, then the soil is unlikely to be suitable for stabilisation without further modification as before. The separation of the soil fractions can be further facilitated by using a suitable dispersant or deflocculant (ILO, 1987; Houben and Guillaud, 1994). Sodium hexametaphosphate (tannic acid) is commonly used. The use of ordinary salt is not recommended as it is a known flocculant causing the agglomeration of clay particles in water (Grimshaw, 1971).

FIELD AND LABORATORY TESTING

LINEAR SHRINKAGE TEST

TEST TITLE: **Linear Shrinkage Test (LST)**

Standard: Webb and Lockwood, 1987; ILO, 1987; Webb, 1988; Stulz and Mukerji, 1988.

Objective: To estimate the proportion of the clay fraction in a soil from its linear shrinkage value and by implication, the stabiliser type and amount.

Precision: Medium to high accuracy.

Duration: 7 to 10 days.

Limitations: Requires at least one week before results can be obtained.

APPARATUS

1. Sieve of aperture opening 6 mm (or 5 mm)..
2. Alcocks wooden mould: internal dimensions 600 x 40 x 40 mm open at the tope with formica lined walling.
3. Wooden spatula (small).
4. Accurate measuring scale (vernier calliper or rule to 0.5 mm).
5. Lubricant: mould release oil, vaseline or silicone grease.
6. Clean drinking water.

TEST PROCEDURE

(i) Take about 1.5 kg to 2.0 kg of the representative soil sample that has passed through the 6 mm sieve and moisten it. Make the soil wet enough to form a paste which when tapped brings water to the surface, thus indicating proximity to the OMC. Confirm the proximity to OMC by squeezing the damp soil lump in the hand and checking if it can retain its shape without soiling the hands. Also drop the lump from about one metre height and check if it does not break into several smaller lumps.

(ii) Measure and record the internal dimensions of the mould and lightly smear the inside with a suitable lubricant. This is done to prevent the soil adhering to the surface of the internal walls of the mould which would interfere with the movement while shrinking.

(iii) Fill the soil into the mould in three equal layers while tapping and lightly pressing it in all four corners using a wooden spatula. This is done to eliminate any trapped air pockets from the soil. Smoothen the top of the final layer using the spatula so that the soil exactly fills the mould box. This ensures that any soil that would have extended over is removed. It would have otherwise increased the drag as the sample dries out and begins to shrink.

(iv) Leave the filled box with its contents in the sun for a period of 5 to 7 days, or in a shaded area for 7 to 10 days. During this period, the mould and its contents should not be rewet, e.g. by rain or addition of more water.

(v) After the above period in (iv), the soil should have dried out and shrunk either as: a single piece, several pieces with cracks across the width; or hogged up and out of the mould in a crescent shape. If the soil dried out in several pieces, gently elevate the box to about 45° on one end and tap it to move all the cracked pieces to one end of the mould. If hogging is the result, then take the dry length as the average length of the upper and lower faces lengthwise.

(vi) Calculate the linear shrinkage by determining the shrinkage gap by deducting the length of the dry soil sample from that of the mould cavity box. The shrinkage is expressed as a percentage of the original mould cavity length, or simply in millimetres.

$$LS = \frac{L_W - L_d}{L_W} \times 100 \ (\%)$$

Where LS = linear shrinkage (%)

L_W = length of the wet bar (mm)

L_d = length of the dry bar (mm)

Results are discussed in Chapters 4 and 5.

RESULTS AND RECOMMENDATIONS

Shrinkage and severe cracking across the width of a soil is an indication of high sand content soils of low clay and silt contents. Shrinkage with hogging up and out is an indication of a high clay content soil.

Soil for CSB production should shrink or swell as little as possible. The more the clay content of the soil, the more it will tend to shrink. Such soils can be modified by controlled mixing with sand, in which case the test has to be repeated using the blended soil. The amount of linear shrinkage in soils have been used to suggest the type and amount of stabiliser to be used (Webb and Lockwood, 1987). Low shrinkage soils (high sand content) are better stabilised with OPC, while high shrinkage soils (high clay content) are better stabilised using lime.

WET COMPRESSIVE STRENGTH TESTING

TEST TITLE: **Wet Compressive Strength Test (WCS)**

Standard:	BS 3921: 1985; BS 6071: Parts 1 & 2: 1981; Neville 1995
Objective:	To determine the wet compressive strength of various categories of blocks
Precision:	High accuracy (BS 1610: 1964 Grade A or B)
Delimitations:	Results can be affected by the sample size, moisture condition, curing age, the rigidity of the testing machine, type of end preparation used, and the rate of application of the load.
Duration:	2 to 5 minutes per test
Specimen description:	Various CSB categories: MCSB, CSSB, CLSB cut to cube size 100 x 100 x 100 mm, 28 days old, pre-immersed in water for 24 hours prior to testing.

APPARATUS

1. Compression Testing Machine: Denison 7231, machine number T91080/ES 8171, calibration certificate number 04818 (re-calibrated December 1998, 1999, 2000). The machine has the means of providing the rate of loading, capacity 100-300 KN. Accuracy complies with BS 1610 grade A and B. The upper platen of the machine is able to align freely with the specimen as contact is made. The lower platen bearing the sample is plain and non-tilting.
2. Plywood packing 105 x 105 x 20 mm; free from knots and new for each sample tested.
3. Masonry saw machine (concrete lathe cutting machine); trademark Clipper, model (t W 2-40-3), MS 27, serial number 606726, 4Kw 50Hz T/M 2900 (Luxembourg). Used to reduce blocks of 290 x 140 x 100 mm to 100 x 100 x 100 mm prisms.
4. Water tank 2000 x 1000 x 600 mm with provision for free circulation of water at bottom of samples (to immerse and soak blocks overnight)
5. Laboratory balance: accuracy up to 0.1% of the mass of the specimen.

TEST PROCEDURE

(i) Take three samples each cut from the various categories of block types; measure and record their area and volume individually.

(ii) Immerse the samples in a water filled tank (temperature 10-25°C) provided with a free circulation frame at the bottom for 24 hours.

(iii) Remove and leave to drain on a stillage or damp sacking until the blocks stop dripping (about 30 minutes).

(iv) Wipe clean the bearing surface of the platens to remove any loose grit. Place the specimen between two new 4 to 20 mm plywood sheets with an over-hang allowance of 5 mm along each edge. Make sure the centre of the mass of the specimen coincides with the axis of the machine.

(v) Make a final check of the correct positioning and packing, then apply the load without shock at a rate of 15 KN/min. Maintain the load up to failure (1 to 5 minutes).

(vi) Record the maximum load at failure and as well as the rate of loading (these were recorded automatically by the machine and a printout obtained).

(vii) Note the type of failure mode and calculate the crushing strength as below:

$$\mathrm{WCS} = \frac{M_L \ (\mathrm{KN})}{A_S \ (\mathrm{mm}^2)}$$

Where: WCS = wet compressive strength (MPa)

M_L = maximum load (KN)

A_S = cross section area (mm^2)

(viii) Calculate the average of 3 tests done on each category of material from the same mix batch and processing method.

Repeat the same procedure to determine the dry compressive strength (DCS) value, except that the samples do not need to be soaked in water for 24 hours as before. Instead they are oven-dried till constant mass and tested as described above. Results are discussed in Chapter 6.

TOTAL WATER ABSORPTION AND VOLUME FRACTION POROSITY

TEST TITLE: **Total Water Absorption Test (TWA)**
Total Volume Porosity (TVP)

Standard:	BS 3921: 1985; BS 1881: Part 122: 1983; ASTM C 642 90
Objective:	To determine the water absorption values of blocks and to calculate the total volume porosity.
Precision:	Medium to high accuracy
Delimitations:	By using the cold immersion method, some air may still remain entrapped in the pores.
Duration:	24 hours
Specimen description:	Various CSB categories (as before); fired brick samples and concrete block samples.

APPARATUS

1. Ventilated drying oven (BS 2648).
2. Tank with bottom grid to ensure free circulation of water.
3. Electronic weighing scale (accurate to 0.1% of the specimen mass).

TEST PROCEDURE

(i) Dry the specimens from each category of blocks to constant mass in the oven at temperatures between 110°C and 115°C.

(ii) When cool, weigh each specimen to an accuracy of 0.1% of the specimen mass.

(iii) Immerse the specimens in a single layer tank immediately after weighing so that water can circulate freely on all sides and bottom of the sample. Leave a space of about 10 mm between adjacent samples in the tank.

(iv) After 24 hours, remove the specimens, wipe off the surface water while shaking lightly with a damp cloth and reweigh each specimen within 2 minutes of removal from the water tank.

(v) Calculate the water absorbed by each sample (TWA) expressed as a percentage of the dry mass using the equation:

$$TWA = \frac{(M_W - M_D)}{M_D} \times 100$$

Where: TWA = total water absorption (%)
M_W = wet mass (g)
M_D = dry mass (g)

Obtain the mean of three samples of the same mix and processing category (Chapter 5).

(vi) Calculate the total volume porosity using the formula.

$$n = \frac{(TWA)\,\rho}{100\,\rho_W}$$

Where: n = porosity (fraction)
ρ = block dry density (kg/m^3)
ρ_W = density of water (kg/m^3)
TWA = total water absorption (%)

The results obtained are discussed in Chapter 6.

THIN SECTION MICROGRAPH OF CSB SURFACES

EVALUATION OF SURFACE PERFORMANCE

SLAKE DURABILITY TEST

TEST TITLE:	**Slake Durability Test (SDT)**
Standard:	ISO (1967); ISRM (1971); Gamble (1971); Franklin and Chandra (1972).
Objective:	To monitor the performance of surfaces of various block samples when subjected to wetting, abrasion and drying.
Precision:	Very high accuracy
Delimitations:	Results can be affected by sample shape, size, weight and number; sieve mesh size, drum size and speed of rotation; state of sample moisture condition; duration of slaking; chemistry of the slaking liquid.
Duration:	10 minutes
Sample description:	Soil type (soil 'S'); sample types (IPD and TDB of varied cc 3% to 11% compressed at 6 MPa and 10 MPa; curing age (7 days, 14 days, 28 days, 56 days). FBS, CBS and RBS also tested

APPARATUS

1. Slake durability test equipment: sieve mesh opening 2mm, drum size (140 mm diameter), 100 mm (long); speed of rotation (20 revolutions per minute); electrically operated.
2. Electronic weighing scale.
3. Standard laboratory oven (105°C)
4. Timer (clock).
5. China clay dish containers (90g to 300g).
6. Laboratory tap water (Coventry).
7. Hand-held magnifying glass.

TEST PROCEDURE

(i) To represent each specimen sample, select 4 or 5 pre-cut samples each weighing between 115g and 125g with a total mass of between 450g and 550g. Oven dry the samples overnight to constant mass.

(ii) Weigh and mark the dish containers separately and then together with their contents from (i) above.

(iii) Place the pre-weighed and oven-dried samples into the drums. Couple the drums to the mortar drive, making sure they are connected in the correct order.

(iv) Fill the tanks with laboratory tap water (about 20°C) to the level indicated on the side of the tanks and immediately set the test in motion using the switch. Run and time the test for 10 minutes.

(v) At the end of 10 minutes, switch off the drive, remove the drums and record the state of the water in each bath and the type of sediments deposited at the bottom of each one. Examine the worn samples using a hand-held magnifying glass.

(vi) Place the removed specimens into their respective china containers and dry them to constant mass using the oven set at 105°C. When successive weighings yield the same result, record the dry mass.

(vii) The slake durability index (SDI or I_d) is then given in percent terms by the ratio of the final to original mass:

$$SDI = \frac{M_f}{M_O} \times 100$$

Where: SDI = slake durability index (%)

M_f = final mass (g)

M_O = original mass (g)

The container mass should be deducted before determining the SDI in all cases.

(viii) Repeat steps (i) to (vii) for all other samples to be tested.

CLASSIFICATION OF RESULTS

Existing and proposed classifications and grading are described in Chapter 7, the results obtained are also discussed in Chapter 7.

Attitudes towards Rainwater Harvesting

0. Summary

- increasing interest and formation of national rainwater associations in East and Southern Africa
- NGOs in West Africa starting to realise the potential of rainwater harvesting; some local cultural obstacles seem to exist
- Donor organisations funding development aid are generally interested in rainwater harvesting. In cases where organisations have specific water policies and strategies, rainwater harvesting is either specifically mentioned as an "alternative water source" or implied under "appropriate technologies"
- Many of the donor organisations who responded to our questionnaire have already funded in one way or the other rainwater harvesting
- Potentials of rainwater harvesting are seen in areas
    - that cannot be served by standard technologies such as groundwater and handpumps or
    - have contaminated/unusable groundwater
- Obstacles to rainwater harvesting are
    - the unconventional approach needed for dissemination and small and very local investment on the household level
    - finance of investment cost for the water storage facility
- Water legislation in South Africa specifically mentions rainwater as a permissible source of water but forces at the same time users to use only water from an authorised service provider

1. Introduction: New developments in rainwater harvesting in Africa

Interest in rainwater harvesting is on the increase in many countries of Eastern and Southern Africa. National rainwater harvesting associations are being formed in Eastern and Southern Africa. The first one of these national associations was the Kenya Rainwater Association (KRA), founded in 1995. Three national associations have been formed in 1998 alone: in Ethiopia, Uganda and Zimbabwe. The associations are usually started at national rainwater workshops. They see their tasks in information dissemination, lobbying and networking.

For SIDA, the Swedish International Development Agency, the

> ***potential for household-level rainwater harvesting in Ethiopia and Eritrea is considered to be enormous and will be investigated.***

There is a serious initiative in Southern Africa to promote knowledge on rainwater harvesting and the implementation of it. Participating countries are Namibia, South Africa, Mozambique, Zimbabwe and Zambia.

2. Local NGOs and rainwater harvesting in West Africa

While a lot of interest is being noticed in Eastern and Southern Africa, no important activities in rainwater harvesting are reported from West Africa. Therefore several video shows and discussions have been organised in selected countries (Senegal, Ghana, Togo, Benin) to see the reactions of NGOs re. rainwater harvesting[i],[ii],[iii].

Some general observations by the organisers of the video shows on rainwater harvesting:

Interest

- Women groups and women departments of NGOs are much more interested than general development departments of NGOs (where usually many men are represented)
- Interest was greatest in areas where there were real (seasonal) shortages of water. This was esp. true for Togo and Ghana with very low water levels of lake Volta leading to rationing of water and electricity. This also affected water pumping and caused many shortages in the distribution system!

Problems

- Rainwater harvesting was sometimes associated with traditional or pagan culture esp. in urban environments
- As rain and rainmaking is often associated with witchcraft, some church groups have difficulties also with rainwater harvesting, being seen as pre-Christian, "backward" practice

Utilisation

- The potential of rainwater harvesting in mobilising own resources, materials and skills was seen by many groups, but not always
- The potential for local artisans and small industry opens chances for local employment
- The improvement of general living conditions by rainwater harvesting was appreciated
- Many people saw rainwater harvesting as an ideal supplement to the public (and unreliable) water supply
- There was a great demand of how-to-do materials (booklets, brochures) to try and put rainwater harvesting into practice as seen in the video.

3. Water Professionals and rainwater harvesting

A letter with an associated questionnaire has been designed. A representative sample of water professionals has been selected. The mailing is being done at present.

4. Donor organisations and rainwater harvesting

4.1. Survey

Donor organisations have been contacted in order to find out their policy and associated strategy, their intervention tools and their partners in project planning and implementation. Questions related also to previous involvement in rainwater harvesting as well as potential advantages perceived as well as objections. Letter and questionnaire sent are given as annex 1, the list of donor organisations contacted as annex 2 (The Collaborative Council made it clear that they are not a donor organisation).

A total of 18 donor organisations were contacted:
- 6 mulitlateral aid organisations
- 8 bilateral aid agencies
- 4 "donor NGOs"

Answers came from 9 out of 18 contacted organisations with varying degree of detail.
Sending questionnaires to unknown people has very little chance of getting an answer, as was also the case in this situation. At least one reminder is necessary. Organisations generally responded to e-mail inquires more readily than to letters sent by fax or mail. Organisations involved in rainwater harvesting were more readily giving some feedback than those not involved.

4.2. Results

4.2.1. Water policies / strategies

Every donor organisation who responded showed interest in rainwater harvesting and often asked for more information or expressed interest in the results of the sudy!
Not every donor organisation has its own sectoral policy for water. Organisations like Water Aid have a strategic framework, which lays out general aims and strategies. But each country office has its own strategies which states how that country office will contribute to the general objectives. So WaterAid could easily have many different views on the appropriateness on rainwater harvesting and find no contradiction in that! Similar approaches hold true for UNICEF (...”our country offices independently design strategy and implementation methodologies”) and many donor NGOs (e.g. church donor organisations).

Out of the four policy documents of contacted donor organisations(see Annex 3), two of them specifically mention rainwater harvesting:
UNICEF gives support to specific “mini-projects” in addition to standard water and sanitation interventions within its “programme strategies”, inter alia:

> ***Rainwater harvesting, using roof tops as well as through the construction of underground check dams and dikes***

NEDA assigns an importance to our topic by stating in the Technology part of the Policy section:

> ***The development of techniques for harvesting rainwater for drinking purposes will be fostered,...***

The two other documents not yet quoted mention explicitly the promotion and support of appropriate technology (or appropriate products). For SDC, rainwater harvesting is included in this context:

> ***In view of our technical strategies related to the use of appropriate technology, rainwater harvesting is very much in line with our sector policy (quote from letter of .SDC to the author).***

SDC further elaborates its strategies in the economic field by stating:

A reliable and sustainable water and sanitation infrastructure depends on

- ***appropriate technology (see above)***
- ***promotion of local construction.***

  <u>Household</u> and community-level water and sanitation installations will stand a better chance of being used in a sustainable manner if they are built and maintained with local material and know-how,...

The emphasis on household solutions is not found in the other documents studied but clearly indicates an important prerequisite for the widespread use of roofwater harvesting.

4.2.2. Current involvement in rainwater harvesting programmes

Half of the organisations (UNICEF, SDC, WaterAid, SIDA) who answered stated that they already had funded projects which included at least a rainwater component. SIDA has – according to the documents received – a defined strategy to promote and spread rainwater harvesting in East and Southern Africa.

4.2.3 Potential applications, obstacles to rainwater harvesting

UNICEF mentions the need to supply people under difficult conditions, where rainwater harvesting will become important:

> ***...as safe water coverage increases, the remaining unserved people tend to be those that cannot be served by more traditional technologies (notably groundwater and handpumps) and thus alternative technologies such as rainwater harvesting will become more important.***

The other important area where rainwater harvesting is seen as a viable solution is in areas, ***where groundwater contamination is on the rise*** (as seen by UNICEF and SDC). SDC mentions the example of Bangladesh with about 2 million handpumps which lay in areas where the groundwater is containing arsenic!

...rainwater catchments maybe another interesting alternative

SIDA talks about HRWH, household level rainwater harvesting. They quote Ministers (e.g. of Uganda) asking donor agencies to consider and give more attention to HRWH. But they also see some difficulties:

- The participatory approach required for dissemination (of HRWH) is unconventional and investments are small, numerous and very local. The existing institutions are not geared to working with this kind of projects and may be reluctant to do so.
- Another main constraint is finance of the investment cost for the water storage facility. Many households have great difficulties to accumulate funds for the investment and have no access to credit.

5. Water legislation in view of rainwater harvesting

5.1 South Africa

Water legislation of South Africa was considered relevant, since it is very recent (1997/1998). South Africa has tried to incorporate present knowledge of water resources and their sustainable use into the new legislation (for details of acts referred to, see Annex 4).

Chapter 1 (Interpretation and fundamental principles) of the National Water Bill (1998) defines the entitlement to water use (chapter 4) and refers to Schedule 1. This schedule (permissible use of water) is mentioning roofwater as a permissible water use:

A person may, subject to this Act -
(c) store and use run-off water from a roof.

However this right is made relative in the Water Services Act of 1997, stating in chapter 1 (introductory provisions), paragraph 6: Access to water services through nominated water services provider:

... no person may use water services from a source other than a water services provider nominated by the water services authority...

Users of rainwater can come into conflict with the water services act, if there is a nominated water services provider in the area. Clarification of this possible conflict will be sought together with the new initiative of rainwater harvesting in Southern Africa.

Attitudes towards Rainwater Harvesting

Annex 1: Letter and questionnaire to donor organisations

Dear water professional,

I'm writing this letter in the hope that you may be able to assist us in our research programme, called „Domestic Roofwater Harvesting in the Humid Tropics". It is a 3-year-programme to generate reliable information for water policy planners, water supply professionals and ultimately householders. The programme just started and is funded by the EU. It involves 4 partners from India, Sri Lanka, England and Germany. Links are being developed with practitioners in Central America and East Africa.
The programme will examine literature and practice from many parts of the world, but it is expected that those from humid tropical areas will be of most use, since Domestic Rainwater Harvesting technology and economics are dominated by factors like climate and culture.

In the view of water resources getting scarce, it is becoming obvious that we should use every available water resource as e.g. rainwater. Rainwater harvesting has been and is successfully practised for millennia around the Mediterranean as a supplementary source of water or the only one available. In many countries of Asia, Africa and Latin America, it is currently newly introduced or its use widened. One of several components of the programme is to define the information needs of organisations active in the water sector. We would therefore like to ask you about your funding policy for the water sector and how it is implemented in the different countries.
We will compile our research findings (we just have started) and will make them available to you if you wish so. They will also be available on a web site, which will soon be established. Please feel free to contact me for any additional information you might want to get.
Thanking you in advance for your time and efforts invested

- also in the name of the other partners involved

Hans Hartung
Responsible Task Manager for Task B: Institutional Values and Decision Making

Domestic Roofwater Harvesting in the Humid Tropics

A. Water programmes

We would be grateful, if you could give us some details about the general way of your funding of water projects
– maybe documents are available which would help us to explain the procedures:

a) Aid policy and strategy related to water
   - in general
   - is rainwater harvesting in line with your funding policy or not?
     If not, why not, are there any objections?

b) Intervention tools for the water sector within you organisation
   - on the policy level
   - on the project level
   - in technical assistance in general

c) Partners in project planning and implementation
   What kind of partners are you working with?

B. Rainwater harvesting programmes

a) Have you already (co)funded projects where rainwater harvesting was involved?

If yes:

Would it be possible to get details about the funded programmes?
(reports if possible?)
What kind of funding strategy did you use?
Do you have general documents on rainwater harvesting considering their successes and failures, highlighting components of the project to be considered in similar projects?

If no:

Do you have general objections to rainwater harvesting and if so, what are they?
In particular do you consider financing single households to be in line with your house rules?
What kind of information on rainwater harvesting would you be interested in receiving?

Domestic Rainwater Harvesting:
Perceptions of Water Professionals and the way forward

1. Survey

A survey of water professionals and their perceptions on rainwater harvesting was done, using a questionnaire and personal interviews

The experience from previous surveys was taken into account: No fax or mail questionnaires were sent out. The distribution of the questionnaires was exclusively done by e-mail. Around 73 professionals of the a.m. groups were contacted. The result was not very encouraging, only around 12% (9 persons) of the contacted people answered, most of them already being familiar with rainwater harvesting.

The mailing list of GARNET, the Global Applied Research Network in Water Supply and Sanitation (called: "water-and-san-applied-research) was also used to distribute the questionnaire to more than 200 practitioners in the water field. Only three people responded.

Beside the mail survey professionals met at conferences (WEDC-conference 1999, Addis Ababa; World Water Forum 2000 in The Hague) or during travels in Africa (Southern Africa, May 2000) were interviewed.

2. Results

2.1 Respondents to the Water Professionals Questionnaire

A total of 26 people answered either orally or by writing.
More than half (14) of the people who answered orally or by writing use either rainwater harvesting in their house or are involved with rainwater harvesting programmes or projects.
Three of them came to rainwater harvesting when assessing water resources of small islands.
It is obvious from the answers, that water professionals are not aware of the full range of possibilities of rainwater harvesting. Instead, they discuss the topic only for a specific application they know (e.g. only rainwater harvesting in the rainy season, only for a desert location,...). Rainwater harvesting is mostly associated with drylands by them so that even the title of the questionnaire/project (Domestic Roofwater Harvesting in the humid tropics) is overlooked.

2.2 Future role of Domestic Roofwater Harvesting

The wording of the question was as follows:

> *"Will domestic roofwater harvesting play an important role for specific areas in securing drinking water needs of the future ?"*

Three people who responded were not in favour of roofwater harvesting: they either had enough water within their own area, did not know anything about it or saw it as only a last resort if everything else fails
All others saw an important role of DRWH for the future in a resource threatened world. Specific geographical areas were mentioned:

- small islands
- peri-urban areas: the opinion on peri-urban areas was divided. While many saw a great potential for rainwater harvesting (corrugated iron roofs, water by vendors very costly, reduces flooding and can increase groundwater recharge) one person opposed: people do not own their shack and its owner does not own the land it is built on, there is generally very little space for storage in these surroundings
- dry (arid and semi-arid) areas (specifically in India, where rainwater harvesting was traditionally practised on a large scale, declined in the last decades and is now starting to be revived).

Problems experienced with water were cited for which rainwater harvesting could make a contribution towards a solution:
- **decreasing water availability** (i.e. in ground- and surface water sources). One person (of several who cite this problem) suggested that by using rainwater for non-potable purposes, drinking water sources could be conserved! (while others see the value of rainwater especially in its good quality!)
- **bad infrastructure** with unreliable supplies, esp in peri-urban areas
- **no access to ground- or surface water**
- **rising water prices** for piped water supplies (esp. in European countries)
- **long distances and time spent** to fetch water in rural areas of the South
- **decreasing water quality** due to contamination of water sources.

3.3 Advantages of Domestic Roofwater Harvesting

Many advantages of domestic roofwater harvesting are seen:
- **closeness** to the home. This aspect was mentioned most.
- **simple technology** and consequently simple operation and maintenance, an advantage esp. for rural areas with weak infrastructure
- **reliable and controllable source (because of individual ownership)** of good quality water. This statement is not shared with other respondents. Some of them point out the reasonable quality of rainwater or the easiness to improve the quality by simple means. Other see (bacteriological) quality as the main concern with respect to rainwater (see chapter 3.4). Good chemical quality is especially valued in areas with highly contaminated groundwater (such as with fluoride or arsenic). The soft rainwater is very suitable for washing with little soap.
- **economic advantages** (compared to standard solutions or water to be bought from vendors). This is certainly site specific and must be established at the location of the intended use of rainwater. The collected rainwater can also be used for kitchen gardens and animals and thus improve the household economy.
- **increases the available options** to a community (in some areas it might be the only option)
- **reduction of soil erosion,** flood water retention, can improve ground infiltration, but also protection of house walls from rainstorms

3.4 Concerns with regard to Domestic Roofwater Harvesting

The wording of the question:

"What are your concerns with regard to domestic roofwater harvesting:
- *water quality?*
- *water quantity?*
- *other concerns?"*

Water quantity was voiced 6 times as a concern. Many respondents are fixed to rainwater harvesting during the rainy season, since otherwise the storage cost would get too high. This shows the very different and often limited knowledge of rainwater harvesting. Reliability of the water source was seen as a draw back as rain does not follow a regular pattern.
In-county information on rainfall data and specific water demand (of different water user groups for different purposes) was considered difficult to obtain in many cases.
Construction skills was seen as a serious concern, because of much damage to rainwater harvesting having been done in the past by bad design and construction. Tank building will always be needed so that specific and thorough training for artisans was demanded.
Maintenance of roofs and tanks was seen missing, i.e. essentially cleaning of these two components in regular intervals.
No standard solutions are available or are considered possible at all by one water professional. Conditions for the use of rainwater are so much different and rainwater harvesting could be serving different purposes in different surrounding so that site specific designs have to developed and experimented with. No design criteria to incorporate the varying parameters are available.
Water quality was the concerned voiced by half of the respondents. This refers to the bacteriological quality. While 3 water professionals are convinced of the "excellent" quality of rainwater (or that its

quality can be kept high), others see rather problems with the (bacteriological) quality of rainwater when its use is intended for drinking purposes:

- problems of birds and their droppings especially on islands
- intrusion of small mammals in the storage container
- cleanliness of roof (and storage)
- collection from thatched and earthen roofs (still used as an important roofing material for houses in rural areas).

There is a persistent misconception of water getting bad over time when stored! This is actually not true; research shows that rainwater quality gets better with time when certain criteria are met (no light into the storage, protection from whatsoever animals, aeration).
For one professional, it is without doubt that the quality of rainwater cannot satisfy drinking water requirements and suggests solutions: solar heating of the water as a treatment process.

3. The next steps

Rainwater harvesting is most often associated with

- rural areas and
- (semi)-arid climates.

The title of the research project "Domestic roofwater in the humid tropics" shows already that the scope for rainwater harvesting is much larger. The humid tropics have indeed some advantages for rainwater harvesting (e.g. small storage size)! At the same time the need for water is getting obvious in towns and cities and also here, rainwater harvesting could play a role.

3.1 Peri-urban areas

Although the introduction of rainwater harvesting into peri-urban areas was discussed very controversial and some respondents were opposed to it, it seems that there is an enormous need for water and a great potential for rainwater harvesting.
Urban water supply organisations seem rather helpless of how to tackle the problem of ever increasing peri-urban areas and their water supply. In the meantime street vendors sell water of doubtful quality at very high prices.
The advantages of domestic roofwater harvesting such as closeness to the home, economic advantages, simple technology and individual ownership (in an environment where often people come from different backgrounds and regions and are not willing to co-operate) combine in favour of its use in this environment. Further action research and closely monitored implementation of larger scale field trials are important!

3.2 Water quality

Half of all people interviewed voiced their concern on water quality of rainwater harvesting. This is the first argument that come to peoples mind when they are asked about rainwater. Quality means in this context always bacteriological quality. (Rainwater is one of the important options in areas with serious groundwater pollution with arsenic of fluorides).

Information on bacteriological quality of stored rainwater but also suggestions for treatment (before entering a storage tank, in it of after its withdrawal) must be made available as clear and simple messages.

3.3 Closing the information

Many people interviewed had never heard of rainwater harvesting as an option in water supply: Yes, in their village at home they tried to collect water from the roof when it rained with a pot but can this seriously contribute to household water supply? Half of all people of the survey specifically asked for more information, some for examples of where it was used with success. How can awareness on rainwater harvesting be created among water professionals? How can information reach the people in demand of water? In what form, in what messages should the information be conveyed?

Annex 1
Domestic Roofwater Harvesting in the Humid Tropics, a short questionnaire

Will domestic roofwater harvesting play an important role for specific areas in securing drinking water needs of the future?

yes, because of

I'm specifically thinking of these areas

no, because of

In order to make an informed decision, I would need reliable information on

What are your concerns with regard to domestic roofwater harvesting:

water quality, please specify

water quantity, please specify

other concerns like

or

Advantages often associated with domestic roofwater harvesting are its being close to the house and the individual ownership. Such harvesting may be operated for full or partial water supply. What do you consider as advantages?

Have you had any close experience with domestic roofwater harvesting?

Yes, I use it in my house

Yes, I have been involved in projects where roofwater harvesting played a role.

We, the Rainwater Harvesting Research Group would appreciate, if you could give us details

No, never had experience but I'm interested

No, I can't think that it can be useful

Yes, I'm interested in roofwater harvesting, specifically in

Thank you very much for your time!

Hans Hartung, FAKT, Kanalstr.23, D-97990 Weikersheim, Germany, fax +49.7934.990031

The inclusion of domestic roofwater harvesting (drwh) in a national water legislation framework

esp. looking at Botswana, Ethiopia, Kenya, Lesotho, Namibia, South Africa, Tanzania, Uganda and Zambia

by Hans Hartung & Christine Patschull, FAKT, Germany

The major objective of water law is to establish a framework for the protection and control of water resources in a country. A Water Law defines the legal entitlement to water and identifies the rights and obligations tied to water use and thus provides the prescriptive parameters for its development.

Until now, water laws don't deal with **domestic roofwater harvesting (drwh)** as the direct collection of roof runoff and storage for later use. So far, drwh is working outside the legal framework on project-level. Practitioners are often rather glad to not wake up sleeping dogs, instead of working on appropriate legislation, and follow a strategy to first create facts without too much government involvement.
This practice implies a lot of limits to drwh. While individual village-level drwh projects may succeed in the short term, their long terms sustainability may be severely tested in the absence of an appropriate institutional and legal framework at all levels. It is also unlikely that widespread replication of appropriate technologies and community-based implementation strategies will be achievable in the absence of supportive institutions at higher levels, even if isolated project success may be possible. Moreover, we will show that the organisation of the water sector has severe direct and indirect implications for the promotion of drwh and thus can't be ignored.

WATER LEGISLATION AND ITS INDIRECT IMPACT ON DRWH

Water legislation of 10 countries in Sub-Saharan Africa was reviewed, looking specifically at how it relates to domestic roofwater harvesting The national water laws of *Botswana, Ethiopia, Kenya, Lesotho, Namibia, South Africa, Tanzania, Uganda, and Zambia* reveal that drwh is nowhere part of a national water management strategy. SA is the only country, where drwh is mentioned as a possible supply for private households. Thus, drwh plays no role in water legislation, but as we will see, the legislation has lots of indirect impacts on drwh.

- **the legal status of (rain-)water**

Except in SA, where everyone has a right to water supply, all water resources including rainwater are treated as a property.

	Water Resources owned by	**Controlled by**	***Quote national water law***
Bots wana	Public	Govern-ment	*There shall be no right of property in public water (II.4)*
Ethio-pia	People		*All water resources are the collective property of the Ethiopian people*

Kenya	Govern-ment	Minister	*The water of every body of water or upon any land is vested in the government. The control of every body of water shall be exercised by the minister in accordance with this Act. The right to the use of every body of water is hereby declared to be vested in the Ministry. (II.3, II.4)*
Lesotho	Nation	Minister	*The ownership of all water within Lesotho is vested in the Basotho Nation. The Power to control and regulate the use of water shall be exercised by the Minister. (5.1., 5.2.)*
South Africa	No pro-perty, but a public right	Govern-ment	*Everyone has a right to basic water supply and basic sanitation (Water Services Act 97, 3.1.) The national Government, acting through the Minister, has the power to regulate the use, flow and control of all water in the Republic. (3.3.)The Minister is ultimately responsible to ensure that water is allocated equitably and used beneficially in the public interest, while promoting environmental values (3.2., National Water Act 98).*
Uganda		Govern-ment	*All right to investigate, control, protect and manage water in Uganda for any use, is vested in the government and shall be exercised by the Minister and the Director in accordance with the provisions of the part of the schedule. (II.I.5)*

- **extra government-permits/ land ownership required**

No matter whether someone is supplied with public water or not, extra permits are required in some countries for the private installation of drwh-tanks on household-level. Public allocation of water resources dominates in these countries through the granting of permits on water use. The state holds water resources as an aspect of sovereignty and cannot alienate such ownership of the basic resource and concomitant responsibility. In some countries you also need to own the land, which probably makes drwh impossible in peri-urban areas

	Permit/ Ownership required	***Quote***
Botswana	No, if you own the land	*The owner or occupier of any land may, without a water right construct any works thereon for the conservation of public water, and abstract and use public water so conserved, for domestic purposes. (II,6,b)*
Ethiopia	**No**	*No person may construct waterworks or withdraw water from a water resource, either for its own use or for the supply to others (5.1./1998) No permit shall be required for domestic use (21.1)*
Kenya	Yes, for the waterworks, you have to own the land	*A permit is not required for the abstraction or use of water from any body of water for domestic purposes by any person having lawful access thereto, if such abstraction is made without the employment of works (VIII, 38.)*

Lesotho	Yes, for the waterworks, you have to own the land	*Any person having lawful access to water may abstract and use such water for domestic purposes (3.2.)* *Whenever a water use requires the construction of water works the water officer shall grant the water use permit subject to the construction of such waterworks within the specified time under specified conditions. (4.6)*
Namibia	(forbidden)	-
South Africa	**No**	*A person may, subject to this Act* *take water for a reasonable domestic use in that person's household, directly from any water resource to which that person has lawful access* *(c) store and use run-off water from a roof*
Uganda	Yes, for the waterworks, no matter if you own the land	*No person shall acquire or have a right to (a) use water, (b) construct or operate any works. (II.I.6)* *A person may while temporarily at any place, or being the occupier of or resident to any land, where there is a natural source of water, use that water for domestic use. (II.I.7,1)* *No person shall construct or operate any works unless authorised to do so under this Part of the Statute. A person wishing to construct any works or to take and use water may apply to the Director in the prescribed form for a permit to so.*

In Europe**, Germany** is leading the way in encouraging widespread utilisation of rainwater catchment systems both for domestic supply and other purposes. Interest in household rainwater catchment focuses mainly on non-potable uses such as garden watering, toilet flushing and use of washing machines (Gould, S. 219).
There is no comprehensive and/or systematic legislation across Germany. Rainwater harvesting in German legislation is hindered through a general obligation to connect to and use mains water supplied by the local service provider (based on local government regulations which originated from health precautions). Service providers can make it difficult to use rainwater on the basis of these regulations. Clients of the service providers have however a right to be granted a partial lifting of the obligation to be connected and use the mains water with arguments of appropriateness and economic reasoning (Koenig, S. 76/77).
Many court cases favour these arguments. There is also a DIN (German standard) being at approval stage at the moment (mid-2001) to standardise rainwater utilisation technically.

The city of **Bangalore, South India** will be the first city in the country to have a rainwater harvesting policy. With an average rainfall of 900 till 970 mm over 7 months, Bangalore is at an elevation of 900 MSL and water has to be pumped in from 400 MSL. Thus, the pumping costs are enormous and so are power charges. Water rates are the highest in the country.
Without back-up by any legal provisions, 500 to 600 houses have drwh systems in place now and the number is growing. The Rainwater Club, a local NGO, developed not only very innovative approaches like the rendering of roofs for rainwater harvesting, but handed in now a draft policy mapping all possible sources for

harvesting rainwater. Cities like Chennai and Hyderabad already have rainwater harvesting regulations incorporated in the city municipal bye-laws, but only for multi-storeyed buildings. The Bangalore approach proposes to incorporate this into bye-laws for all new constructions and has taken into consideration all land uses – residential, institutional and commercial. Some of the government buildings will be used for demonstration. (For more information: www.inika.com\rainwaterclub)

WATER SECTOR ORGANISATION AND ITS DIRECT IMPACT ON DRWH

Each of the reviewed countries experienced a **water sector reform** during the 90s and thus, modernised the water law. The new laws reflect the global trend to decentralisation and commercialisation/privatisation of management, operation and maintenance of water services. The new laws will have an impact on the attitude (and the fact) that water is no longer supplied by the central government, but it will not necessarily get down to influence the traditional practice of multiple sourcing. There is a tendency that the newly established regulators will push for 100% metering and billing of water according to consumption without leaving customers the choice to select their water source (according to purpose or availability) and develop their own initiatives. The decentralised and privatised water sector doesn't solve the problem of access to water in rural areas.

- None of these reforms includes rwh as element of a multi sourcing-strategy. As legal schemes remain only pipelines, wells and tankers. One element of each reform is the push for 100% metering and billing without choice.
- Decentralisation took place only as far as Operation + Maintenance is concerned. The service functions became local while decision and regulatory functions - i.e. the power to implement a drwh-policy - remain central.
- Still communities are not allowed to develop their own drwh-policy.

In **Ethiopia**, the water sector was reorganised in 1992 with the establishment of federal regional water bureaus nominated by the Minister as one major renewal. The ownership as well as operation of maintenance of water services were thus decentralised on regional level, and the introduction and implementation of rwh-policies are legally up to the concerned regional bureaus since "no municipality or town shall engage in the planning and development of water supplies from any water resource or in the construction of water works without the permit issued by the implementing organ." (22.1a) Hence, there still are no self-reliant community-water-politics in Ethiopia possible that would allow users to be supported (at least with a legal framework) in having multiple sources to have a secure household water supply.

In 1999 **Bolivia** privatised Cochambamba's water system under instruction from the World bank. The British-based company that took over increased water prices by up to 200 %. Even collecting rainwater in rooftop tanks became illegal without a special permit. The crippling price rise sparked mass protests, in which tens of thousands of people took to the streets. In the end the government took back control of the water supply and re-legalised rwh. (For more information see www.peopleandplanet.org/tradejustice/briefing.asp)

	Water Sector Reform	Implementation of rwh-politics by
Ethiopia	Reorganisation of the water sector in 1992 establishment of regional water bureaus, nominated by the Minister, which own and operate supply systems	the implementing organ is the ministry as regards transboundary rivers and water bodies that flow across more than one regional government a, and the concerned regional water bureau as regards regional water resources (Art.2 def.) No municipality or town shall engage in the planning and development of water supplies from any water resource or in the construction of water works without the permit issued by the implementing organ. (22.1a)
Kenya	Decentralisation currently in progress: The role of the government will be redefined with emphasis on the regulatory and enabling functions as opposed to direct service provision. The government will ensure private sector participation (psp) and community management of services backed by measures to strengthen local institutions and sustaining water and sanitation programmes. Development of an institutional capacity building policy for the entire water sector, Legislation will be reviewed and updated, Of major concern will be the legislation as regards transfer of water facilities from one institution to another.	Defined by the government Community participation in O+M: the Government will endeavour to hand over Urban Water Supplies and Sanitation facilities to autonomous departments within the Local Authorities and Rural Water Supplies to the communities.
South Africa	Before 1994 no national institution was responsible for ensuring equitable and sustainable access to water supply or sanitation services and no structured national legislation existed regulations the provision of these services. Now, the South African constitution guarantees everyone the right to access to sufficient water and states that one of the objectives of local government is to ensure the provision of services to communities in a sustainable manner. The act says that everyone has a right to basic water supply and places a duty on all water services institutions to take reasonable measures to realise this right.	Water services are a local government function, (ownership and O+M) The minister of water affairs and forestry sets national standards to ensure enough continuous, affordable, and equitable water services Schedule 4B identifies water and sanitation services limited to potable water supply systems and domestic waste water and sewerage disposal systems

	Water Sector Reform	Implementation of rwh-politics by
Tanzania	In 1999 the responsibility for O+M was being moved to local communities realized through water committees or water user associations (wuas). The policy requires that all villages with or without facilities should establish a water fund. For urban centres the government envisages facilitation of PSP Major parameters of national water policy are community participation, community-based management, cost sharing for rural, full cost recovery for urban, full ownership , involvement of the private sector	Water supply systems are owned by the central government, while O+M is run by local communities Communities are encouraged to organize themselves in managing their own water supplies in order to reduce the dependency on the government. The government is to promote the private sector and individuals to participate in the planning, construction, supply of materials and equipment as well as in the management of water supply schemes
Uganda	Decentralization program started in 1999. The 1999 national water policy's key directives are an integrated, sustainable management with full participation of all stakeholders based on management responsibility and ownership by all users within a decentralized. Water resources in rural areas belong to the users, while urban and sewerage systems remain with the central government	In contrast to the 1995 Water Statute all water sources in rural areas now belong to the users. For urban and sewerage systems, the system ownership remains entrusted to the Central Government.
Zambia	Since 1994 Local Councils are operating water schemes or in most of the cases now own the infrastructure by holding shares. PSP und inter-community cooperation is possible, local authorities may resolve to establish a utility (PPP, together with other communities, joint ventures with other local authority or several local authorities)	A local authority shall provide water supply and sanitation services to the area falling under its jurisdiction, expect in any area where a person provides such services solely for that person's own benefit or a utility or a service provider is providing such services. (IV.10.1) A utility or service provider may construct any facility within or outside its area (24.1)Everyone can apply to be a service provider, a service provider may construct any facility within or outside its area.

SUMMARY OF SURVEY RESULTS

A survey was conducted among water professionals and activists in all 10 countries. For the complete answers see Annex II.

- Small-scale traditional practices of drwh as a precondition for the technology's acceptance exist in nearly each of the reviewed countries.
- There is little tradition of community level initiatives taking up its own water affairs.
- Awareness creation is generally weak, activists are mainly non-governmental organisations and depend on donor-funds.
- Water professionals pay little attention to drwh.
- Training: there is often too little capacity in training or implementing drwh installations: in Uganda there were funds available but not enough expertise.
- Drwh has a project image, it seems to survive mostly in donor sponsored projects.
- The perception that the water sector organisation has an impact on the spread of drwh is very weak
- There is very little experience in legal matters; conscious battling through legal conflicts would depend on donor funds
- The potential of drwh is perceived as nearly unlimited both in urban and rural areas.

EMAIL-CONFERENCE

A summary of contributions to the GARNET email conference on Policy and Professional Attitudes on rainwater harvesting, held between 10 and 24.11.2000 reveals that a comprehensive framework for legal and policy issues regarding drwh is still missing. Meanwhile there are lots of - often isolated - experiences in the regulation of drwh. Their benefits need to be highlighted now with regard to mainstreaming drwh in other countries and regions.

CONCLUSIONS

There is still no professionalisation of drwh within the scope of national water management strategies. Drwh does not play a role here since it is simply not considered. Traditions in drwh remain informal and the best way of promoting drwh at the moment is still the neighbour's tank.
While water laws are surely not the key to promoting drwh, they can certainly hinder it. Although there is a growing demand for domestic roofwater harvesting on local level, the laws remain silent on this subject.

- **All water laws except the one in South Africa totally ignore rainwater harvesting**. Neither is it part of a national water management strategy, nor it is mentioned as a way in which unconnected and/or connected households could be provided/supplemented with water for their domestic use. In Namibia drwh even seems to be forbidden (according to our correspondence with Namwater, the countries bulk supplier).
- All water laws except in Ethiopia and South Africa treat **(rain-)water as a national property**, not as a major human need or even as a right.
- The private installation of "rainwater-works" (rainwater catchment systems) for domestic uses legally requires the **ownership of the land** plus an **extra permit** in those countries where rainwater (just like all other water resources) legally belong to the state: Kenya, Lesotho, Tanzania (and Ethiopia). Independent from the land-ownership a permit is required in Uganda. No permit is required in Ethiopia and South Africa.
- Major policy functions like the power to define **legal public water schemes** - as a major precondition for the inclusion of drwh in the national water supply strategy - remain vested in the central Ministry of Uganda and Tanzania and in regional authorities of Ethiopia. In South Africa public water services are limited to potable water.
- An **independent communal drwh-policy** would legally be possible only in Kenya.

RECOMMENDATIONS

A structual change of the water sector and its process of decision-making is necessary in order to achieve long term effects. If drwh shall be more than a vague option for the left-offs in water supply, there's a need for both bottom-up and top-down approaches

- National governments should consider the role of drwh and its contribution to the overall supply.
- For the **mainstreaming of drwh**, projects and activities should concentrate more on **institution-building processes** to gain sustainability.
- A designated water services provider should not be granted the right of having to use "his water" only for all possible uses.
- More flexible approaches in water legislation. The idea of one water source for all uses was devised in water rich countries and doesn't make sense in many water scarce countries. It doesn't follow present practices. Water professionals need to take this into account.
- The principle of reasonable and equitable utilisation of water as a customary rule that governs the legitimacy of uses proved to be successful at international level. This principle can also be used at local level. The flexibility is its real strength, because the principle requires that all factors be considered in the assessment of a reasonable and equitable use when contesting for water and thus deterring the legitimacy of new or increased uses.
- In a time of increasing private sector participation (rain-)water is to be considered not as a property but as a basic human right. An example of best practice regarding the legal status of water is SA.
- Private drwh should be made possible without extra permits and
- Independent from land-ownership. Best practice here is the roof-rendering in Bangalore.
- On community-level there is a need for building a strong force to manage local resources through networking with NGOs, donors, banks and water user associations (wuas).
- Local empowerment-activities are important to push the government to allow an independent community rwh-policy (implicits a chance in laws).

A Watershed-management-project was established in Maharashtra/ India aiming at qualifying local self-help-groups through an Indian NGO. The next step was the establishment of a network between sector specific institutions: NGOs, banks and donors with the target to enforce independent local watershed-management-institutions. The result was not only the sustainable development of the *watershed* but a fundamental change in water law: Since March 2000 there is a "common guideline for watershed development" regulating. ANNEX I:

The Water Laws and their Indirect Impact on Domestic Rainwater Harvesting

BOTSWANA: The Water Act, Ch. 34:01, 1968.

1) Is rainwater utilisation mentioned at all in the legislation ?	No
2) If yes, in which context? (Give §§ and cite)	-
3) Is the legislation - helpful for rainwater h.? - restricting the use of rainwater ? - indifferent ?	Legislation is rather unhelpful as far as rwh is concerned Because it is unclear whether rainwater legally belongs to public water. "water works" is defined as works constructed for or in connexion with the (..) storage(..) of public water, (..) or the conservation of rain water (I.2) As far as public water is concerned, Part II describes the ownership of and inherent right to the use of the water as follows: "there shall be no right of property in public water" (4). "any person may, without a water right, while he is at any place where he has lawful access to a public stream or to a natural lake, pan or swamp, take and use public water therein for the immediate purpose of (a) watering stock (b) drinking, washing, and cooking; or (c) use in a vehicle, but nothing in this section shall be construed as authorizing the construction of any works (II.5.) So, **the owner or occupier of any land may, without a water right** (b) construct any works thereon for the conservation of public water, and abstract and **use public water** so conserved, **for domestic purposes** (II.6.)
4) Are there any §§ which make rainwater utilisation impossible ? In which context ? Why ?	-
5) Are there any direct or indirect prohibitions of rainwater utilisation ? How do they argue ?	-

***ETHIOPIA**: Proclamation No. 92/ 1994 – A Proclamation to provide for the utilization of water resources; Federal Water Resource Code of Ethiopia, 1998.*

Ownership	All water resources are the collective property of the Ethiopian people
1) Is rainwater utilisation mentioned at all in the legislation ?	No
2) If yes, in which context? (Give §§ and cite)	-
3) Is the legislation - helpful for rainwater h.? - restricting the use of rainwater ? - indifferent ?	No permit shall be required for domestic use (21.1) In order to minimize and misuse of water for domestic uses the implementing organ may, as necessary, issue appropriate directives and restrictions. (21.2.) ("Implementing organ " means ministry as regards transboundary rivers and water bodies that flow across more than one regional government, and the concerned regional water bureau as regards regional water resources. (Art.2. definitions)) (21.2.) No municipality or town shall engage in the planning and development of water supplies from any water sources or in the construction of water works without a permit issued by the implementing organ (22.1.a)
4) Are there any §§ which make rainwater utilisation impossible ? In which context ? Why ?	(5.1.) 1998: subject to the exceptions stated in 21.1 and 27 of this code no person may (a) construct waterworks, or (b) withdraw water from a water resources, either for its own use or for supply to others, or may supply water, whether withdrawn by him from a water resource or received by him from another supplier 3.1. (1994) A permit issued by the appropriate authority shall be required to use water resources for the following purposes: f) municipal and urban water supply, j) any use requiring construction of water works (1998) No person may engage, for profit or otherwise, in the business of (a) the construction of waterworks (as defined as " ..)) or consultancy services related thereto without holding a license duly by the implementing organ in the consultation with the concerned professional organisation, if there are any.
5) Are there any direct or indirect prohibitions of rainwater utilisation ? How do they argue ?	

***KENYA**: The Water Act, Ch. 372, 1972; Sessional Paper No.1 of 1999 on National Policy on Water Resources Management and Development*

1) Is rainwater utilisation mentioned at all in the legislation ?	No.
2) If yes, in which context? (Give §§ and cite)	-
3) Is the legislation - helpful for rainwater h.? - restricting the use of rainwater ? - indifferent ?	The 1972 Water Act states the following: The water of every body of water under or upon any land is vested in the government, subject to any rights of users in respect thereof which, by or under this Act or any other written law, have been or are granted, or recognized as being vested, in any other person. (II.3.) The control of every body of water shall be exercised by the minister in accordance with this Act (4.II) The purposes for which a permit may be acquired are as follows – (a) domestic purpose, which expression means the provision of water for household and sanitary purposes and the watering and dipping of stock; (35, VIII) In all cases of proposed diversion, abstraction, obstruction, storage of water from a body of water other than those referred to in section 38 of this Act, application must be made in the manner prescribed by this Act for a permit for such diversion, abstraction, obstruction or storage of water from or in such body of water (36.1.VIII) (a permit is not required – (a) for the abstraction or use of water from any body of water for domestic purposes by any person having lawful access thereto, if such abstraction is made without the employment of works; (38.VIII) works means any structure, apparatus, contrivance, device or thing for carrying, conducting, providing or utilizing water, excepting hand utensils or such contrivances as may be specified by the Water Apportionment Board)) **Thus,** according to the Water Act all water is vested in the government, and for rwh for domestic purposes a permit is required.
4) Are there any §§ which make rainwater utilisation impossible ? In which context ? Why ?	
5) Are there any direct or indirect	

prohibitions of rainwater utilisation ? How do they argue ?	

LESOTHO: Water Resources Act No. 28 of 1978.

Ownership	5.1. the ownership of all water within Lesotho is vested in the Basotho Nation 5.2. the power to control and regulate the use of water shall be exercised by the Minister.
1) Is rainwater utilisation mentioned at all in the legislation ?	no
2) If yes, in which context? (Give §§ and cite)	-
3) Is the legislation - helpful for rainwater h.? - restricting the use of rainwater ? - indifferent ?	3.2. any person having lawful access to water may abstract and use such water for domestic purposes 4.6.whenever a water use requires the construction of water works that water officer shall grant the water use permit subject to the construction of such waterworks within the specified time under specified conditions
4) Are there any §§ which make rainwater utilisation impossible ? In which context ? Why ?	
5) Are there any direct or indirect prohibitions of rainwater utilisation ? How do they argue ?	

SOUTH AFRICA: Water Services Act No. 18522, Dec 1997.

1) Is rainwater utilisation mentioned at all in the legislation ?	No.
2) If yes, in which context? (Give §§ and cite)	-
3) Is the legislation	(3.1.) Everyone has a right to basic water supply and basic

- helpful for rainwater h.? - restricting the use of rainwater ? - indifferent ?	sanitation. (11.1) Every water services authority has a duty to all consumers or potential consumers in its area of jurisdiction to progressively ensure efficient, affordable, economical and sustainable access to water services. (11.2) This duty is subject to – (a) the availability of resources; (…) (e) the duty to conserve water resources. (11.3) In ensuring access to water services, a water services authority must take into account, among other factor – (a) alternative ways of providing access to water services. One of the limitations that applies to the right to basis water supply is that access to water services must be gained through the water services authority and that nobody may utilise water services from another source without the authorities approval. Exactly what basic water supply is will be prescribed by the Minister.
4) Are there any §§ which make rainwater utilisation impossible ? In which context ? Why ?	
5) Are there any direct or indirect prohibitions of rainwater utilisation ? How do they argue ?	(6.1.) no person may use water services from a source other than a water services provider nominated by the water services authority having jurisdiction in the area in question, without approval of that water services authority. (6.2.) A person who, at the commencement of this act, was using water services from a source other than one nominated by the relevant water services authority, may continue to do so – (a) for a period of 60 days after the relevant water services authority has requested the person to apply for approval; and (b) if the person complies with a request in terms of paragraph (a) within the 60 days period, until – (i) the application for approval is granted, after which the conditions of the approval will apply; or (ii) the expiry of a reasonable period determined by the water services authority, if the application for approval is refused. (8.1.) a water services authority whose approval is required in terms of sections 6 or 7 – (a) may not unreasonably withhold the approval; and (b) may give the approval subject to reasonable conditions.

SOUTH AFRICA: National Water Bill (B34B – 1998).

1) Is rainwater utilisation mentioned at all in the legislation ?	Yes
2) If yes, in which	Schedule 1.1.: A person may, subject to this Act – (a) take water

context? (Give §§ and cite)	for a reasonable domestic use in that person's household, directly from any water resource to which that person has lawful access (c) store and use run-off water from a roof
3) Is the legislation - helpful for rainwater h.? - restricting the use of rainwater ? - indifferent ?	(4.1.) A Person may use water in or from a water resource for purposes such as reasonable domestic use, domestic gardening, animal watering, fire fighting and recreational use, as set out in Schedule 1. (12.1.) As soon as is reasonably practicable, the Minister must prescribe a system for classifying water resources. (2) The system for classifying water resources may – (a) establish guidelines and procedures for determining different classes of water resources; (3.2.) the Minster is ultimately responsible to ensure that water is allocated equitably and used beneficially in the public interest, while promoting environmental values. (3.3.) The National Government, acting through the Minister, has the power to regulate the use, flow and control of all water in the Republic.
4) Are there any §§ which make rainwater utilisation impossible ? In which context ? Why ?	
5) Are there any direct or indirect prohibitions of rainwater utilisation ? How do they argue ?	

TANZANIA: Water Act Bill (1999), Water Utilization Act No. 42 of 1974.

1) Is rainwater utilisation mentioned at all in the legislation ?	No.
2) If yes, in which context? (Give §§ and cite)	-
3) Is the legislation - helpful for rainwater h.? - restricting the use of rainwater ? - indifferent ?	In Tanzania water is regulated through two broad legal frameworks namely: I) water resources management, governed by the **water utilization act No. 42 of 1974**, which relates to the granting of rights to the user of water and ii) water supply governed by the **Urban water act No. 7 of 1981**. the acts provides for the regulation of the water utilization in urban areas

	through the National Urban Water Authority. Other relevant legislation exist including international river basin treaties (?) The **National Water Policy** is based on the following development objectives: to identify and preserve water sources and catchment areas and to increase the population's health through the provision of safe and adequate water supply. Major parameters addressed in this policy are: community participation, community-based management, cost sharing for rural and full cost recovery for urban, full ownership of the projects, involvement of the Private sector, water resources. The policy aims at ensuring that all sources are protected and optimally utilized. In the past, the responsibilities of operation, maintenance, and administration of water schemes was vested in local councils. This is being moved to local communities. **Community-based management of schemes is either realized through water committees or wuas**. The policy requires that all villages with or without facilities should establish a water fund to demonstrate their willingness to sustain water facilities. Communities are encouraged to organize themselves in managing their own water supplies in order to reduce the dependency on the government, and subsequently consumer will take full control of their water supplies and ensure sustainability. The government is to promote the private sector and individuals (!) to participate in the planning, construction, supply of materials and equipment as well as in the management of water supply schemes.
4) Are there any §§ which make rainwater utilisation impossible ? In which context ? Why ?	
5) Are there any direct or indirect prohibitions of rainwater utilisation ? How do they argue ?	

UGANDA: Water Statute No. 9 (Dec. 1995), Ministry of Water, Land and Environment: A national water policy (1999).

1) Is rainwater utilisation	No

mentioned at all in the legislation ?	
2) If yes, in which context? (Give §§ and cite)	-
3) Is the legislation - helpful for rainwater h.? - restricting the use of rainwater ? - indifferent ?	The 1995 Water statute restricts the use of rainwater as follows: All right to investigate, control, protect and manage water in Uganda for any use, is vested in the Government and shall be exercised by the Minister and the Director in accordance with the provisions of this Part of the Schedule (II, I, 5). Notwithstanding any other law to the contrary, no person shall acquire or have a right to – (a) use water, (b) construct or operate any works. (II, I, 6) Subject to Section 8 a person may – (a) while temporarily at any place, or (b) being the occupier of or a resident to any land, where there is a natural source of water, use that water for domestic use, fighting fire or irrigating a subsistence garden. (II, I, 7; 1) In addition to that right to use water the occupier of land or resident on land may, with the approval of the authority responsible for the area, use any water under the land occupied by him or is resident on any land adjacent to that land. (II, I, 7, 2) The rights under subsections 1 and 2 do not per se authorise a person to construct any works. 8. The Minister may, in relation to any water source where the situation so requires, by notice published in a manner appropriate for the area as the Minister may see fit – (a) prescribe places from which water may be extracted for use, (b) prescribe the time and manner in which water may be used, (c) at times of shortage or anticipated shortage – (i) regulate water to be used for particular purposes, or (ii) regulate, restrict or prohibit the application of a water permit (..), (iii) on the advice of the water Policy Committee, declare any part of Uganda to be a controlled area and establish a comprehensive and integrated plan for managing land, water and other natural resources within the area, (d) temporarily or permanently prohibit the use of water from a given source on health grounds. (8, 2) No person shall extract water unless authorised under this Part of the Statute.
4) Are there any §§ which make rainwater utilisation impossible ? In which context ? Why ?	
5) Are there any direct or indirect prohibitions of rainwater utilisation ? How	3, 18,1: No person shall construct or operate any works unless authorised to do so under this Part of the Statute. (2) A person wishing to construct any works or to take and use water may apply to the Director in the prescribed form for a permit to do so. (5) the director may grant the permit under sub-section (4) on

do they argue ?	conditions that he may think fit and such conditions may – (a) require the payment of fees or charges that may be prescribed under this Statute – (6.32.1) The Minister may .. fix fees and charges for (b) the taking or use of water under a water permit granted under this Part of the Statute

ZAMBIA: Ministry of Energy and Water Development: National Water Policy, Nov. 1994; The water Supply and sanitation Act No. 28 of 1997.

1) Is rainwater utilisation mentioned at all in the legislation ?	No.
2) If yes, in which context? (Give §§ and cite)	-
3) Is the legislation - helpful for rainwater h.? - restricting the use of rainwater ? - indifferent ?	IV.10.1. notwithstanding any other law to the contrary and subject to the other provisions of this act, a local authority shall provide water supply and sanitation services to the area falling under its jurisdiction, except in any area where a person provides such services solely for that person's own benefit or a utility or a service provider is providing such services. IV. 12.1. Everyone Can apply to be a service provider.
4) Are there any §§ which make rainwater utilisation impossible ? In which context ? Why ?	
5) Are there any direct or indirect prohibitions of rainwater utilisation ? How do they argue ?	

ANNEX II:

The Survey – questions and answers

	I. People often know little about the possibilities of a decentral harvesting of rainwater (rwh), at least in countries without a tradition in rwh like India or a lot of smaller islands. ***- If there is some traditional rwh practises in your country, could you describe them in a few words?***
ETHIOPIA	Yes, in Botswana the practise that has been commonly adopted and used is the roof catchment and the threshold (ground catchment. The roof became common in use when other people begun construction using tin roofs. Otherwise from the thatched roofs, people are often have been discouraged by the quality (brownish colour etc) of the water harvested from the thatched roofs. Some have even preferred to just put their buckets or drum in the open space than along a thatched roof. The other method that has been commonly used in some areas of Botswana is the one in which the threshold is used as the catchment. In all of these methods, the storage facilities range from the use of buckets, drums and some ferrocement tanks. But in most cases people have found considered the tanks expensive and are therefore not willing to invest in them. Therefore their supply is usually of a very short term.
KENYA	Yes, there are many types of traditional RWH technologies in Kenya, difficult to describe without diagrams, but they include using clay pots and using natural depressions such as rock crevices.
LESOTHO	Well, a great deal of work has been done to equip school buildings and others with rwh systems. From my experience, however, the water is poorly managed and usually wasted. The episodic tendency of the weather leads to a condition where: you do not have water when you need it; you do not need water when you have it. There must be a much broader strategy implemented with respect to water, and rwh (→ Roof water harvesting, GN) is only one component. On our campus we have a well, 2 spring supplies, a stream supply, lots of tanks, 3 rwh systems, plus an elaborately designed landscape of earthworks, terraces, diversions, and stone retaining walls, and swales. Earlier this week we had very heavy rains, and the earthworks were working wonders. They are cheap, efficient, and should be installed prior to rwh. Roofs are only a small part of the potential catchment. (IY) Generally spoken, rwh is unknown and not practised. The only exceptions are the dams' structures, manly for irrigation purposes. (GN)

NAMIBIA	Yes, traditionally roof water harvesting is known and practised on a small scale throughout the country, where people actually try to conserve every drop of water they can get hold of, but it is illegal. All the water during a rainy season - when occurring - is supposed to recharge the aquifers (Grundwasserleiter) instead of evaporating in drums. Furthermore in the cities rainwater is supposed to reach the drainage of the sewage systems, because water is hold back that might cause damage due to too little water to flush the systems. In Windhoek for example we are the only city world-wide cleaning sewage to drinking water quality, therefore an diluting rain is usually very welcome, but therefore it is also illegal to do roof water harvesting.
SOUTH AFRICA	What would you regard as traditional? All the practices I have seen in South Africa emanate from having access to manufactured products. These products were often developed for other uses but used for RWH by innovative individuals. Most systems in South Africa are straightforward guttering leading to some form of surface mounted tank. In Namaqualand in the older houses the tank has been built underneath the house and is raised out using a simple pump.
ZAMBIA	No, there seems to be no extended tradition of rwh in Zambia, although, drums to collect rainwater are used by individuals in the southern part of the country where the rain season is much shorter then in the rest of Zambia. additionally farmers dig shallow wells (in southern province called "chikala") for domestic water supply. Shallow wells are the main source of domestic water supply between December and June/July. This supply is dependent on the water table fluctuations. The other common method is to collect rainwater directly during a rainstorm using a bucket or a drum.

	II. Once people are confronted with the idea of dwh, they usually start to show much interest. And if dwh is already realised locally, most of the people are very satisfied. Thus, rwh for domestic uses often seems a question of awareness. - ***Are there any actions taken in Lesotho to increase the use of and awareness for dwh (by government, development cooperation, ngos)? Could you describe their major achievements or bottlenecks ?***
BOTSWANA	Yes, recently there has been a lot of activities geared towards the promotion of rainwater harvesting in Botswana. My organisation has been pioneering in most of these activities. There are some government bodies which have

	also been involved in the practise of harvesting rainwater especially the local authorities at household level and the ministry of agriculture at agricultural level (livestock watering and irrigation). Well I will start the bad news first, yes there has been a lot of bottlenecks, obviously. Some of the tanks which were constructed some years back have now become white elephants simply because people have alternative piped water supplies. There is poor maintenance of rwh facilities with gutter falling down or the water left to rot for ages inside the tanks. In some villages which we visited people complained of the bad odour of the water after having stored for long. Some have even cited that tadpoles even develop inside the water tanks. In areas of very severe or less severe water scarcity the tanks that have been provided in schools and clinics are still being utilised fully. It's only that there was no involvement of end-users so most people do not know how to take care of the facilities to ensure that there are no contaminants into the water as result of foreign material going inside the tanks such as bird droppings, dead leaves etc Attempts have been made to formalise a Botswana Rainwater Harvesting Association, which will involve or bring together various practitioners in this field. The good news is that I think there is a possibility of getting government funding to support some of the rwh programs such as pilot projects etc. There needs to be countrywide campaigns to assist in the promotion of this practice.
KENYA	No. Awareness creation in Kenya is very weak, partly due to the costs involved and the thin number of active professionals in RWH. However, Awareness creation has been made by: Demonstration training sessions, usually by NGOs such as KRA, Mass media (mostly radio), Pamphlets and newsletters (mostly by NGOs)
LESOTHO	I think also the technical problems have not really been addressed. It is not simple to collect water off very large roofs. The guttering and piping has to be very carefully installed. On large roofs, the gutters often sag after a few years and start tearing off, and are not maintained. On a long roof the gutters are carrying a heavy load and have to be carefully set to gradient. In addition, they need reinforcing. For example, just last week we put up gutters and tanks on a new building. I used aluminium strapping to tie back the gutter brackets onto the roof. This adds enormous rigidity and strength to the installation. My office is above a roof water cistern on my own house, and getting the water around a big building is a thorny problem. I used a funnel set-up, buried pipe (40mm) to get the water around the back of the house, and this system works very efficiently. (IY) Awareness building will be a starting point, for rwh as any

	other appropriate technology. The technical problems should not be underestimated, neither the institutional requirements involving any innovation. (GN) I don't know of any Governmental initiative on rwh (but this does not mean that nothing is ongoing). In our Helvetas NRM programme (1997-2005), we have defined water management practices as one key component. Rwh is part of it. BBCDC is one partner in that programme and can be considered as a leading competence centre in water management in Lesotho, including rwh. The main achievements: 7 years of experiences on site based water harvesting techniques and training of hundreds of rural students. Establishment of the competence centre, various action-research activities, holistic approach. Bottlenecks: lack of professionals/committed people in action-research, lack of medium or long-term commitment by donors, weak institutions on NGO and Government side. We from Helvetas don't have the means to fully promote the concept as we would like. Our programme will be phased-out in 2005. (GN) Generally open earth dams have been since the fifties/earlier the main approach. But GoL with its water diversions encouraged loss of water rather than its collection. Lately, roof water harvesting has been popularised in drier south of Lesotho through the Soil + Water Conservation Division of government in collaboration with donor supported projects (MDP/GTZ; Swedeforest & PTC II projects now adopted by RSDA in the permaculture intervention). (LM)
NAMIBIA	.
SOUTH AFRICA	As far as I am aware only one NGO has tried to raise awareness around RWH. The problem with their approach is that they tried to provide in one go the full requirement. This proved too expensive for the householders. I think one of the manufactures of the galvanised tanks has given some support as in the Eastern Cape a number of small businesses developed assembling the tanks and transporting them to the houses. Most awareness has been created by a household successfully implementing rwh and neighbours copying.
ZAMBIA	1) We have no information on concrete actions on rwh in Zambia but have been informed that some officials have participated in regional conferences on this subject i.e. a workshop in Tanzania was attended by Zambians from MEWD, National Institute for Scientific and Industrial Research and from World Vision 2) A number of RWH activities have been initiated in Zambia through governmental and non-governmental organisations. An assessment of RWH activities in Zambia (Malesu, Phiri and Muzyamba, 1999) conducted in

	December 1999 revealed that the concept is relatively new and practised by a handful of households and institutions (schools and clinics). **A training of trainers course in Rainwater Harvesting was conducted between 10th April and 28th May 2000. The Regional Land Management Unit (RELMA) based in Kenya in conjunction with MAFF/LM&CF sponsored this training. Thirteen (13) participants were drawn from southern, eastern and Lusaka provinces. The training took place in Choma and four demonstrations were set up at farm level. The main focus of this training was on imparting practical skills in designing and construction of RWH structures.** Follow up on the trainees to this course has revealed that the knowledge gained is used in different ways. Most interesting is one case in Southern province where an officer has used the knowledge gained to construct sinking wells for farmers at a fee. The officer has been motivated to carry on practicing rainwater harvesting to supplement his income. One trainee in the Eastern province mobilised a community interested in constructing a roof catchment structure and asked them to contribute bricks, sand and stones. The community is currently scouting for funds to purchase cement and start construction of the tank. Most trainees have sat down waiting for the Project Support Office to provide funds for them to implement rainwater harvesting. Formation of the Zambia Rainwater Harvesting Association (ZARHA) The LM&CF programme facilitated the formation of ZARHA towards the end of November 2000. In view of the training in RWH conducted by the programme it was important to form an association that would fully facilitate the implementation of RWH activities in Zambia. The second national workshop was sponsored by RELMA and it was at this workshop that an executive committee was put in place. ZARHA will utilise the capacity built to enhance RWH activities in Zambia. Three ZARHA members, namely Mrs. Glenda Mulenga Kasuba, Mr. Bob Muzyamba and Mr. Maimbo Malesu were invited to attend the Southern and Eastern Africa Rainwater harvesting Network (SEARNET) conference held between 10 and 14 December 2000 in Nazareth, Ethiopia. The conference was a forum for exchange of information and experiences as well as planning for country activities. Zambia was proposed as the venue for the next conferences in December 2001. Constraints • *Inadequate co-ordination among co-operating institutions,* • *Inadequate training in RWH* • *Inadequate of government policy on RWH* • *Poverty*

	• *High cost of construction materials* • *Inadequate community organisation*

	III. Full rwh often seems too expensive for the poorer half of the population except under the most favourable climatic conditions. So either partial rwh can be used, or it s introduction is part of an aid package, or it is accepted to be the means by which (richer ?) households increase their water security. - ***Could you shortly describe the attitudes of water professionals on (multiple sourcing of water and therefore of) partial rwh ?***
BOTSWANA	There has been only a few believers in the practice of rainwater harvesting. However, other professionals have seen the need to revisit this practice which was done by our ancestors. It is not a new practice. Therefore, with the move towards being a water conservative society most professionals cannot ignore the fact that rainwater harvesting is a very powerful water conservative tool given the country's finite water resources. This would be useful for both urban and rural Botswana. Most of our rural population rely on borehole water which is a very unreliable resource taking into account that the recharge rates of groundwater are very low in most parts of the Botswana. Some rural areas have very saline water from the boreholes which is even unsuitable for livestock watering too. With the new Water Conservation Policy there has been some aspects of rainwater harvesting included in it. Other professionals need a push or need to seed something tangible out of the benefits of rainwater harvesting. Sometimes it is difficult to promote something unless people see and start getting affected by a problem that is how most of us tend to learn.
KENYA	Traditionally, the attitudes in Kenya have been that water is supplied by the Government. However, due to the failure of the Government to meet these expectations, communities have learnt to either form groups through which they work collectively at RWH projects or seek donor funding (mostly cost-sharing). The latter option has been more successful. But even then, only a very small proportion of the potential households in Kenya that could benefit from RWH has been lucky to benefit.
LESOTHO	The earth dams promoted by the soil/water conservation division (MOA) is hidden under their objective of soil and water conservation. (LM) For example, the Governmental Department dealing with rural water supply (DRWS)- a long- term partner of Helvetas- has not yet started with

	including rwh into the technical packages. Rwh and a more holistic water management concept are important topics to be included in its future business. So generally, I think rwh are more or less unknown and/or not systematically promoted up to now. And that in a country known for its regular water shortages/droughts! (GN)
NAMIBIA	.
SOUTH AFRICA	Most professionals in South Africa totally ignore rwh and concentrate on unsustainable piped schemes, including desalination plants. Very few look at using different sources of water for different purposes as the communities are doing at present. Although only the rich can afford custom installations because of the large manufacturing base in SA and the mobility of the population, it is relatively easy to obtain old containers. For example in the Eastern Cape a 200 l chemical drum costs R80. Before it is used it is cleaned using boiling water to get rid of the chemical residue. Using a number of these containers significant storage can be built up over a period without incurring huge expense. **- What are in your opinion the strongest arguments for rwh in South Africa ?** the fact that we have a well developed manufacturing base, good distribution but large numbers of rural people without access to sufficient water supply is a compelling case for promoting rwh. Coupled with water conservation and re-use of water rwh could quickly raise the standard of living of many people without incurring vast O&M costs.
ZAMBIA	Water professional in Zambia seem not to pay much attention to rwh

	IV. How do you estimate the influences of good legislation and a decentrally organized water sector on the promotion of rwh?
BOTSWANA	This question is not very clear to me. Could you kindly try and explain this one to me
KENYA	1. Good legislation is very important, as until recently, the water Act was silent on RWH. Even now, this needs strengthening. 2. Kenya is in the process of decentralising the water sector and letting communities manage their water. This is in the right direction, so long as water resources are looked at from a hydrological point of view. One advantage in using RWH is that there are few conflicts of hydrological nature, as RWH systems are mainly household based. This strength should be highlighted.

LESOTHO	Legislation is absolutely irrelevant. Dissemination of current best practices is what is required. (IY) Legislation focussing on rwh is irrelevant at this stage. We need to look at it in the context of water affairs whose legislation is available but rather unhelpful in our case. (LM) Legislation is just one element. It should reflect the real intentions and commitments of the stakeholders. Legislation alone is irrelevant, if no institutions and people are behind it. (GN)
NAMIBIA	.
SOUTH AFRICA	legislation is not the key to promoting rwh. SA law has no problem with domestic rwh but at the moment there is a huge debate over free water. This will have a bigger effect, especially on poor communities as they will reason why invest in rwh when the government has promised the water for free.
ZAMBIA	1) The new water policy and the activities of the new Regulator NWASCO will have an effect on the operation of the provider of water and sanitation services. One of the main issues is the reduction of unaccounted for water, which means the reduction of wastage by the consumers. The Regulator will push for 100% metering and billing according to consumption implying that consumers will not have the choice to water their vegetable garden or lawn with tap water unless there are prepared to pay a cost covering price, and possibly a subsidies for the consumption of the poor. This might have an impact on the need to harvest rainwater 2) The decentralised water sector still favours supply of good quality water to the urban areas and less to the rural areas where clean water is an issue. The private sector is only interested in supplying water to the consumers at a cost (which is more sustainable). Water providers in the rural areas concentrate on drilling boreholes and constructing earth dams for communal use. These options are expensive to implement and maintain. RWH has not been clearly defined in the current water policy as an option for water supply. However, the current policy presents an opportunity for ZARHA to lobby for the strengthening of RWH policy in Zambia.

	V. Is the current national water-legislation helpful for rwh or rather restricting it ? in practice, how relevant is it ?
BOTSWANA	Besides the Water Act, there is also the Waterworks Area Act which defines areas that have been declared as

	catchment areas for some of the dams here. Therefore if there is any activity going on within this area the government is bound to intervene especially that involving surface water. There is apparently not much restriction in using any borehole water within your own plot, and again I think that there is no borehole water act! One thing that I have observed also is the clashing of water development guidelines especially that of the department of water affairs and the ministry of agriculture. What is happening is that, a syndicate of farmers after having acquired a land right can approach the ministry of agriculture and request to be built a small earth dam which they could either use for livestock watering and/or irrigation. However, before this can be done the department of water affairs would have to be contacted to ensure that this dam is within designated catchment areas for bigger dams. The farmers have to pay 10% of the total cost for this dam. I do know if I am actually answering your question or have gone off tangent. Otherwise water legally belongs to the government, but within you own plot you can sink a borehole depending on whether there are no alternative piped supplies nearby especially in areas that are not serviced or very remote areas where you have been allocated a farm or whatever.
KENYA	There has been a more recent water policy (1990), which mentions RWH. This is better than nothing, but more legislation is necessary to include emerging technologies and modern thinking. I will need to do more research on the legal meaning of the Water Act (1972) -as I'm not a lawyer to understand it fully. However, to answer your questions on the other aspects: 1. A permit is not required for RWH, so long as no pumping device is used. However, if a pump is used, a permit is required. Very confusing. For instance, if two farmers make RWH systems of similar capacity say 150 cum., one has tanks above the ground and therefore doesn't need a pump, while the other lets the water flow into a dam where he pumps it up. The latter requires a permit.
LESOTHO	It is overly negative. Lesotho allows water to blow out of it at a massive rate each rain event. The opportunity to reduce this without depriving anyone else of water, is virtually infinite. Witness current flooding in Mozambique. Government does a poor job of innovating or implementing; it should mediate and disseminate, and outside that, interfere as little as possible. (IY) I see no impact (see above). (GN) - In practice, how relevant is this for rwh? Irrelevant. (IY, GN)
NAMIBIA	.
SOUTH AFRICA	None
ZAMBIA	6) The Act 28 gives exclusivity of service provision to the providers and the right for individuals to generate these

	services for themselves, but does not exclude the delegation of these services by the providers to third parties. The Regulator will put this in practice as we can see from his policy.

	VI. On local level, communities have the possibility to raise their own regulations and bylaws. ***- Do you know cases where communities took use of their right to develop their own rainwater policy ? what where the results?***
BOTSWANA	No. unfortunately there has not been something like that here. And like I have indicated most communities are of a very marginal status to be able to afford bigger tanks or facilities for harvesting rainwater at household level. But where there are community structures built for rainwater harvesting especially for livestock watering, The community seems not eager to carry their responsibilities of maintaining the structures. After completion of the structure it is handed over to the community for operation and maintenance. I think that probably this may be due to lack of operation guidelines.
KENYA	Many of the RWH projects in Kenya have been achieved through community efforts, and they have been successful (Govt projects usually involve river developments).
LESOTHO	Our campus has a very elaborate reticulated multiple source water supply system. There has never been any clash between local or national water regulation, and no one has had to concern themselves. Our efforts are making more water available to the general community, and not less. Following recent rains, the level of water in our 5 meter deep well, rose by 3 meters...all due to careful landscape design. (IY) With regard to earth dams, ownership can be of 2 categories (even on public land) – individual or community. I am not sure how one can own a dam privately on public land. (LM)
NAMIBIA	
SOUTH AFRICA	No, don't know of any council which has taken this step. just one clarification only Local government can promulgate bylaws, it is not a national competency.
ZAMBIA	No. We have no knowledge of communities developing a rwh-policy, but as the councils are operating the water schemes or in most of the cases now own the infrastructure by holding shares in a CU, I can see no obstacle for them to develop such a policy if it is of benefit to their community.

	VII. Where do you see the best chances for rwh in Lesotho and why: in urban, peri-urban or rural areas ?
BOTSWANA	Both. the urban and peri-urban areas together with the rural areas have an equal chance into rwh. The water tariffs in the urban are quite high because there has been a lot of expenditures towards the development of the water infrastructure involving a more 400km water pipeline from north of the country down south to the capital city Gaborone. This is reason for increased water tariffs. Now, really I think that society can move from using clean piped water for gardening or washing cars or other external uses and instead harvest rainwater and use it for those activities to reduce strain on the already existing water supply resources . As mentioned earlier, there are some rural areas in which there can be an absence of water for more a two days or so. This at times may be due to a breakdown inside the borehole, or that the water level has gone much lower and so on. Now with rainwater as an alternative resource this can reduce the impact of these kind of incidents on the communities affected. Rainwater harvesting also can reduce the impact of drought on especially the most vulnerable communities. The health/socio-economic status of people in rural areas who are very vulnerable because most are unemployed can improve as they eat healthier food which they could have grown out of rainwater or even use the money for income generation.
KENYA	RWH in urban and peer-urban areas can be successful among the wealthy and middle class. This is because they live in spacious compounds where RWH can be practised. The poor live in slums, where RWH infrastructure is either not practical or there are dangers of pollution.
LESOTHO	Virtually unlimited potential for exploitation. Earlier this week, small stream beside our campus was estimated to be flowing at a rate of 20 cubic meters / second during rainstorm......Water scarcity is a myth.... poor management is a fact. (IY) Urban and peri-urban areas are excellent for roofwater harvesting for obvious reasons; while the general rwh as put to us in this questionnaire has unlimited potential in rural communities. (LM) rwh can be multiplied faster in urban and peri-urban areas because of the better conditions for awareness creation and service delivery. But the chances for improved rwh in general are very good anywhere. It’s just a question of organisation (commitment, communication, project management, fund raising). Helvetas would be keen to do more, but time and money are running out…(GN)

NAMIBIA	
SOUTH AFRICA	In rural areas where there the possibilities of getting communal water systems to household level remain remote. However in urban areas this might change as water becomes more scarce in SA and the marginal cost rises making it more attractive to recycle grey water for irrigation/flushing of toilets and using rwh to reduce demand from the municipal system
ZAMBIA	1) The best changes to introduce rwh in Zambia a probably in the south of the country in rural areas, in low income areas where a network or Kiosks do not exist and in urban areas where big plots are maintained (gardens and lawns) 2) The promotion of RWH has the best chance of success in the rural and peri-urban areas of the country. Dwellers in these areas are faced with serious water shortages especially during the dry season. In the rural areas people have to walk long distances to access relatively clean drinking water whereas the peri-urban communities are also faced with problems of contaminated drinking water caused by poor sanitation and high population density.

DTU

Ram Pump Programme

Ram pump system design notes

Suitable areas for a ram pump system

Although all watercourses slope downwards to some degree, the gradient of many is so shallow that many kilometres of feed pipe or canal would be needed to obtain a fall of water large enough to power a ram pump. Ram pumps can be made to run with drive heads of less than one metre but they are not normally considered viable unless heads of two metres or more are available. If it would take a long length of feed pipe or canal to achieve this head, a ram pump system would be prohibitively expensive. The best geographical area for ram pumps is one which is hilly, with rapidly dropping watercourses and, ideally, springs.

In some areas of the world good regional records of rainfall and flow from springs and in watercourses are kept in government offices and libraries. In others, another agency may have carried out recent relevant studies. If any hydrological studies are available for the region in which you plan to install ram pump systems, you can save time, effort and costly mistakes by consulting the records and using their findings in your site design.

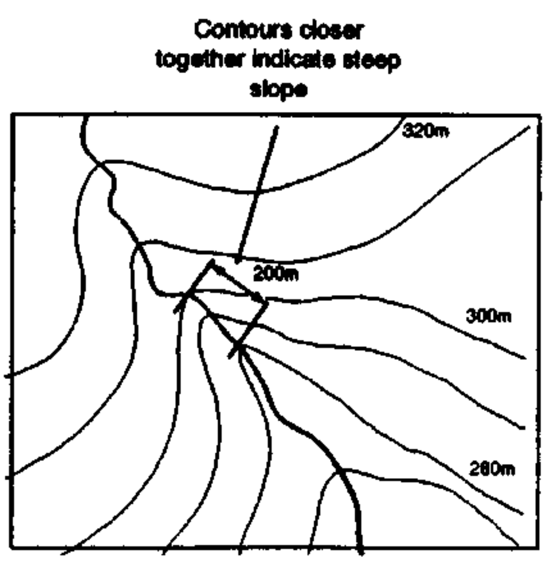
After potential sites have been identified, they must be surveyed. The survey yields information about site dimensions and the materials required to construct the site as well as, when more than one site is surveyed, yielding a cost and performance comparison.

Designing a good drive and pump layout is crucial to achieving good system performance and limiting the amount of maintenance required. The aim is to be able to achieve a large head of water between the drive tank and pump, while using a short drive pipe to connect them. The best and cheapest sites are those where the land falls rapidly, allowing all pipework to be short.

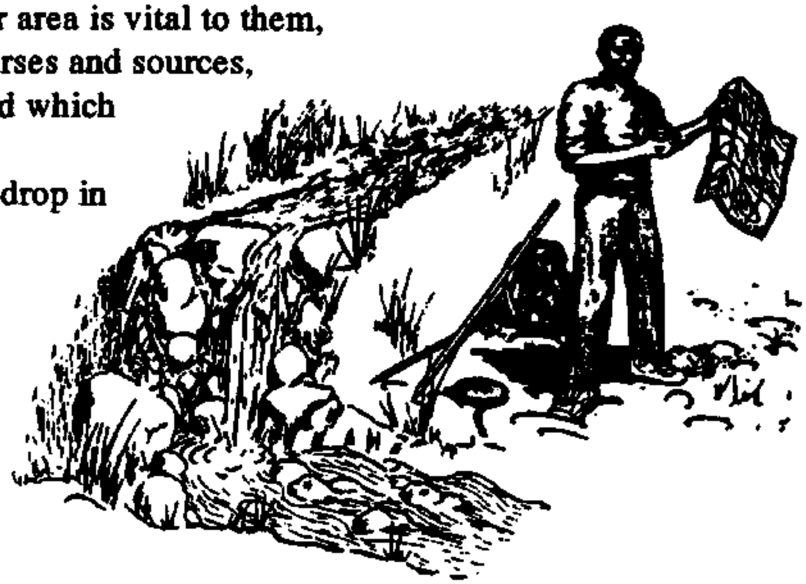
What to look for

Before arriving at a community to survey for a ram pump system, consult any available large-scale contour maps of the area. Look for places near to the community where streams cross contour lines and measure the distance along the stream between two contours. The average stream gradient can be obtained by dividing the height change between contours by this distance. An average gradient of at least 0.02 (0.02 or 2% is the same as 1 in 50) is needed for a water supply ram pump system. The pump will often be installed alongside rapids or a waterfall. If stream flow data for the area is available, look for seasonal variations, particularly during the dry months, and also for any data on the increase of flow during floods.

The section of stream shown in the map alongside falls quite rapidly. Where the contours are closest together on the stream's course, there is a drop of 20m over a distance of 200m, giving an average slope on that section of 10%. This site would be worth looking at.



People living in a community are frequently the best source of reliable, up-to-date information about that particular area. The water in their area is vital to them, so ask them about local watercourses and sources, which ones they prefer to use, and which ones regularly dry up.

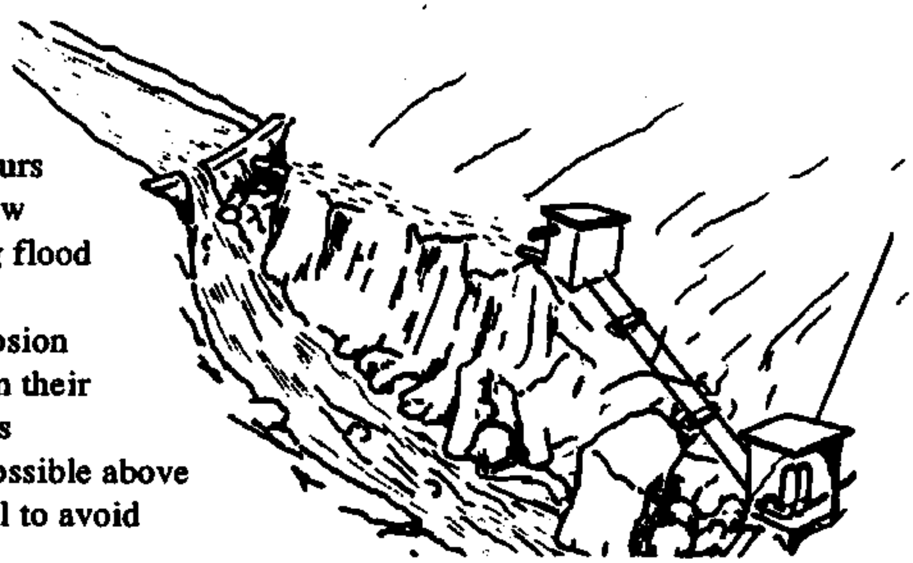


Sound is a good indicator of a drop in water. Where a watercourse is noisy and turbulent it will be dropping rapidly. It can save surveyors a lot of time to ask local people to show them places where the water is noisy, where it falls rapidly, and where there are rocks in the stream bed. Also ask to be shown any springs in the vicinity, particularly any with a source at the side of a valley along which a stream flows.

Allowing for floods

It is important to find out how the watercourse changes during a flood. Although spring-based systems are less susceptible to the extremes of flooding, it is still worth investigating and being aware of flooding as a potential problem when using a spring.

In very heavy rainfall, watercourses can swell to many times their normal flow within a short space of time. Design of a drive system must take account of these worst weather conditions, even if they only last a few hours each year. Ask local people how far the water rises during a big flood and look for evidence such as deposited rocks and stream erosion on the banks to help to confirm their reports. Keep the pumps and as much of the drive system as possible above the maximum flood water level to avoid unnecessary damage.



In the system sketched here, the main flow of flood water and debris is guided past the pumps by the large boulder or outcrop. Whilst the pumps may be submerged in a very high flood they will be protected from damage by most water-borne debris.

The one part of the system that will always be in the path of a flood is the dam or diversion structure. Bearing the expense in mind, this must either be built to withstand the worst flood conditions or built to be easily repairable. Some protection against the worst damage to a dam should be included in the design, including a cage protection for the system intake, a floodwater overflow in the dam wall and boulders anchored into the stream bed above the dam to reduce the impetus of rolling stones.

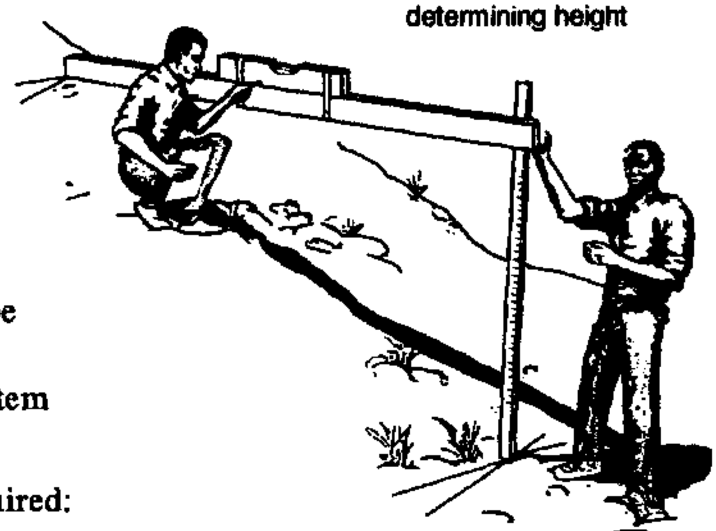
Normally the pump(s) should be sited above floodwater level, but in some cases (particularly where the drive head available is marginal) this can be impractical. In these circumstances the pumps need to be sited so that they are protected from any debris in the flood, or so that they can be easily removed when a flood is expected.

Site surveying

Surveying should be in two stages, a preliminary assessment to locate potential sites, and a full survey to select the best option. In brief, the *preliminary survey* will involve the following:

- consulting any relevant maps and hydrology studies;
- travelling to potential sites to make a preliminary assessment and consult local people;
- selecting one or more sites with a high potential that will be surveyed fully.

Simple method of determining height



The *full survey* of selected sites must be sufficiently detailed to provide all the information necessary for accurate system design.

The following information will be required:

Water source flow This figure must reflect the minimum flow of the water source in a normal year and so the measurements must be taken during the dry season. In order to ensure that the figure represents a typical minimum, local people should be consulted about the flow patterns over recent years. Some indication of maximum expected flows should also be obtained.

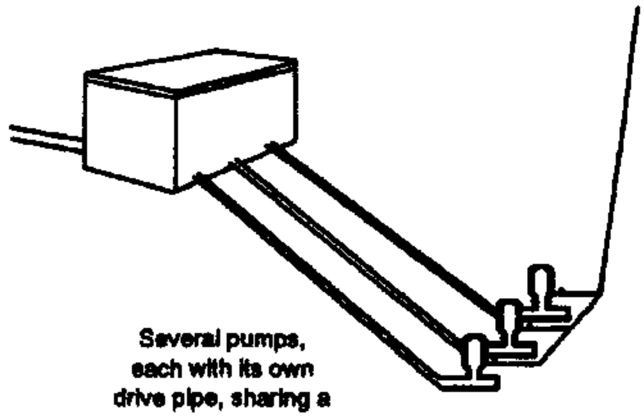
Drive head The maximum possible drive head of the site or the average angle of the slope below the water source should be measured.

Delivery head The height from the water source to the expected point of delivery should be measured. This will provide a rough estimate of delivery head but to be accurate the drive head should be added to this figure to give the actual delivery head.

Water requirement This should be estimated with reference to the population to be served (allowing for growth) or the area of land to be irrigated.

Pump selection

When selecting a ram pump there are often a number of decisions to be made concerning both its type and size. To make these decisions wisely, it is helpful to have some information about the site where the pump will be used. An estimation of the available drive flow and delivery head are needed, along with the anticipated delivery flow requirement. Knowing these will help to ensure that the correct pump is chosen. The main decisions to be made are:



Several pumps, each with its own drive pipe, sharing a common drive tank

- whether to buy an imported pump or to manufacture one locally;
- the size and number of pumps to be used.

Pumps with drive pipes of between ¾" and 4" are often commercially available or can be imported fairly quickly from manufacturers in Europe, N. America, etc. Larger models, with up to 12" drive pipes are also obtainable but usually have to be manufactured to order. Choosing between pumps from different manufacturers is not always straightforward. Comparisons of flow and efficiency can be made if the data is available. Cost, however, is normally very important, and varies considerably from pump to pump and manufacturer to manufacturer. The need to import spare parts and their cost should also be carefully considered. Where the source flow is large the choice is often between using one large pump or a number of smaller ones to meet the required delivery. Each model of ram pump with its recommended drive pipe will operate over a specified range of drive flows. In general, pumps are more efficient towards the lower limit of their drive flow, but produce a greater power output with large flows. A number of pumps can be used in parallel sharing a single drive tank and delivery pipe, but they must have separate drive pipes.

Using several small pumps rather than one large one can have the following advantages:

- each pump can be set for high efficiency;
- if the source flow falls below the required drive flow one pump can be stopped, allowing a reduced delivery flow to be maintained;
- a single pump can be stopped for maintenance work to be carried out without stopping all delivery flow;
- smaller sizes of pipe are often more readily available, whereas large steel pipe may have to be imported at high cost: it is also harder to work with large diameter pipe and to transport it;
- the maximum delivery head is generally higher on smaller pumps.

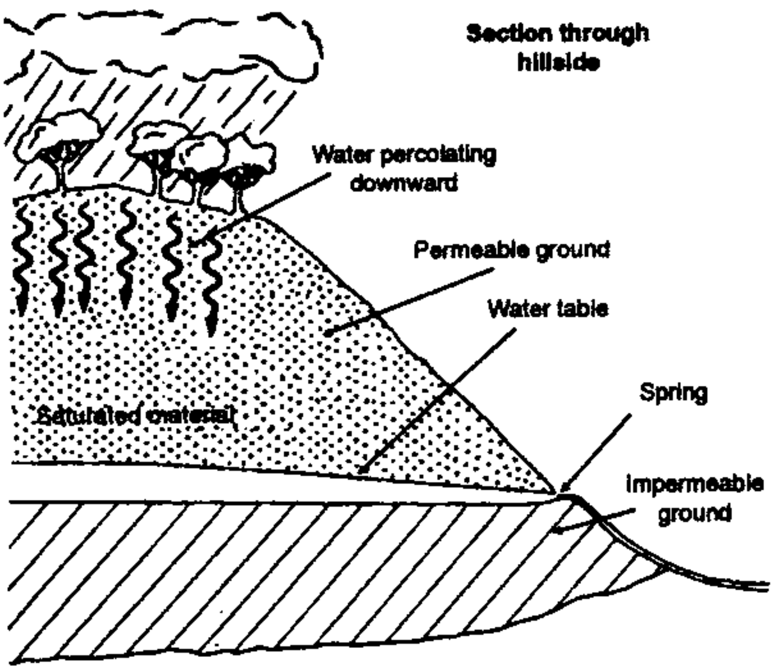
The cost of using a number of smaller pumps may be greater than using one large one but the benefits mentioned above need to be balanced against the extra cost.

Intake design

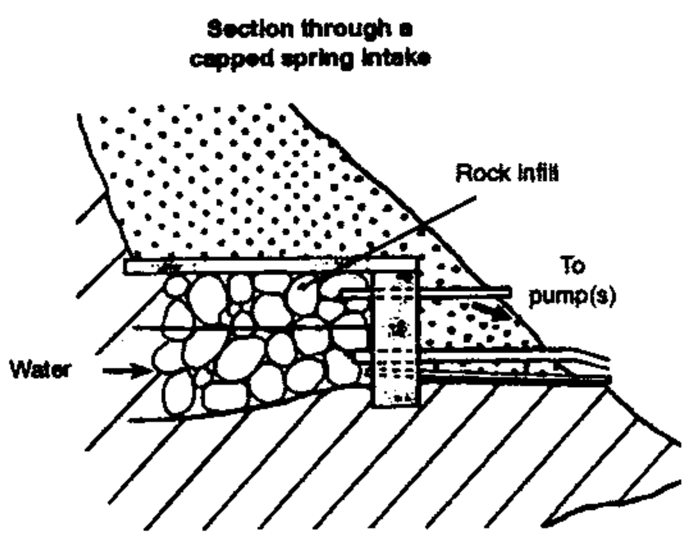
The drive water for ram pump systems is normally drawn from a spring or a stream and diverted into a feed pipe. An intake structure is required at the chosen water source to collect the water and keep the feed pipe properly supplied.

Spring intakes

When rain falls on high ground, some of the water soaks into the ground and seeps down through the permeable soil until it reaches an impermeable layer — usually clay or rock. The water collects on this layer, forming a water table of saturated material. The term water table refers to the upper level of the saturated material, and may rise and fall to reflect variations in rainfall throughout the year. As the level of the water table rises, the water spreads out until it reaches the side of the hill, then flows out as a spring.



The nature of the permeable layer influences the kind of spring that occurs. If it is soft, sandy soil through which the water can travel easily, there may be many small springs as the water emerges all along the hillside. If the permeable layer is rock, with cracks through which the water sinks, there is usually one distinct spring.



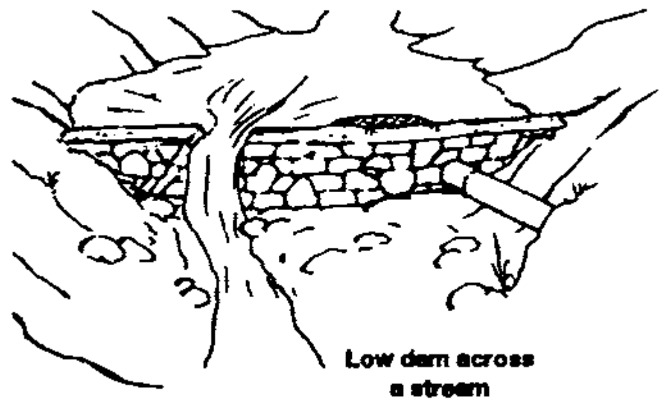
In most situations water emerging from springs is completely pure and safe for drinking, whereas by the time it flows into a stream or river it has often become contaminated. This is why it is preferable for a ram pump system supplying drinking water to be served directly by a spring.

Spring flows are often quite low and in many cases it is necessary to combine the flow from several springs to obtain enough drive flow for a ram pump system. When this is done, the drive head available to the pump(s) is the drop from the lowest of the springs to the pump(s).

Seasonal variations in spring flow must be allowed for. In most cases the users require the same amount of water at all times through the year, so the system must be designed to use the amount of flow available when the springs are at their lowest. If this is not done, there may be times during the year when there is not enough water delivered, or when there is too little water to run the pump(s) at all.

Stream intakes — dams and weirs

On streams and small rivers the feed pipe must draw water from a relatively deep pool to ensure that the end of the pipe remains below water level. To achieve this it is usual to build an obstruction across the stream to raise its level, and to run the feed pipe through it. The obstruction can either be a dam with a specific overflow point (a spillway), or a weir where the water flows over it across its whole length.



Low dam across a stream

The types of dam or weir normally constructed are relatively small and simple as the increase in level needs only to be around 300mm. In situations where the drive head must be increased significantly in order to make a system viable, larger dams may be necessary. In many parts of the world, simple, cheap designs of dam have been developed that suit the local conditions and use readily available materials.

Siting the intake The best site for a dam or weir is where the gradient of the stream is large, such as just above an area of rapids or a waterfall. This enables a high drive head to be obtained within a small distance and so helps to reduce the length of feed and drive pipes. In situations where the gradient of the stream is fairly constant, constraints on siting other components of the system may determine the location of the intake. On streams with a low gradient there are two ways of obtaining a suitable drive head. One is to build a small, cheap dam some distance upstream and run a long and therefore expensive feed pipe to the drive tank. The other is to build a much taller, more expensive and complex dam and run a short length of feed pipe to the drive tank. Siting the dam in a narrow section of stream can greatly reduce the amount of material required in construction, particularly where a taller dam is to be built.

When choosing a site, careful attention must be given to the foundation on which the dam structure will be built. Solid rock foundations ensure a firm base but require the use of cement or concrete to attach the structure securely. If building on loose material, such as soil or gravel, it is necessary to dig a trench across the stream bed to provide a firm anchor for the structure. The foundation should extend well into the banks on either side of the stream, especially where these are soft.

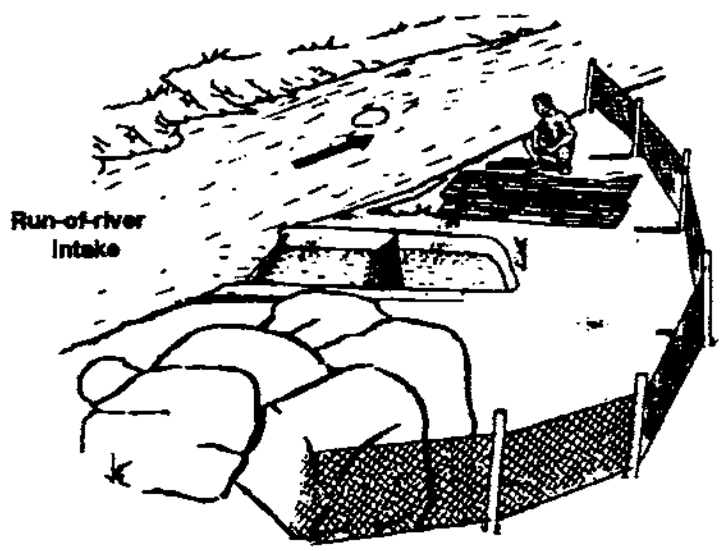
The size of expected floods and the type of debris carried by the floodwater also affects the type and site of the intake structure. A low, well-anchored dam or weir can be designed to allow floodwater to pass straight over it so that, apart from the additional build-up of silt and other debris behind it, the structure is little affected by floods. Larger dams should be built strongly enough to withstand flows much higher than the normal operating levels expected. A spillway will normally take excess water over the dam, but can rarely be large enough to cope with floodwater levels. In some cases a bypass can be built for floodwater but care should be taken to prevent the stream from establishing a new course along the bypass route after the flood.

Components of an intake A number of features should be built into any dam or weir intake:

- Feed pipe socket — a socket built into the structure to enable the end of the feed pipe to be disconnected in case repair or cleaning is required;
- Screen — a coarse wire mesh covering the inlet of the feed pipe to prevent larger debris such as leaves and sticks from entering the system with the drive water;
- De-silting pipe — a small bore steel pipe built into the base of the dam or weir to allow periodic or continuous removal of silt from behind the structure. Silt must be removed before it reaches the level of the feed pipe and starts to enter the system.

Run-of-river intakes

Where the flow of a watercourse is too great to allow construction of a suitable dam or weir, an intake can be built into one of the banks. Such a run-of-river intake diverts a portion of the water from the main flow of the watercourse and channels it into the feed pipe. The intake must be positioned at a site where there is fairly deep water near to the bank. It is also necessary to design and site it so as to prevent excessive silting.



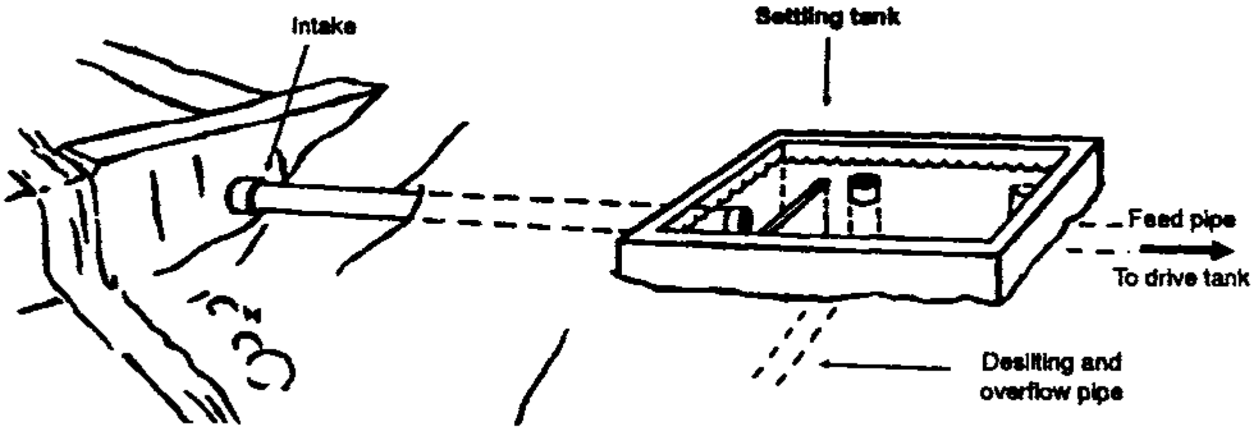
The spiralling flow of water on a bend tends to cause sedimentation on the inside of the curve, so intakes should never be sited in such a position. Siting an intake on the outside of a bend can be advantageous because the water tends to be deeper and silting reduced, but this position can leave it liable to damage by floating debris, especially during floods.

Section through river on a bend

Settling tank

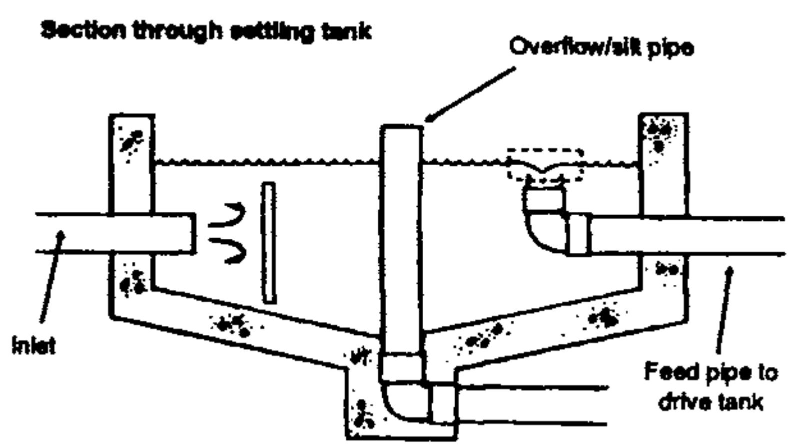
Water, particularly in streams and rivers, can carry a large amount of small pieces of soil and sand — often referred to as silt. The amount of debris carried by water depends upon its velocity and the type of ground over which it has travelled. Silt can cause damage by eroding pipework and pumps as it is forced along by moving water, or by settling and building up to create blockages. When it is planned to use water that has a large silt content for a ram pump system, it is wise to include in the system a means of removing the worst of this debris.

When the velocity of flowing water is reduced, the particles of silt being carried tend to fall slowly and settle out. In some systems, the large pool of water behind a dam or in a spring box can slow down the water sufficiently to allow silt to settle out. A large drive tank will also reduce the velocity of the water sufficiently to allow some settling to occur.



In situations where the source has a particularly high silt content and no large pool of water at the intake, a purpose-built settling tank should be included in the system. The settling tank should be designed to reduce the velocity of the water sufficiently to allow much of the silt to drop to the bottom of the tank rather than being carried with the water further into the feed pipe. The most convenient place to site a settling tank is near to the intake structure. If the system uses several springs, the settling tank can also be the most convenient place to combine the flows from each of the springs.

Settling tanks need regular maintenance. If they are well designed, a large amount of silt will collect very quickly and the tank will need cleaning. A removable overflow that serves as a silt pipe installed as shown can make cleaning fairly simple. Withdrawing the overflow pipe from the elbow in the base of the tank causes a large flow down the silt pipe, removing settled debris from the base of the tank.

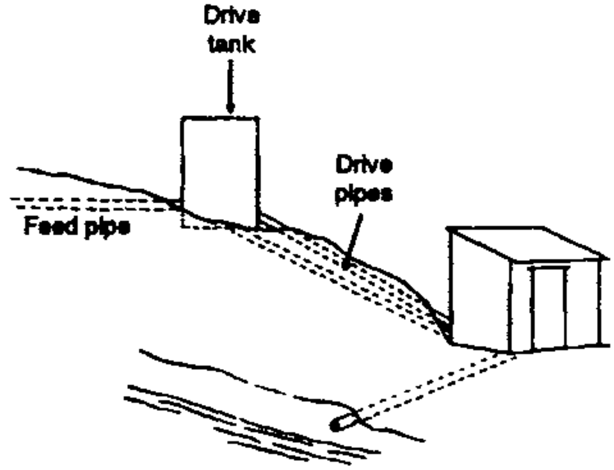


Drive system

The drive system is the part of a complete ram pump installation that receives water from the intake and feeds it to the pump(s).

It normally comprises three main items:

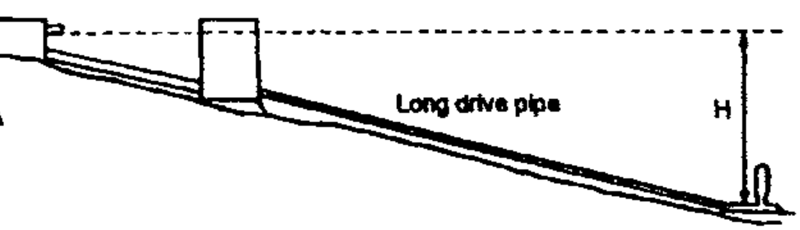
- a feed pipe that carries a constant flow of water from the intake to the drive tank;
- a drive tank that provides a store of water at the top of the drive pipe(s);
- the drive pipe(s) that supply water from the drive tank to the pump(s).



When first designing a drive system for a ram pump, all three items must be considered together because decisions involving any one of them will affect the design of the other two. In any particular situation there is a balance to be found between each of the items in the drive system. The balance involves the site layout and the relative costs of different types of pipe and of tank construction.

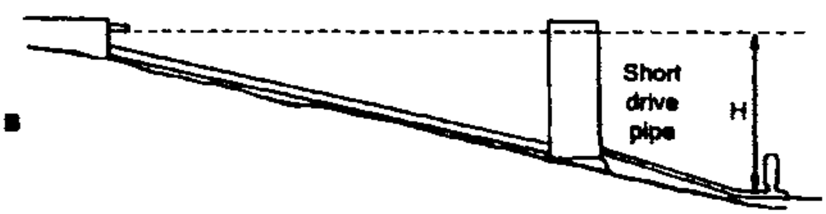
The system sketched below shows how the required drive head can be achieved in two different ways at the same site. Case A shows a small drive tank linked to the source by a short length of feed pipe. To reach the necessary drive head (H) a long drive pipe has to be installed to each pump.

Case A



Case B uses a very tall drive tank being fed from the intake by a long feed pipe and supplying the pump through a much shorter drive pipe.

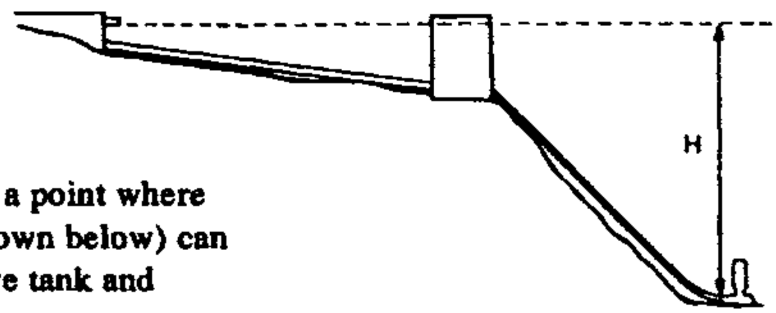
Case B



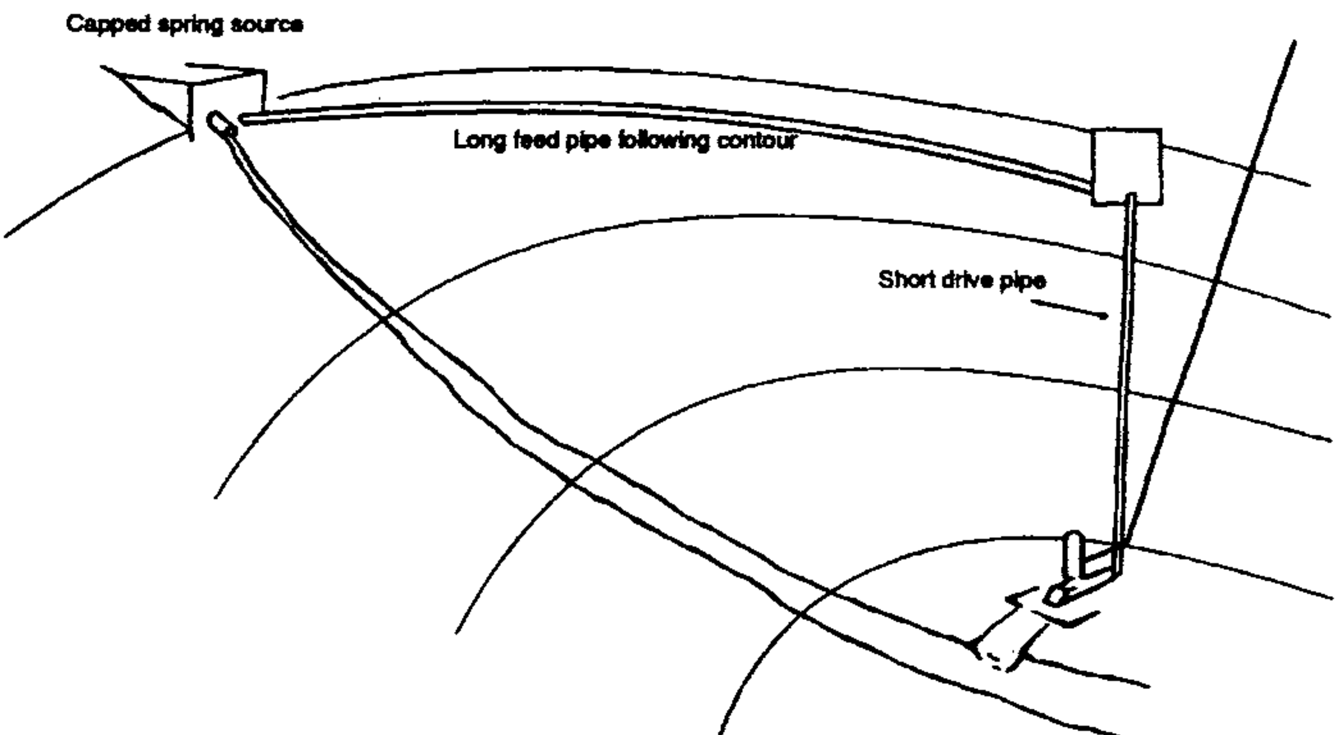
The final design choice in any situation will depend on the cost and the availability of materials and construction techniques.

Small drive tanks are generally cheap and simple to construct whereas tall ones require better foundations, reinforcing and more complicated construction techniques. On the other hand, galvanised steel drive pipe is usually far more expensive than low pressure plastic feed pipe and this cost constraint would often make Case B, using a long feed pipe with a short drive pipe, the more attractive option.

When designing a drive system it is best to look for an area below the proposed intake site which has a particularly steep slope. To obtain a certain drive head (H), the cheapest and most suitable site will be one that allows a small drive tank to be built at the top of a steep slope with a short drive pipe leading to the pump at the bottom as shown below. This will sometimes require a long feed pipe to carry water from the intake to the drive tank.



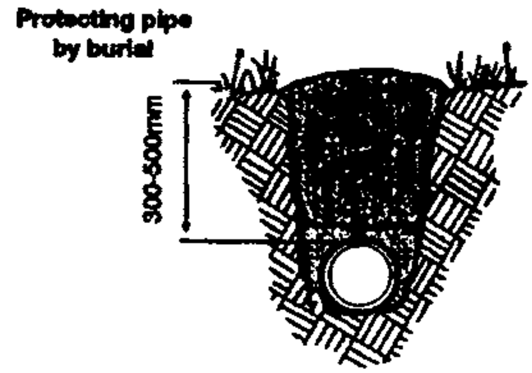
When using a spring or stream in a valley, the sides of the valley are often much steeper than the slope of the stream itself. Diverting the drive water in the feed pipe around the contour of the valley to a point where the side slopes more steeply (as shown below) can often enable the use of a small drive tank and relatively short drive pipe.



Feed pipe

The feed pipe carries a steady flow of water from the intake to the drive tank. It must supply sufficient water to feed all of the ram pumps running from the drive tank plus a small surplus that will overflow from the tank and ensure that a constant level is maintained inside. In small spring-based systems (or those using very small streams), all of the available source flow may be diverted into the feed pipe and the excess allowed to overflow from the drive tank. All feed pipes must be sized to carry enough water to supply all the pumps installed, plus an allowance for the overflow and any planned expansion of the system at a later date.

The pressure of the water in the feed pipe is generally very low, so cheap, low-pressure plastic pipe is usually adequate. If this type of pipe is used it should be buried or well covered in some way to protect it from damage by animals, farming, or strong sunlight.



The water flowing through the feed pipe will experience some friction against the pipe walls. This friction takes up some of the energy of the water and means that the water level in the drive tank under normal operating conditions will be lower than the level at the intake. This head loss caused by the friction of the flowing water must be taken into account when choosing the diameter of the feed pipe. In situations where there is plenty of drive head available a smaller and cheaper pipe size can be used. To achieve the required drive flow, the water in a small pipe will have to flow faster, with more friction and therefore a higher head loss, but when there is plenty of drive head available this will not matter. In situations where the drive head available is very limited, very little head loss in the pipe can be allowed and a larger diameter pipe through which the water flows relatively slowly should be used: the low velocity of the water in a large diameter pipe reduces the friction and therefore reduces the head loss.

Drive tank

The drive tank is an important component in the operation of a ram pump system. It performs the following tasks:

- it keeps a steady water level, ensuring a regular supply to the pumps and a constant drive head;
- it provides a large body of water with an open surface that reflects the pressure waves travelling up the drive pipe when the pump is running;
- it also prevents air from being sucked into the drive pipe.

Very occasionally systems can be sited on a steep slope (more than 30 per cent) directly beneath the water source and can be designed without a drive tank. This can reduce the cost and complexity of the system but extra care must be taken in the design of the water catchment structure, which must then also perform the functions of a drive tank.

One common mistake when designing drive tanks is to have the entrance to the drive pipe too close to the surface of the water. In such cases air is drawn into the drive pipe as the water accelerates down it. This can interrupt the operation of the pump and frequently leads to failure at the top of the drive pipe due to an effect called cavitation. It is recommended that the depth of water above the drive pipe inlet(s) be at least 500mm.

The volume of water in the drive tank, and in particular the cross-sectional area, must be large enough to maintain a steady level in the tank despite the intermittent outflow to the pump(s). As a rough guide, the cross-sectional area should be at least 20 times the total area of the drive pipes being supplied from it.

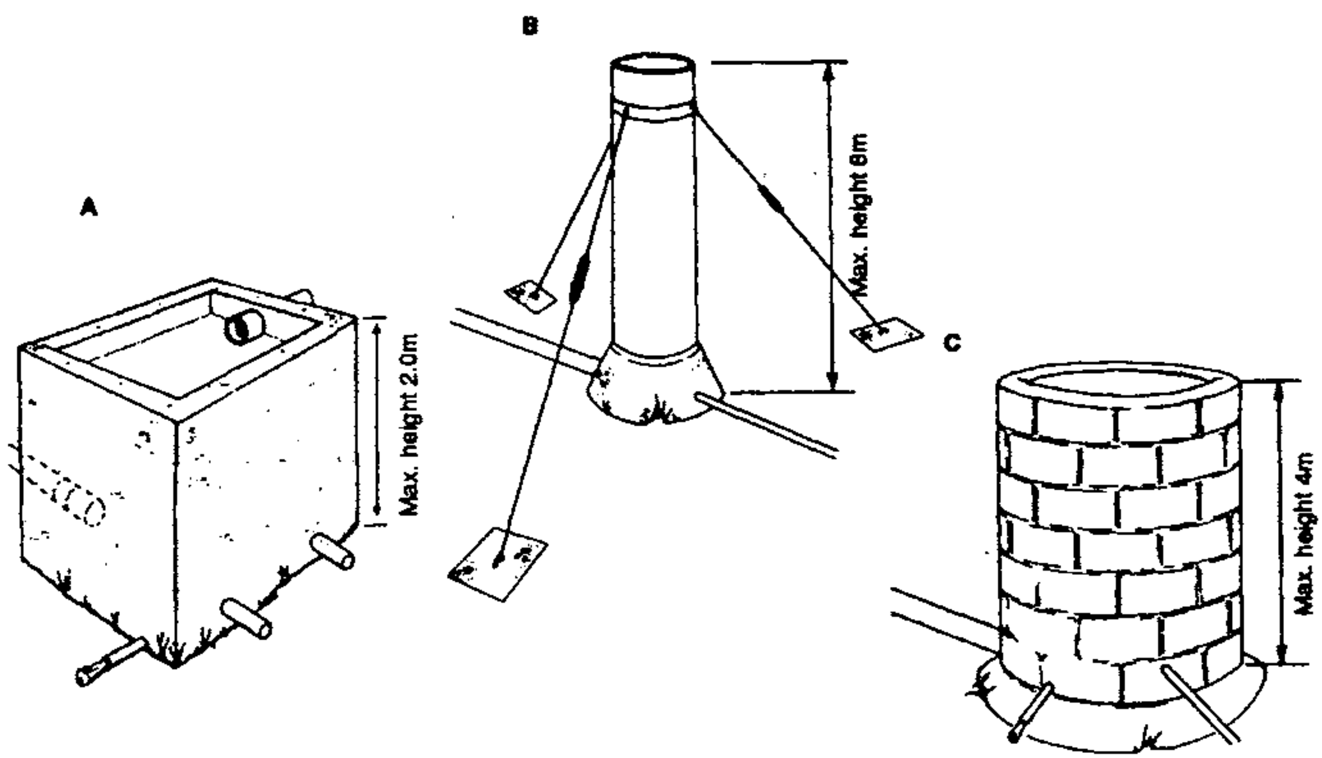
A number of types of drive tank can be considered. The choice between them depends both upon site conditions and the materials and skills available for their construction. From the authors' experience, three main types are useful, each with its own normal range of use.

A A square or rectangular tank made from cement block or fired brick and plastered inside and out. The height of these tanks is usually not greater than 2.0m.

B Large diameter PVC pipe set in a concrete base: restraining lines are recommended to ensure stability. These tanks are only appropriate for use in systems with small drive flows — particularly those systems that are spring- based. The height of these tanks is usually not greater than 6m.

C Circular tank made of cement blocks with re-bar (reinforcing bar) running vertically and horizontally within it. The height of these tanks is usually between 2 and 4m.

Care must be taken to site the drive tank conveniently for operational reasons and to ensure that it is stable. A large tank full of water is very heavy and the foundations must be strong enough to support this weight without movement. Where possible tanks should be built on a solid rock foundation.



Drive pipes

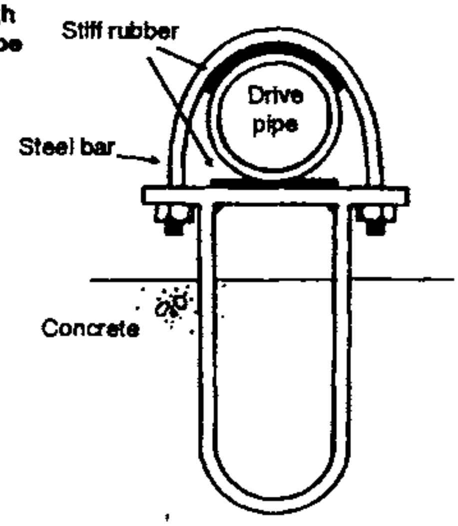
Most pumps are designed for a particular diameter of drive pipe and this recommended size should be used under normal conditions, i.e. in the normal range of drive flows and pipe lengths. Selection of drive pipe diameter is a compromise between having a large diameter to reduce friction losses and a smaller diameter to give adequate water velocity. Never install a pump with a drive pipe diameter larger than the diameter of the drive pipe connection to the pump. Research has shown that many traditional pump designs actually underutilise their drive pipe capacity and so, where drive pipe lengths and drive flows are towards the lower limit of their range, the next standard size of drive pipe below that recommended can be installed. For example, the DTU M8 and M6 steel pumps are normally driven via a drive pipe in internal diameter 2" (50mm): for drive flows (not delivery flows) of less than 70-80 litres/minutes, a 1½" (38mm) drive pipe can be used instead. Despite its higher friction, the smaller diameter pipe will give better overall efficiency (and output) for the available drive flow because the velocity of the drive water through it is higher. This is especially so when the delivery head is towards the top of the pump's range. It is generally true of all ram pumps that at low flows and high heads reducing the drive pipe diameter leads to an increase in pump efficiency.

There are limits to the length of a drive pipe in a ram pump system. These limits can be calculated by reference to several theories that take account of such factors as the energy available to the pump, the friction in the system and the movement of pressure waves within the pipe. A complete explanation of the theory involved would be too complex to give here, so only some basic guidelines are described.

A short drive pipe, that is, one with a length less than about twice the drive head, will give a very high frequency of operation. This can reduce efficiency and will shorten the life of the pump. The advantage of keeping the drive pipe as short as possible is that its cost is reduced. As a general guide, it is recommended that the length of the drive pipe be kept to between two and four times the drive head, but should never be less than 6m. For example, a system with a drive head of 5m should be designed to keep the length of the drive pipe between 10 and 20m. Systems with drive pipes longer than about five times the drive head may not be able to operate at the optimum efficiency or peak output levels quoted by the manufacturer. Ram pumps with very long drive pipes will operate satisfactorily in many situations but are inefficient and unnecessarily expensive.

The angle of the drive pipe is not a critical factor and will normally be dictated by the particular site conditions. The manufacturer's recommendations for the correct angle for a drive pipe can be ignored provided that the guidelines for pipe length given above are followed. The drive pipe can have gentle bends along its length but it must be very firmly secured near to these points.

Section through simple drive pipe anchor



Drive pipes are normally made from galvanised steel pipe, which is the usually the cheapest and most readily available material with adequate strength and life. Well sealed, threaded joints can be used in most situations, provided that the pipe is properly anchored and cannot vibrate. In systems with very high delivery heads (over 100m), threaded drive pipe connections are sometimes inadequate. In these cases flanges should be welded to the ends of the lengths of drive pipe so that they can be bolted together. The same flanged connections should be used when the threads on the pipe are of poor quality, or when large diameter drive pipe is being used.

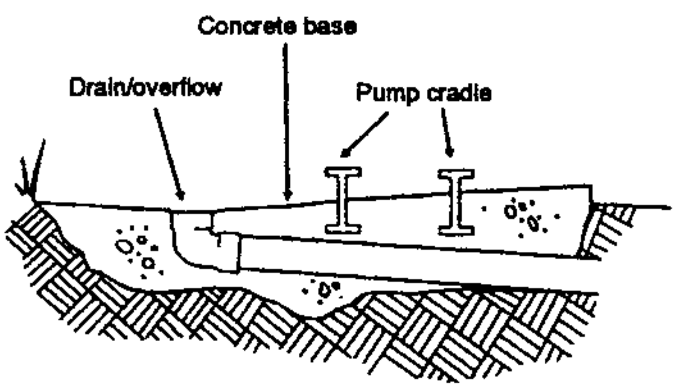
Pump

The pump itself should be considered as one component of the whole system. It needs to be carefully selected and sized in the same way as a tank or pipe, and its installation must be carried out carefully. The section on pump selection earlier in this pamphlet describes the process of choosing a ram pump or pumps to suit a particular set of conditions. After the particular requirements and constraints of an installation have been identified by the site survey, the pump(s) should be the first component to be selected. When the number and type of pump to be used is known, the sizing of tanks and pipes and the detailed design of the rest of the system can be carried out.

Pump base

It is essential that each pump be held rigidly to prevent it moving and vibrating with each pumping cycle. If a pump is not firmly secured, energy is lost as it moves and pipe joints will quickly break. The best way to secure a pump is to attach it firmly to a large concrete base. Some manufacturers recommend securing their pumps by setting bolts into the concrete but the difficulty of replacing these bolts when their threads rust or become damaged makes this unwise. A better method is to cast a steel frame, referred to as a pump cradle, into the concrete base.
There can be either a separate cradle for each pump or a single cradle to support them all. This can be made of angle-iron or other steel section welded together. The top of the cradle is left jutting out of the concrete and has holes pre-drilled through it so that the pump can be bolted down on it. If the securing bolts are damaged, they can be cut off and replaced without the need to recast the concrete base.

Section through pump base

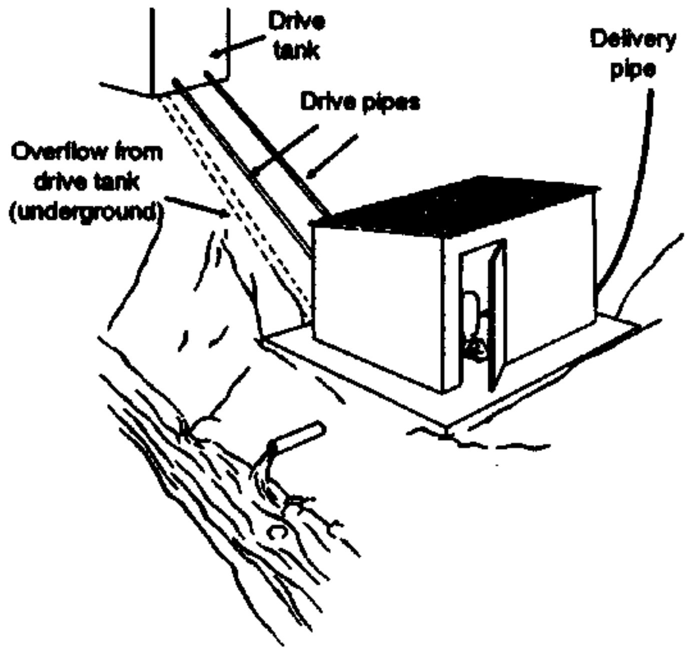


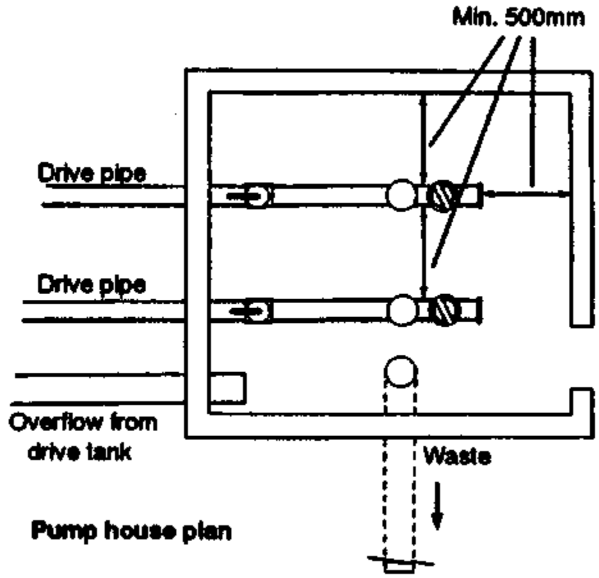
The shape of the cradle required will be different for each make of pump depending on the fixing methods incorporated by the manufacturer.

When designing a drive system, choose a suitable site for casting the pump base. The concrete base must be firmly anchored to prevent the continual vibration of the pump(s) damaging it, or separating the entire base from the material surrounding it. The site must also allow for drainage of the waste water from the pumps to prevent flooding around them.

Pump house

A structure built around the pumps is not essential to the operation of a ram pump system. However, a pump house is recommended to provide security and protection. Curious children can easily damage a ram pump left operating in the open and it also makes an easy target for thieves. The pump house must be made large enough to allow complete access to all parts of the pumps for installation and maintenance. As a general guideline, allow at least 500mm between any part of the pump and the walls of the pump house or another pump.





Pump house plan

Delivery manifold

The delivery manifold connects the outlet from one or more ram pump's air vessels to the delivery pipe that carries the water to the point of use. It also traps air and collects silt.

Delivery pipe

The delivery pipe is an important part of any ram pump system and in many cases its length leads to it being the most expensive item. This is true despite the fact that, unlike drive pipes, many pumps can share the same delivery pipe. The delivery pipe must be sized to suit the expected delivery flow and the cost constraints. The larger the diameter of the delivery pipe, the more expensive it will be, but the lower the friction losses within it. Relatively cheap delivery pipe with a small diameter will impose high friction on the delivery flow, causing a high head loss. The pumps will have to overcome this head loss as well as lifting the water to the point of delivery. Choosing a diameter for the delivery pipe is therefore a balance between having a small diameter pipe to reduce costs or having a large diameter pipe to reduce head loss and maximise delivery flow.

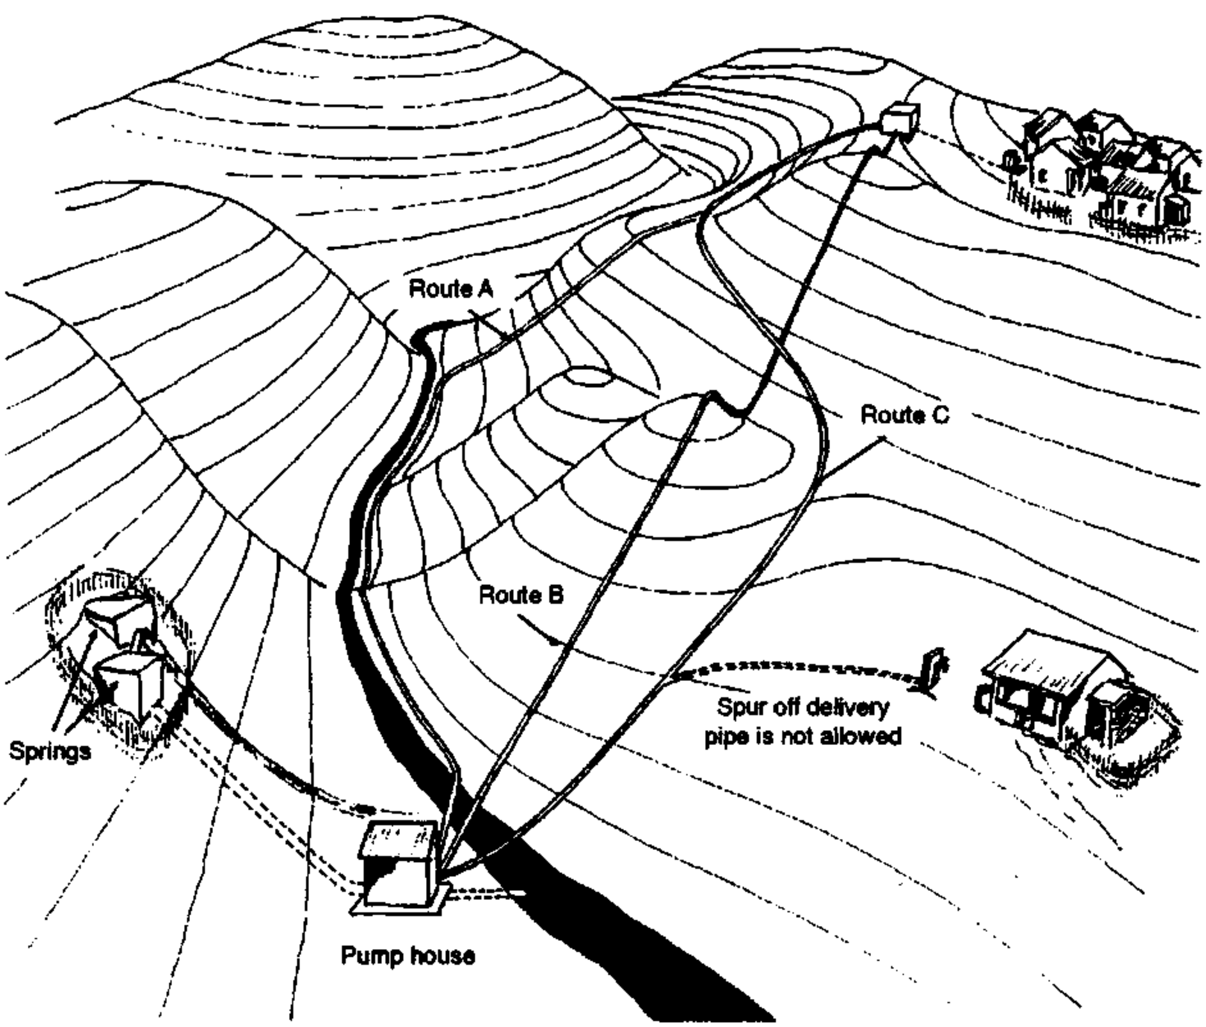
As a rule of thumb, the calculated head loss in the pipe when it is carrying the predicted delivery flow should be between 5 per cent and 10 per cent of the delivery head.

Where there is plenty of delivery water available and low cost is important, a small diameter delivery pipe can be used to reduce cost. If the expected delivery flow is only just sufficient for the users, a larger diameter pipe with a lower head loss should be chosen.

The route chosen for the delivery pipe should be as short as possible to reduce cost and head loss. However, the shortest route may not be technically feasible or necessarily the cheapest.

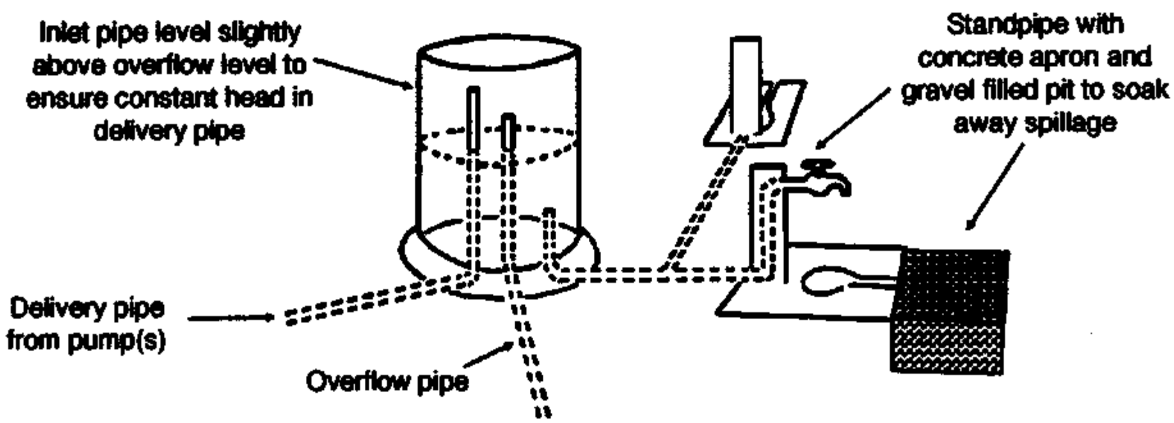
The sketch below shows a system with three possible delivery routes.

- Route A follows the lowest ground for much of its length: it is not recommended because a large section of the pipe is under high pressure and high pressure pipe tends to be more expensive;
- route B takes the most direct line but is not recommended because it has high points in which air would collect, causing air locks and reducing delivery flow;
- route C is the best route, rising quickly from the pump and then following a steady upward incline to the delivery tank. Only a short length of pipe is under high pressure and the line is fairly direct. A spur off the delivery pipe below the delivery tank should never be installed.



Distribution system

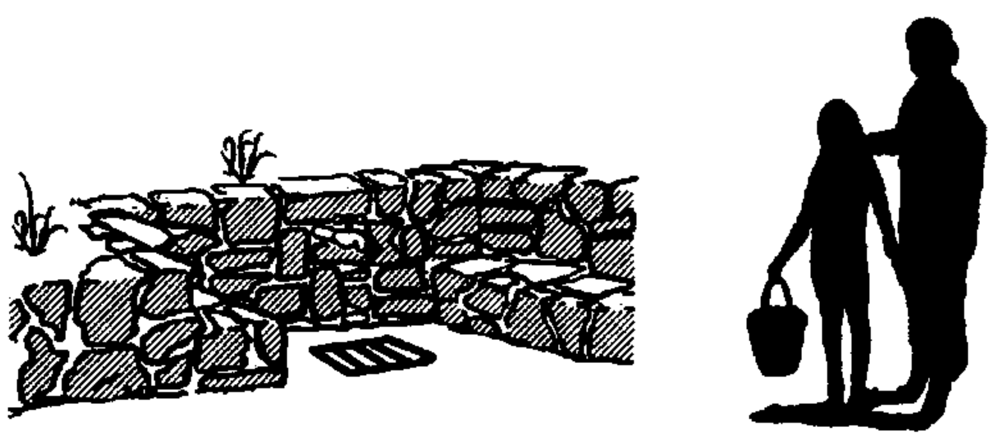
After installation and commissioning, most of the components of a ram pump system are forgotten by the users of the water supplied. The water is collected every day from stand pipes and it is the design of this distribution system that will be most relevant to them. It is particularly important to involve the whole community in the design of the distribution system and that the social organisation of water use is planned before construction.



Most ram pump systems for domestic use will require a storage tank at the end of the delivery pipe. A ram pump operates for 24 hours each day, so the water pumped overnight must be stored for use during the times of peak demand. If there is to be more than one storage tank, the water should be pumped to the highest one and then fed by gravity down to the others. Alternatively, if valves are fitted on the inlets to each tank (except the highest one) the flows can be controlled so that all subsidiary tanks fill at the same rate. The total capacity of the delivery tank or tanks in the distribution system must be large enough to hold all of the water pumped overnight. They should therefore be sized to hold at least 12 hours supply and preferably 16 hours supply. The storage requirement can be calculated using the rule:

$$\text{Storage required in litres} = \text{delivery flow in litres/minute} \times 60 \text{ minutes} \times 16 \text{ hours}$$
$$= q \times 960$$

Thus, for each litre per minute of delivery flow, provide about one cubic metre (= 1000 litres) of storage.



The delivery tank should either be conveniently situated for direct use or feed water into a distribution system. In many cases distribution can be directly through stand pipes connected to the delivery tank and fed by gravity. Larger systems serving bigger communities may require a number of distribution points each with a secondary storage tank and stand pipes. These tanks can either be assigned a priority — where the overflow from one tank feeds the next in a chain — or can be fed equally from the main delivery tank.

Single and multiple tank delivery systems

Single delivery tank

Priority chain delivery system

Equal priority multiple tank delivery system

Water drawn from springs and high mountain streams is often very clean and can be used without any form of treatment. Where the water to be used in a ram pump system is drawn from a dirty source, filtration of the water delivered may be necessary. Simple sand filters when carefully installed and maintained can be very effective in improving water quality. The details of filter design and construction can be found in many publications and are beyond the scope of this book. From a system design point of view, however, it is worth noting that the delivery tank can itself be a filter tank as shown below. The delivery/filter tank feeds clean water to a second storage tank from which water is drawn for use. The top of the link pipe in the distribution tank should be a few centimetres higher than the level of the sand in the filter tank: this ensures that the sand never dries out.

Simple method of filtering delivered water

DRINKING WATER: THE INDIAN SCENARIO

The Global Dimension

Water is life. This colourless, odourless and tasteless liquid is essential for all forms of growth and development - human, animal and plant. Also, water is a fundamental basic need for sustaining human economic activities. Not only does water support a wide range of activities, it also plays a central symbolic role in rituals through out the world and is considered a divine gift by many religions. Availability of water in the desired quantity and quality, at the right time and place, has been the key to the survival of all civilizations. No other natural resource has had such an overwhelming influence on human history. As the human population increases, as people express their desire for a better standard of living, and as economic activities continue to expand in scale and diversity, the demands on fresh water resources continue to grow.

While water is a renewable resource, its availability in space (at a specific location) and time (at different periods of the year) is limited, by climate, geographical and physical conditions, by affordable technological solutions which permit its exploitation, and by the efficiency with which water is conserved and used. Much of the world's fresh water is consumed by the agricultural, industrial and domestic sectors. Increasing water demands and the inadequacy of these sectors to effectively manage this resource, has lead to crises situations in many parts of the world - crises over the availability of adequate and appropriate quality water. The limits of sustainable use in each climatic region are determined by local climate, hydrological and hydro-geological conditions. In many parts of the world, the amount of water being consumed has exceeded the annual level of renewal, creating a non-sustainable situation. The International Drinking Water Supply and Sanitation Decade and other international declarations have clearly recognized that access to water is a fundamental right of people.

Fresh water lakes and rivers, which are the main sources of water consumed by people, contain an average of 90,000 cu km of water, or just 0.26 percent of total global fresh water reserves. This tiny fraction is distributed in a very uneven manner on earth, creating wide range of environments, from arid regions and deserts to humid areas which experience regular flooding. In many parts of the world, the rainfall pattern is highly skewed and is characterized by small periods of intense precipitation followed by long, dry periods. Great disparities may even be seen on the same continent. About 20% of the total global run-off flows in the Amazon river in South America, while the Atacama Desert has consistently received non annual rainfall.

Such variations become very important as human activities diversify geographically and in scale. In many water scarce parts of the world, human engineering initiatives have been geared towards balancing this spatial inequity. In South-Western USA, e.g. engineering interventions in the form of extensive dams have already exhausted most possibilities for enhancing fresh water availability. In many other parts of the world, future options are becoming extremely complex and uncertain as the levels of total fresh water consumption approach the limits imposed by the annual renewal of fresh water resources.

Advances in climatology and hydrology have contributed to improved, quantitative estimations of the processes which make up the global hydrological cycle. Though this knowledge has resulted in increased availability of water in some situations, an almost exponential growth in the level of utilization of this resource has balanced off the advantages so created. In this way, in spite of advances made on the scientific front, human survival and well being today are probably no less dependent on fresh water availability than in the early years of human civilization. Not with standing some impressive records in activities related to the UN Drinking Water and Sanitation Decade (WHO 1990), the provision of water at affordable cost and of acceptable quality is emerging as a major environmental challenge. In particular the all dependence of future food security on the availability of irrigation water, as well as growing awareness of water resources for conservation purposes has created widespread concern.

There are distinctions between `water scarcity', `water shortage' and `water stress'. Water scarcity is a relative concept intended to convey the imbalance between supply and demand under the prevailing legal, institutional, regulatory and where applicable, price arrangements. Water shortage is an absolute concept indicating low levels of water supply relative to minimum levels necessary for basic needs. Water stress signifies acute water shortages for prolonged periods.

In this respect, it is important to examine whether the emerging water scarcity in various parts of the world is absolute, needing drastic reductions in demand, or can be adequately addressed through new and holistic management strategies and restrained consumption patters. The need for a totally new perspective and the manner in which people use fresh water has been felt and the existing perceptions of engineers regarding water supplies has been questioned.

The need to adopt a systems approach to water management has been stressed. Along with the various ecological linkages governing the flow of fresh water in the hydrological cycle, the need to understand the use of water in its many diverse roles and its economic implications is also being recognized. The Earth Summit Agenda 21, specifically calls for local and national level actions.

Delhi and Dublin Principles

Delhi "some for all rather than more for some". Guiding principles:

- protection of environment and safeguarding of health through integrated management of water resources and liquid and solid waste;
- institutional reforms, integrated approach and full participation of women at all levels;
- community management and strengthening of local institutions in implementation;
- sound financial practices.

Dublin: Emphasis on sustainability and the need to consider water as an economic good. Guiding principles:

- fresh water is a finite and vulnerable resource essential to sustain life, development and the environment;
- water development and management should be based on a participatory approach involving users, planners and policy makers at all levels;
- women play a central part in the provision, management and safeguarding of water;
- water has an economic value in all its competing uses and should be recognized as an economic good.

Water: The Indian Scenario

In a country where the first measurement of rainfall was made by Kautilya as early as AD 1200, it is surprising that estimates of the total availability of water in India are only quite recent. The total average annual run-off of all river systems in India is estimated to be 1,674 billion cubic metres (BCM).

The National Water Policy estimates that total precipitation in India is around 400 million hectare metres. In addition, ground water potential is about 42 million hectare metres (GOI 1987). The first estimates of ground water resources on a scientific basis was made in 1979 by the Central

Ground Water Board. Recent estimates based on a state-wise assessment have put the annual replenishable ground water resources of the country at 453 BCM. With a provision of about 15% (69.8 BCM) for drinking, industrial and other uses, the utilizable ground water resources for irrigation is computed as 383 BCM (GOI/CGWB 1995).

The amount of available aggregate annual utilizable water in India, surface and ground is about 1,100 BCM. Population growth is expected to result in a decline in the per capita availability of fresh water. In 1947, this was measured at 5,150 m^3. By the year 2000, it is likely to be 2,200 m^3.

Such aggregate figures, however, are quite misleading, since there is considerable spatial and temporal variation in rainfall. Some areas receive slight rainfall, whereas others experience monsoon conditions which often result in flooding, loss of life and increased poverty. To better understand such variations and their consequences on people's lives, it is necessary to examine specific situations at the village or community levels under different ecological situations.

Attention must, however, also be given to fast growing urban centres, where water requirements are expected to double from 25 BCM in 1990 to 52 BCM in 2025. The situation concerning industrial supplies is even more difficult to analyse. It has been indicated that industrial water demand would increase from 34 BCM in 1990 to 191 BCM by the year 2025. Agriculture, the largest consumer of water resources in India, will probably require 770 BCM by the year 2025 to support food demand. The total estimated demand of 1013 BCM by the year 2025 would be close to the current available annual utilizable water resource of India.

With predicted demands such as these, the supply of rural drinking water and requirements for ecosystems conservation are sure to face an uncertain future unless anticipatory policy measures are taken. It is evident that the politically and economically powerful urban-industrial sectors would obtain the water resources they need by organising long distance transfers from surrounding rural areas or even by inter-basin transfers. In such a scenario, alternative solutions of conservation and sustainable management of fresh resources will find little support. In view of this, the focus has to be on the requirements of rural drinking water and ecosystem conservation, while at the same time suggesting alternative approaches for meeting urban demands.

The National Policy

The government's concern since independence, has been raising the quality of life and the health of the people. Several initiatives were taken at policy formulation level leading to various programmes in this direction. Supply of safe drinking water and provision of sanitation are the most important contributing factors for improving the health of the people in any country. As per a World Health Organization (WHO) report 80% of the diseases are due to unhygienic conditions and unsafe drinking water. It is estimated that every year about 1.5 million children under five years die in India of water related diseases. The country loses over 200 million man days each year due to water and sanitation diseases. Age old cultural practices coupled with illiteracy and lack of awareness further complicate and exacerbate the problem. Supply of safe drinking water has therefore, been given very high priority in Indian Planning.

Providing drinking water in rural areas is the responsibility of the state governments and the funds were provided for the purpose in their budgets from the first five year plan. During 1954 National Water Supply and Sanitation Programme was introduced in the social welfare sector. The states built up gradually the Public Health Engineering Departments (PHEDs) to attend to the problems of water supply and sanitation. Under the programme 100% grants-in-aid to implement the different water supply schemes for the `problem villages' were provided by the government of India. In the mid 1960s it was realised that these schemes were implemented only in the easily accessible villages and in the process the hard core `problem villages' remained unattended. The government of India during the fourth five year plan took steps to provide assistance to the states to establish special investigation divisions for the problem villages.

In order to accelerate the pace of coverage of problem villages, the Government of India introduced the Accelerated Rural Water Supply Programme (ARWSP) in 1972-73. During 1974-75 the Minimum Needs Programme (MNP) was introduced because of which the ARWSP was withdrawn but it (ARWSP) was reintroduced in 1977-78 when the progress of supply of safe drinking water to the identified problem villages was not found to be satisfactory.

In the year 1977 the United Nations Water Conference separated the issue of drinking water and sanitation from other water issues to stress the seriousness and magnitude of the problem of drinking water. The conference recommended that each country should develop national plans and programmes for water supply and sanitation giving priority to the schemes of the population which require greatest attention. India was a signatory to the resolution seeking to achieve the target by 1991. The water decade programme was launched in India on 1st April, 1981 to achieve definite targets of coverage of entire population by 31st March, 1991.

In August, 1985 the subject of rural water supply and sanitation was transferred from Ministry of Urban Development to Department of Rural Development with the objective of securing implementation of the programme and their integration with other rural development programmes.

The National Drinking Water Mission was launched as one of the five societal mission in the year 1986. The mission was since named as Rajiv Gandhi National Drinking Water Mission (RGNDWM) in 1991. Government of India continues to give highest priority to rural drinking water sector through the activities of the mission and ARWSP. It also forms the part of the state funded MNP and point No. 7 of the twenty point programme, 1986.

It is claimed that the RGNDWM over the last decade has successfully covered the majority of habitations with hand pumps/stand posts. However, it has now been realised that the objective of supplying safe water would not be achieved to the extent and satisfaction expected unless the pollution aspects of water supply, as well as the issue of sanitation were addressed simultaneously. The focus has now shifted from water to water and sanitation. The mobilisation of large funds and efforts through RGNDWM in this direction have not yielded the desired impact on the health of the general population. Many reasons could be advanced to explain the not so satisfactory results of the efforts under water and sanitation programmes over the years.

During the 1970s, there was a marked departure from sustainable utilization of water resources. Food scarcities of the 1960s encouraged government policies towards increased irrigation. In this way, the users of drinking water and irrigation, which had until then been a singular entity, started to be separated. This shift affected the management of common water resources in basic ways. One of the most visible changes was the manner in which upper catchments were managed, leading to a degradation of water resources in tanks, lakes and rivers. It also led to ground water being extracted from greater depths, making the shallow hand dug wells, which until then had provided drinking water, redundants. The situation has been described as human induced water scarcity, normally mistaken as being the result of natural drought. What made the situation even worse was increased pollution of both surface and ground water resources which are of both man made and natural origin. In this perspective, unless pre-sumptive measures in terms of new regulatory and policy instruments are adopted, the water situation in India is certain to become chaotic.

National Water Supply and Demand

The changing socio-economic situation in India is leading towards higher levels of ground water exploitation. With the increasing availability of more sophisticated drilling and pumping technology, the search for ground water is bound to increase. The results of excessive ground water use is already showing. Small streams, are drying up due to insufficient catchments even during the monsoon season, and in both rural and urban areas people are drilling deeper and deeper borewells. In other situations, a significant amount of rain might fall, but it is not possible to store it for domestic needs. In the hills, deforestation and reduced ground cover results in very little rainwater percolating into the soil to feed the springs. Soil erosion further reduces the capacity of the ground to retain water. Cheerapunji in eastern India, for example, may receive 10.5 m of rainfall in the short monsoon period, but it too suffers from water scarcity!

India is heavily dependent on ground water sources. It is estimated that this source provides about 80 to 90 percent of domestic water supply in rural areas, 50% of the urban and industrial demand, and 50% of the irrigated area through over 17 million energized wells. In drought years, ground water represents the primary reliable source for irrigation. (World Bank/ GOI 1997a &

1997b). However, domestic water needs account for only about 5% of the total water extracted from the ground.

A dramatic increase in ground water extraction took place in India from 1951 to 1990. The number of dug wells increased from 3.86 million to 9.49 million, shallow tubewells from 3,000 to 4.75 million and public tubewells from 2,400 to 63,600. The number of electric and diesel pumps also increased during this period, from 21,000 to 8.22 million and from 65,700 to 4.36 million, respectively, electric pumps becoming more common as a result of rural electrification. In gross terms, however, the current level of ground water use is 32%, suggesting that there is still vast potential for its further development, but there are significant variations with a number of blocks in the country classified as `dark areas' or `over exploited' with more than 85 and 100% of ground water development, respectively (GOI/Central Ground Water Board, 1995).

With the heavy dependence of the country on ground water, the government's strategy has been based on using the dynamic component of ground water (i.e. the amount available in the zone of water level fluctuation), and temporary use of the static component (i.e. the amount available in the permeable portion of the aquifer) to cope with drought situations. The National Water Policy (1987) sets out the framework for the implementation of this strategy. Current legislation (common law) assigns property rights of surface (natural) water resources to the state, while rights to the extraction of ground water, which is the major source of drinking water in India, rest with those individuals who own the land above the aquifer. There is no limit on the quantity of ground water that a landowner can extract.

<u>National Water Policy (1987)</u>

- Water is a prime natural resource, a basic human need and a precious national asset.
- Periodic scientific assessment of the ground water potential, taking into consideration the quality of water and economic viability.
- Exploitation of ground water resources should be regulated so as not to exceed recharging possibilities and to ensure social equity with ground water recharge projects formulated and implemented for augmenting the available supplies.
- Integrated and co-ordinated development of surface water and ground water and their conjunctive uses planned right from the start of a project.
- Avoidance of over exploitation of ground water near the coast to prevent ingress of sea water into sweet aquifers.
- Drinking water needs of human beings and animals should be the first charge of any available water.

The water supply and sanitation sector, particularly in rural areas, has been given priority from the inception of the five year planning process in India. In total, during the five year planning periods 1951-56 to 1992-97 Rs. 336 billion or 3.3% of the total government budget has been allocated to this sector of which 60% (Rs. 202 billion) was for rural areas. Government investment in rural water supplies and sanitation was Rs. 143 billion upto 1996. From 1991 to 1995 total external support to the water supply and sanitation sector amounted to US $ 330 million or US $ 56.5 million per year which represents 2 per of total external disbursements in India. But it is also noted that the utilization rate of both multilateral and bilateral assistance in India is low. For example in 1992-1993 it was only 10% of commitments (World Bank/GOI 1997b). Estimates of private investments are not available, but they are likely to far exceed that of the government if irrigation and domestic expenditures in water extractions are included.

According to the Rajiv Gandhi National Drinking Water Mission (RGNDWM) a total of 520 million people have been provided access to public water supply since the launch of the first national water supply programme in 1954. During the period 1954-55 to 1994-95 it is estimated that 478 million rural people were covered with water supply. By 1994, 95% of the rural population had access to a `safe` source of water, with 52% fully covered with 40 litres per capita per day (lpcd) or more, and 48% partially covered with 10-40 lpcd. Only about 5 percent of the rural population were without access to safe water.

In terms of physical infrastructure, more than two million handpumps have been installed on drilled tube and borewells, 1,16,000 mini and regional piped schemes have been constructed supplying 1.5 million standposts and 4.3 million house connections. Moreover, handpumps account for 95% of the total number of publicly funded rural water supply schemes, serving almost 395 million people, or 75% of the rural population.

A 1994 Government of India survey examined the status of handpumps. It found that many required repair (more than 33%), or rehabilitation (22%), or were completely defunct (12%). In the case of piped water supply the situation was less serious with about 26% requiring repair or rehabilitation. Eighteen percent of all standposts were found to be without taps (World Bank/GOI, 1997b).

The RGNDWM Validation Survey has also reported significant problems with water quality. Approximately 82,000 habitations or about 4 million people are suffering from water quality problems as a result of excessive quantities of fluoride, iron, nitrate and arsenic or excessive salinity. The Ground Water Sub-group of the Water Resource Management Sector Study by the World Bank and Government of India reports that arsenic is a recognized problem in West Bengal (1,000 habitations or an approximate population of 5,00,000), fluoride levels are considered high in Andhra Pradesh, Gujarat, Haryana, Karnataka, Punjab, Rajasthan, Tamil Nadu and Uttar Pradesh (28,000 habitations or an approximate population of 14 million), high iron levels have been found in the north-east and eastern parts of the country (58,000 habitations or an approximate population of 29 million), and high salinity is prevalent in Gujarat, Haryana, Karnataka, Punjab, Rajasthan and Tamil Nadu (World Bank/GOI, 1997b).

With an area of 3,268,100 km^2, India has 33 meteorological sub-divisions. Almost one-third of the country, 99 districts in 13 states, covering 108 million hectares have been classified as drought prone. As of March 1994, out of the 7024 blocks, Mandals, Talukas and watersheds in the country, 537 blocks and Mandals (102 Mandals in Andhra Pradesh, 32 in Haryana, 9 in Karnataka, 3 in Madhya Pradesh, 73 in Punjab, 68 in Rajasthan, 97 in Tamil Nadu, 65 in Uttar Pradesh, 2 in West Bengal), 45 Talukas in Gujarat and 35 watersheds in Maharashtra were classified as `dark` or critical where the projected net extraction in five years would be in excess of 85% of the ground water resources utilizable for irrigation. Another 600 blocks, Mandals, Talukas and watersheds are classified as `grey` or `semi-critical` with projected extractions in the 65-85% range.

In response to the emerging problems of ground water, the RGNDWM has as far back as 1987 identified strategies for the short and long term for meeting drinking water needs and micro-watershed management such as the conservation of water and recharging of ground water aquifers and a model bill has been proposed by the Central Government.

Technology Mission: Some approaches for the conservation of water and recharging of ground water aquifers

- collection of hydro geological and related data in problem areas;
- reconnaissance to verify the available data and to update micro level data base;
- **chemical analysis of water for evaluating its suitability for drinking;**
- construction of suitable structures for ground water exploration and periodical monitoring of their performance;
- **designing and construction of suitable structures for rain water harvesting;**
- **artificial recharge of aquifers (wherever feasible);**
- development and adoption of measures for reduction of evaporation losses from surface water bodies;
- conservation of water through adoption of appropriate irrigation practices;
- identification of micro-watersheds in problem areas;
- assessment of hydro geological parameters of aquifers;
- estimation of recharge to ground water regime;
- assessment of total water potential in basins and micro-watersheds;
- scientific management of water resources using computerized mathematical modeling.

Key components of the Ground Water Model Bill

- Control and/or regulation of the extraction of ground water in any area deemed necessary and notified by a Ground Water Authority;
- Need to obtain a permit to extract and use ground water in the notified areas;
- Registration of existing and new users in the notified areas;
- Monitoring and enforcement of the controls and regulations by the Ground Water Authority.

In 1992, the constitution act (73rd amendment) gave responsibility for drinking water and sanitation to the Panchayati Raj Institutions. The underlying rationale is that the public health engineering departments and water boards are centralized, monopolistic, overstaffed, and lacked accountability to users. The Gram Panchayats as the local level tier are now expected to be responsible for choice of technology, recovering costs and operations, and maintenance of rural water supply and sanitation. The assets would be owned by the community. This process is, however in a very early stage in most states, but Gram Panchayats are now almost entirely implementing development programmes that are handed down to them by the state and central governments. However, because the governments continue to control the grants to the Panchayats, they continue to exercise control on the day-to-day functioning of the panchayats, and the state governments still continue to act as the providers of minimum coverage of free water supply in rural areas.

The broad picture of the demand and availability of fresh water has typically suggested certain generalized solutions such as the need for resource management rather than controlled resource extraction and improved environmental management in critical zones. Alternative mechanisms for water allocation in such a complex situation have been studied by Meinzen-Dick and Mendoze (1996). Specific solutions have pointed to the promotion of water markets, reforming the tariff structure of electricity, prohibiting certain crops in water scarcity areas, creating legal and institutional frameworks, and re-orienting investments in the sector.

The ability of some suggested changes has often not taken into account the regional and ecological differences that prevail in the nature and assessment of the fresh water situation, including social and cultural factors. Policies and plans developed at the national level, and calculations of per capita fresh water needs based on national data have little meaning in a country of this size. The water issues in India must be analysed in a dynamic context, both over time and for specific locations.

Drinking Water: Current Problem and Perspective

The lives of women and children as well as the environment have been seriously threatened by water shortages in the country.

- As a result of excessive extraction of ground water, drinking water is not available during the critical summer months.
- About 5 percent of the rural population does not have access to regular safe drinking water and many more are threatened by less and less access to safe drinking water in the not so distant future. Water shortages in cities and villages have led to large volumes of water being collected and transported over great distances by tankers and pipelines.
- High levels of fluoride, arsenic and iron, lead to major environmental health problems and in the case of iron, people simply do not like to drink the water because of its smell / taste.
- Ingress of sea water into coastal aquifers as a result of over extraction of ground water has made water supplies more saline, unsuitable for drinking and irrigation.
- Pollution of ground and surface waters from agro-chemicals (fertilizers and pesticides) and from industry poses a major environmental health hazard, with potentially significant costs to the country.
- The World Bank has estimated that the total cost of environmental damage in India amounts to US $ 9.7 billion annually, or 4.5 percent of the gross domestic product. Of this, 59 percent results from the health impacts of water pollution.

- It has been recently estimated that by 2017 India will be `water stressed' per capita availability will decline to 1600 cu m. Cities generate 2000 crore litres of sewage but treat only 10% of it. Poor drinking water and sanitation infrastructure will lead to high levels of water related diseases and death. It is estimated that 60% of irrigation water is wasted by seepage through unlined field channels and due to over application.

Evidence suggests that not only is there an emerging water crisis at the global scale, but that the crisis is already happening in many parts of India. Ground water is being over exploited, surface water is utilized inefficiently, as is water used for irrigation and urban water supply and water pollution is escalating at exponential rates, not least because of poor sanitation. The poor in rural and urban areas, particularly women and children, continue to be hard hit by these emerging problems. There is a fear that unless urgent measures are taken, present and future generations of children will have to bear immense health and economic costs. The government has recognized that there is a problem with availability of quality water.

India's National Water Policy recognizes the importance of providing safe drinking water to its people. It states "Drinking water needs of human beings and animals should be the first charge on available resources". For children, specifically, this right is also enshrined in article 24 of the convention on the rights of the child (CRD) ratified by the Government of India. It has been recommended that water be treated as not just as an `economic good' but as an `economic resource' which is essential for growth and development. But many aspects of the National Water Policy, legislation and regulations and the rights of children under the CRC have not been implementable in the Indian context for various reasons.

Water for irrigation is available as a `free' resource apart from its extraction costs, and while industry may be paying for water through a metering system, water is not treated as an `economic resource' whose price reflects its demand and supply in its competing uses. Ground water is considered a `free good', despite the fact that it comes from common pool aquifers. Subsidized water is often cornered by rich farmers who also cause long term aquifer damage due to excessive withdrawal by taking advantage of energy or water subsides intended for small farmers. The greatest pressure and the most serious impact is on availability of water for domestic uses which faces competition from irrigation and industry. The selling of water through water markets for irrigation has developed in parts of the country. There is, however, no effective regulatory mechanism to ensure ecological sustainability. Sustainable domestic water supply cannot be assured without at the same time addressing the inter-linked issues of water for irrigation, industry and ecosystem sustainability.

Market and state regulatory mechanisms which allocate water resources to competing uses agriculture, industry, domestic and ecosystem sustainability respond to different signals. The price of agricultural products, the major consumer of ground water, is a key determinant of the crops grown and the cropping pattern followed along with the soil, climate and water situation. However, partly because legal rights have been conferred to water which lies below an individual's land, and there has been no pricing of water, the cropping pattern does not take account of the cost of over-extraction. the issues in the case of industry are water tariffs based on usage, water pollution and recycling. Without an effective pricing and regulatory mechanism, the cost of water pollution may not be factored into the price of manufactured goods.

The fresh water problem in India, therefore, as suggested by existing analyses and policies, is that adequate quality fresh water is not available at an affordable cost in the right place at the right time for basic needs and ecosystem sustainability.

The problem is conceptualised further in terms of control and management issues. The fresh water resource from surface and ground water is physically available to each of the levels household/community, district, state, national and international. At the lowest level, a household, village or community has access to a well or surface water within its own boundaries, which is not shared with other levels. Water may also be obtained from an aquifer or surface source which is shared with other levels, from the household to the village/community, district, state, national and international levels. In these cases, if a household or community is using water from a shared aquifer, then the rate of extraction at each level will affect the level of availability at the other levels. Thus, concerns over water access may range from those of villagers in an isolated area, to people many kilometers .

The interlocking nature of concerns at different levels results in legal, institutional and economic issues which must be taken into account. While a household/community has control over a water resource wholly within its land, its ability to manage the resource varies as it is shared at successively higher levels. This has implications, for instance, for community management of water resources.

Conceptually, this also suggests that when designing actions, the shared nature of the resource must be taken into account. Although this would suggest that ground water should be regarded as a public good, the existing system of `water rights' and the grandfathering of the rights prevents the design of policies and programme along these lines alone. The fact that these rights has been conferred, and millions of ground water extraction structures created, that there is heavy reliance on ground water is a political look in India, all mean that the economics of water resource management in Indian will be quite complex. The conceptual framework itself suggests that actions will be required at different levels, household, village/community, district, state, national and international.

Thus the problem has to be addressed at all these levels. The integration of the issues of fresh water supply and demand and the water balance, technology, institutions, and the legal and socio-economic aspects at the local level have to be meshed into policies for water resource management.

Domestic Roof Water Harvesting (DRWH): How Relevant?

From the above discussions it is clear that all possible approaches must be tried to mitigate the immediate problem of drinking water, maximising the control of the households with regard to their own water security. Domestic roof water harvesting seems to be an appropriate option under these conditions provided it is cost effective. Infact traditionally this was the major option to the population in water scarce areas where the people had also learnt to control their demands, conserve water to the extent possible and manage to fulfil drinking and other domestic water needs, essentially by water harvesting. Given the ubiquitous contamination of not only surface but also ground water by pathogens and chemical contaminants induced by population growth, intensive agriculture and industrialization, DRWH has become more relevant than ever, even in areas which enjoy high rainfall. Infact these regions could be the best models for testing the feasibility of water security at affordable costs by DRWH. Fortunately the government is also supportive of propagation of DRWH. Water harvesting has been recognised as one of the appropriate technologies useful in different parts of the country (Ref. `Directory of Rural Technology', Volume 3, 1989. Drinking Water. Council for Advancement of People's Action and Rural Technology, New Delhi). A number of NGO's have shown interest in testing and propagating DRWH. In vies of this, the Indian partners of the current project on DRWH have taken up the study with special focus on Water Quality (WQ). In the subsequent chapters, the role of DRWH in international / national context is reviewed with focus on the WQ aspect.

SECTION II
ROLE OF WATER HARVESTING IN INDIA

Introduction

Water harvesting is the deliberate collection and storage of rain water that runs off a natural or man made catchment surface. Catchments include roof tops, compounds rocky surfaces or hill slopes or artificially prepared impervious/semi-impervious land surfaces. Storage, on the other hand, may be done into tanks, lined pits, small dams or in the sandy beds of seasonal rivers. The `stores' are filled during rainfalls. Water users are thus left with a fixed volume of water until the next rain comes. The amount of water harvested (collected and stored) depends on the frequency and intensity of rainfall, the catchment characteristics and water demand and how quickly and how much runoff occurs (or conversely, how easy it is for the water to infiltrate through the surface to recharge the aquifer).

Water harvesting has been of particular importance in the arid and semi-arid regions and remote isolated habitations and in difficult terrains, where it may often provide the only feasible solution for an improved water supply. Hence in India, traditionally water harvesting technique had sustained in certain areas . For example, the type of water harvesting systems in different kinds of terrain's have been documented by Agarwal (Dying Wisdom, 1997).

Unfortunately traditional water harvesting techniques have been severely eroded. Modern attempts to restore them must reckon with the causes of their decline. Also since in the modern context, the problem of water scarcity (in terms of availability of uncontaminated water source) has become more wide spread and varied, the technology must be examined in the different eco-regions of India. The government of India has focussed on regions which suffer water scarcity, shortages or stress at some time during the year. The following have been identified as the main parameters which should be considered:

◊ Precipitation and topography
◊ Hydrological characteristics
◊ Geo-hydrological characteristics
◊ Level of industrialization
◊ Intensity of irrigation
◊ Level of urbanization

While combinations of these parameters can generate a wide range of situations, some broad generalization may be made. For example, India can be divided into several eco-regions which represent a broad range of situations where water resources are a major concern. These are:

- Arid and semi-arid regions in the west
- Rain shadow of the Western Ghats
- Drought prone regions
- Coastal regions
- Mountains and highlands
- Plains of the Ganges river
- Deserts
- Urban and metropolitan areas
- Other regions with severe chemical pollution

Realising importance of water related issues, various state governments as well as CAPART (Council for Advancement of People's Action and Rural Technology) and RGNDWM (Rajiv Gandhi National Drinking water Mission) have supported different projects on watershed management and RWH. Specifically DRWH has also been supported.S.E.R.C.(Structural Engneering Research Centre) has played a leading role in developing ferrocement technology and propagating this for building appropriate storage tanks. They have developed and commercialised a variety of techniques such as (I) Skeletal cage technique ,(II) SERC segmental casting technique and (III) Sac mould tecnique.

Dr.P. C. Sharma of SERC has also conducted several training programmes in South East Asia and India. However most of the Water Harvesting systems created by then are in the hilly areas of North and North eastern states.

However this technology has not been tested to a significant extent. A few leading NGO's and researchers have in the last 2-3 years, put up WH units on an experimental basis.(See Section iii). Keeping this in view in the current project, special attention has been paid to Kerala state which has good amount of biennial rain so that precipitation will not be a restricting factor. Rainfall pattern in Kerala is examined in the background of rainfall in India.

Rainfall Pattern in India

India (Fig. 2.1) has very good rainfall averaging around 1050 mm though it fluctuates widely over the country. Regions can be broadly classified according to rainfall figures: Desert (0-100 mm), Semi-desert (100-250), Arid (250-500 mm) and Semi-arid (500-750 mm) and medium-high rain fall areas (1000-3000 mm).

The coastal areas of the states receive high rainfall, decreasing over the interiors. The entire west coast covering the coastal areas of Maharashtra, Karnataka and Kerala receives annual rainfall of the order of 2500 mm. The rainfall increases all along the western ghats to 4000 mm. The rainfall decreases rapidly on the lee side of the western ghats over the plateau areas on the eastern side to about 500 mm. As we move further eastwards, the annual rainfall increases again to about 1000 mm along the eastern coast of Tamil Nadu and Andhra Pradesh. The states of Orissa, MP and coastal area of south Gujarat receive annual rainfall in the order of 1500 mm whereas the interior portion of Gujarat receives about 750 mm further decreasing to 400 mm over the extreme west. India's desert and arid regions are characterized by low and highly variable annual rainfall, strong variations in rainfall through space and time, high temperature and evaporation levels.

Under the current project, DRWH systems will be tried in state of Kerala (Fig. 2.1) as representative of humid tropics receiving a high annual rainfall.Therefore the variation in rainfall within the state of Kerala is discussed in detail. Representative sites will be selected based on both, rainfall and other considerations, for DRWH implementation in this state.

Rainfall over Kerala

Kerala which lies at the extreme southern parts of the peninsula is one of the smallest states in India. Through out the year Kerala receives rainfall, though the major rainy season is the South West monsoon period from June to September. The annual and seasonal distribution of rainfall is described briefly.

Climatology

Kerala occupies the portion of the subcontinent bounded by Lat. 8^o-13^oN and long. 75^o-77^oE. By physical features Kerala is divided into 3 natural divisions: (i) the low lands consisting of coastal areas, (ii) the middle land and (iii) the high land or the forest area of the Western Ghats on the eastern side. The extreme southern parts of the Ghats run along the eastern boarder of Kerala around 560 km in length.

The climate of the state is typical tropical monsoon with seasonally excessive rainfall and hot summer. There are basically 4 seasons (i) March to May the summer or pre-monsoon season, (ii) June to September the south west monsoon season (iii) October to December north east monsoon and (iv) January-February the winter season.

Rainfall

The annual rainfall in the state varies from 3800 mm in the north to 1800 mm in the extreme south. The annual average rainfall for Kerala is 3070 mm and the departure from this in different years is shown.(Table 2.1).

Seasonal Rainfall: South West Monsoon

The major rainfall season for Kerala is the south west monsoon period from June to September. The normal date of onset of south west monsoon is 1st June. During this period the average rainfall expected is 213o mm (Table 2.2) which constitutes 70% of the annual rainfall. This also varies from north to south, the variation being 85% in the north to 54% in south. The district wise normal rainfall during south west monsoon period is given in the tables (2.21-2.24). The captions in the tables are derived from the names of the district.

It can be seen that lowest rainfall during south west monsoon is being received in Thiruvananthapuram (TRV) district while the highest rainfall is in Wayanad (WYD) district. The annual highest average rainfall is in Kozhikode (KZK) district. The heavy falls during south west monsoon is due to the monsoon depressions which form over Bay of Bengal and Arabian Sea.

Next to the south west monsoon, the other principal rainy season is the northeast monsoon period which starts from October and ends with December. During this period Kerala receives 16% of its annual rainfall, i.e., 500 mm and there is a reversal in the order of rainfall activity from north to south. When the southern district receives around 600 mm of rain, only 350 mm of rain is received in the northern districts during this period.

During the summer period, i.e. March, April and May, Kerala receives 40 cm of rain which is 13% of the annual rainfall. This is mostly due to thuderstorm activity which is purely a local phenomenon.In winter season, i.e., January-February, only 1% of the annual rainfall is received. This amounts to only 3 cm of rain.

The state receives an annual rainfall of 307 cm which is much above the average rainfall (110 cm) for the entire country 86% of the total rain is being received during the two monsoon seasons, i.e., June to December. It may be noted that this rain water is the main source for the next 6 months, i.e., January-May for the different kinds of use in various activities. Any failure in the southwest monsoon or northeast monsoon will result in scarcity of water. This will also affect the availability of drinking water, electricity production and agriculture (see deviations in annual rainfall, Table 2.2). All efforts should therefore be made to plan and manage the use of water with utmost care so that even when the monsoon fails, water scarcity is not felt. Collection of rain water during the rainy season both for drinking and other purposes would hence be most useful.

In terms of water security, it may be that among the 35 Meteorological Sub-divisions in India, Kerala receives the maximum annual rainfall. Considering the area and population, around thirteen thousand liters of water is available per head per day out of which perhaps only one or two percent is sufficient for meeting the daily needs of a person. Thus water security in terms of quantity especially in the high rainfall areas of Kerala, is very good. This state is hence highly suitable for testing DRWH in terms of economic viability and water quality visa-vis other alternatives for at priding water.

SECTION III

`DRWH' AND WATER QUALITY: A DESK REVIEW

Background

Effectively a modern DRWH system has to take into consideration 4 aspects:

i. Technology – Maximising efficiency of collection and storage at minimal cost.
ii. Water quantity/water security.
iii. Water quality to meet the current standards for drinking water.
iv. Attitude of people, policy makers, planners/administrators.

Under the EC project, all the above are being studied each aspect being led by one of the partners. A study on WQM is lead by I.I.T., Delhi, with support from the University of Warwick.

Water quality is a very important issue. According to WHO, 80% of diseases are caused due to contaminated water. The major contaminants may be classified into biological and non-biological. The diseases related to some of these are listed in the table 3.1 and 3.2

The water quality standards recommended for drinking water by WHO and other similar bodies are stringent. The maximum permissible limits of various physico-chemical parameters defining water quality (WQ) are given in table 3.3-3.6 as prescribed by the Indian RGNDWM and WHO. Each country while generally following international standards may provide for slight deviations depending upon the agro-climate, availability of water resources, socio-cultural practices, water conservation rates etc.

In the developing countries biological contaminants arising from water pollution by faecal waste and excreta of various animals are prevalent and is a major cause for concern. On the other hand a variety of metal ions which are highly toxic originate from improper handling and discharging of industrial effluents. Contamination by salts, fluoride and arsenic of geo-chemical origin also occur due to changing pattern of water use, resulting from over exploitation of water resources. Pesticides and other agro-chemicals originate from adoption of intensive agriculture practices for high yielding varieties of crops. Fortunately in `RWH', by the very nature of water collection process, many of the contaminants are not expected to be present in the water. For example ,if water is collected directly from roof and stored above ground, bacterial contamination should be minimal or absent unless the roof is accessible to human and animals. Bird droppings can be an issue and have to be guarded against by not having perches such as trees, in the vicinity. Also storage under anaerobic condition is expected to check the proliferation of bacteria due to lack of air and nutrients, even if it has been introduced from the roof. Problems of bacterial contamination may arise in ground water storage if there are cracks in the lining and contaminated water leaks into it.

As for chemical contaminants, these may arise from a variety of materials with which the rain water comes into contact starting from the atmosphere. Rain water could dissolve gases and wash off chemicals from contacting dust particles and roof materials. It could dissolve the metals or derived chemicals. Elution of chemicals from the walls is also possible from the storage tank.

The Global Scenario

A review of DRWH literature reveals that out of the large number of papers published, only a few have reported on `WQ'. In the traditional system, generally WQM is not done systematically WQ seems to be accepted as long as the water doesn't cause any diseases and the looks and taste are satisfactory. In the modern context however, the physical parameters are measured in terms of pH, turbidity, colour, odour and TDS. In addition tests are made to quantify various biological and chemical contaminants. The available literature related to WQM from different continents and sub-continents is summarised below.

Africa

- J.E. Gould[3.1] has discussed bacteriological analysis (total coliform, faecal coliform and faecal streptococci) from roof tank water. Accepted water qualtiy standards of Botswana is also tabulated. Generally high quality of properly stored rainwater is seen.

  Periodic chlorination is the most economic solution as suggested by the author. However the factors which will determine whether a water source is used or not are more likely to be related to taste, colour and odour, rather than necessarily directly to quality as stated in the paper.
- Gould and McPherson[3.2] have described bacteriological analysis of water samples from 13 roof tanks and 8 ground catchment tanks in Botswana. The results show that rainwater collected from corrugated iron roofs and stored in covered tanks is of high quality compared with traditional water sources. Water from roof catchment systems in Botswana presents a serious health hazard.
- Mayo and Mashauri[3.3] have given the bacteriological (total and faecal coliform and faecal streptococci), chemical (pH and total hardness) and physical (turbidity & colour) analyses of water samples from rainwater cistern system at the University of Dar es Salaam in Tanzania between October, 1988 and December, 1989. The results showed that 86% of samples were free from faecal coliform. However, faecal streptococci were obtained in 53% of the samples and 45% of the samples tested for total coliforms were positive. About 54% of the consumers raised objections over the taste of water. The pH range was found out to be 9.3-11.7 which is above standard limits.
- Otieno[3.4], Kenya has established from a study that except for the initial rainfall, the quality of rainwater is quite high, comparing favourably with river waters. (He has tabulated comparison of rainwater from roof catchment with river water and WHO standards). Guidelines for prevention of cisterns have been described and the need for maintaining quality of the stored water is emphasized.
- Bambrah and Haq[3.5] have discussed the suitability of using untreated rainwater for human comsumption in Kenya. They have reviewed existing literature on rainwater quality in their country. Guidelines for drinking water quality and various physical and chemical treatments have been described for disinfecting the stored water.

Australia

- Ghafouri and Phillips[3.6] have tabulated water quality guidelines by NSW recycling coordination committee. WQ of stormwater from urban catchments has been given. They have mentioned that roof water is seen as one of the possible sources of collecting rain water.
- Most extensive study on quality aspects of water stored in domestic rainwater tanks has been given by Fuller et al[3.7]. For South Australia. Water samples from three different areas (Vineyard and Orchard areas: 7 cities), industrial areas: 4 cities, and residential areas: 2 cities) were collected which reflected conditions in water stored in domestic rain

water tanks through South Australia. Galvanised iron tanks within the range of 10,000 to 25,000 liter with closed tops were selected. Tanks which had catchments of unpainted galvanised iron were chosen. Also householders were aksed to answer a series of question regarding use and maintenance of their tanks. Microbiogiological parameters, heavy metals (Pb, Zinc, Cd), pesticides and other physico-chemical tests (temperature, pH, suspended solids, total dissolved solids and salinity). Results of the study are summarised:

i) Coliform bacteria: coliform bacteria were present in 12 of 41 tanks, up to 500 coliforms/100 ml were recorded.

ii) E. coli: E. coli was detected in 6 tanks 15% of 41 tanks levels up to 220 E. coli/100 ml were recorded.

iii) Plate counts gave an indication of the general level of microbiological contamination of water. Plate counts in most rainwater tanks were in excess of 1000/ml.

iv) Heavy metals:
   - Cadmium: One of the tanks reported relatively high cadmium concentration (0.018 mg/l). This could be a sampling error or contamination caused by an isolated event.
   - Lead: Concentrations of lead in rainwater from tanks in Port Pirie were significantly higher (0.061 & 0.072 mg/l) than other sites. This could be a result of dust from surroundings country sides washed from roof tops with each rainfall.
   - Zinc: Zinc concentrations were found to be excess of 15 mg/l

v) Pesticides were not detected in the majority of samples.

vi) Suspended solids: Concentrations were negligible in all samples.

vii) pH: range of pH values was 6.1 to 9.2 low. pH values can accelerate corrosion problems in domestic appliances while high pH is an indication of undesirable biological activity in the tank.

viii) T.D.S.: Only samples taken from 2 rainwater tanks had T.D.S. concentrations in excess of 100 mg/ml (caused by sea spray).

Europe

- Per Jacobsen[3.8] has tabulated concentrations of lead (0.1 mg/l) and Zinc (0.1-1.00 mg/l) exceeding the standards for drinking water in Denmark. Lead, Zinc, Cadmium and copper were estimated.
- Wilhelm Meemken[3.9] has tabulated quality of rain water collected from roofs in Germany. Chemical parameters included (Fe, Mn, Cu, Pb, Zn, pH, Ca, Mg, Na, K, NH_4^+, SO_4^{2-}, Cl^-, NO_3^-, NO_2^- and electrical conductivity. The table showed the rainwater collected from roofs could be used for flushing toilets, washing cloths and watering plants without special treatment.

Asia

- Appan[3.10] has described roof water collection systems in some southeast Asian countries (Thailand, Indonesia, The Philippines, Malaysia and Singapore).

  Thailand: Physico-chemical parameters (pH, colour, turbidity, iron, manganese, lead and cadmium) and bacteriological analysis (T. coli, F. coli) has been tabulated. In terms of physico-chemical parameters, more than 83% of the samples were satisfactory except for about 40% of the samples exceeding the allowable limits of lead. In terms of E. coli, more than about 76% of the samples had values exceeding the WHO guideline standards.

In another series of bacteriological tests conducted in three locations in Khon Kaen, 709 water samples were collected from tiled roofs and gutters, containers located in homes, jars and the point of consumption. In terms of the three coli groups, only 10% to 67% of the samples were within the WHO guideline values. Samples other than those collected from the container showed that, due to an FC/FS ratio of less than one, 79% to 82% of the contamination could have emanated from animal droppings. In the same study, only manganese (in 2-20% of the samples) and zinc (in 4-26% of samples) did not meet the guideline levels.

Indonesia: Although RWCS seem to have been practiced with extensive experimentation using different types of materials, there is practically no available information on the quality of collected water. It has been observed that some measures such as fish rearing within the tanks have been practised so as to keep the water clean.

The Philippines: In a study spread over a period of one year in three villages in the Province of Capiz involving 25 ferrocement tanks, it was shown that not less than 24% of the samples had T. coli exceedings the WHO guidelines values.

Malaysia: The quality of rainwater and roof runoff has been monitored and 72 samples were collected from two types of roofs in West Malaysia. The range of turbidity, lead and F. coli values far exceeded the WHO guidelines values. The pH value of rainwater also has a tendency to lie towards the lower range of the guideline values.

Singapore: Roof water was monitored from a high rise building in the Nanyang Technological University for six years from May 1989. The values appear to be acceptable in all the physico-chemical parameters except pH which is quite low. T. coli and F. coli values also exceed the guideline values. Earlier field investigations have also shown that, during January 1974 to July 1983, the range of pH in 11 monitoring stations distributed throughout Singapore was 4.8 to 5.5.

- Appan[3.11], in a case study on rainwater catchment systems has summarised data on quantity and quality of water for non-potable uses. Physico-chemical parameters (pH, colour, turbidity, salinity, TSS, TCC, TDS, oil and grease) of raw rainwater and treated water are tabulated. Rain water is effective for non-potable uses like flushing, cleaning, gardening etc.
- Xijing et al[3.12]. from China have analysed and assessed WQ of the catchment and storage rainwater physico-chemical testing result have been discussed. pH, Cu, Pb, Se, Zn, K, nitrites, total alkalinity have higher values in the rainwater contained in concrete water cellars with cement or grey tile catchment surfaces. The indices of As, Fe, Ca^{2+}, Mg^{2+}, total hardness have higher values in the rainwater contained in soil water cellars. Total coliform become fewer in rainwater contained in concrete cellars with tile surfaces. The author emphasized that the problem could be solved through changing the building materials of catchment surfaces and water cellars, improving hygienic conditions and taking some effective disinfectant measures.
- Kita and Kitamura[3.13] from Japan have described fluctuation in the quality of rainwater stored in container during storage. The results are:
  - pH & COD remains constant
  - NH_4 first increases then decreases and finally remains O mg/l
  - Color and turbidity remain constant
  - Results of coliform group of bacteria were positive throughout the periods.

- Feasibility of using roof rainwater catchment systems in West Bank (Palestine) as supplementary water source have been investigated by Sharekh[3.14] water quality issues and discussed. Physico-chemical and bacteriological test results tabulated have been (pH, Ec, TDH, Ca, Mg, Na, K, Cl, CO_3^-, HCO_3^-). It was found, rainwater stored in cisterns was used for drinking and domestic purposes. Level of total coliform contamination were found 27%>0 coliform. Concentration of major constituents well within the prescribed limits.
- Metals (Fe, Zn, Pb) concentration greatly exceeded the standards in a study of rainwater collected from roof tops in Japan (Tachi-kawa).
  In Chiyuda city (Japan), quality of 1st flash of rainwater after a 11 day dry spell have been investigated physico-chemical (Fe, Cd, Cr, Cu, Mn, Ni, Pb, Zn) parameters tabulated initial rainfall upto 1.5 mm shows that the voluem of pollutants had accumulated on the roof for a 11 day dry spell.
  Nariyuki Fukano[3.15] (Japan) has discussed, prevention of mosquito breeding in rainwater storage tanks. As for rainwater storage tanks installed in large structures, mosquito breeding can be prevented by installing insect proof nets or other insect proof devices in vent routes. In home use tanks, water is always consumed and replenished, so rainwater does not stay in storage tanks for a long time. Therefore, even if insect eggs are mixed into tank water or a misquito enters into the tank and spawn eggs, there is virtually no likelihood of mosquito proliferation. Mosquitoes seem to breed easily in rainwater drainage pits that drain rainwater from roofs and the ground surface into sewers because many leaves tend to accumulate producing a condition conducive to mosquito breeding. To change conventional rainwater drainage pits to ones made to permeable material is a good solution to avoid mosquito problems, even if some cost is involved because the rainwater in permeable rainwater drainage pits infiltrates into the grouns so mosquito larvae cannot breed there.
- Water shortage in various regions in Japan is taken care by utilizing rainwater as an alternative as reported by Kitamura et al[3.16]. Although rainwater quality is acceptable, variations take place during storage.
  - Physico-chemical parameters studied for rainwater and ground water
  - No bacteriological studies were reported.
  - Stored rainwater pH were almost constant except for the last 3 weeks duration.
  - Turbidity varied during first two weeks
  - Ammonia nitrogen varied decreasing storage, which was probably caused by the bacterial activities. Bird droppings and insect carcasses were stored together with collected rainwater. It was a sanitary problem.
- When the alternative water source which had normal fluoride levels such as rainwater is adopted, the water borne disease/fluoride endemics can be controlled or possibly eradicated as reported by Bo-ling[3.17] in China. Investigation demonstrated the highest fluoride contents were in the well water. 24-40 mg/l while the lowest was in the rainwater: 0.78 mg/l.
- Physico-chemical quality along with bacteriological quality has been tanlated for 3 selected sites in Sri Lanka by Heijen and Mansur[3.18]. Color/turbidity are a bit higher than expected. Dirt on the roof and the non-application of a first flush device or a simple filter were the likely causes. E. coli count was consistant low, though 21% of samples shown 100 colonies/100 ml of total coliform.
- Hussain et al[3.19]. in the paper described RWCS, storage and purification practices in 3 locations. Also it described materials used in gutters, rainfall, method of collection,

maintenance and water use. Periodic cleaning of tanks and proper closure of the month of the storage container was desired. Water quality control was not often practiced. Few villagers tried to maintain quality of water due to fear of water borne disease. Biological, chemical, filtration and sedimentation were some of the methods for water quality control.

- National Water Supply and Drainage Board, Sri Lanka[3.20] has tabulated all chemical and bacteriological analysis (total coliform, E. coli and faecal striptococci) report. No chemical pollution has been found, bacterial contamination was there and the board recommended boiling of stored rainwater before consumption.

India

- Sh. P.K. Sivanandan[3.21] has reported chemical analysis of water sample from open wells in Adimalathura area, Kerala (Jan.-Feb., 99). 11 samples from all around villages were collected and chemical testing was done. Parameters studied were pH, EC, D.O., chloride, total hardness, Ca hardness, Mg, total alkalinity, bicarbonates and carbonates). Results indicated that chemical quality of water had potable status.
- Mitraniketan[3.22] (Kerala) in a project report tabulated rainwater analysis. Chemical parameters included pH, alklanity, chloride, iron, nitrate, nitrates, sulphate, total solids and hardness. Bacterial examination was also done. In a span from 10.6.98 to 26.7.98, the results revealed that the stored water had potable status.
- Ruchi[3.23] (Solan, Himachal Pradesh) stated that water quality was tested. Initially and was suitable for drinking purpose.

Conclusions

The literature on WQ generally has reported on pH , EC, turbidity, total hardness etc. However correlation of these with details on technology of water (type of roofing/guttering) and storage are missing. The methodology for valuation of WQ is also missing. Besides quality of water one of the other concern is insect breeding in DRWH. Mosquito breeding would be a health hazard. Hardly any data related to this is available. To collect more authentic details of WQ, a survey format has been designed by IIT Delhi and will be administered in different parts of the country. Based on limited data is seen that generally metal ions and other chemical contaminants are reported. The survey is designed to get data for correlating WQ with DRWH design parameters based on which optional designs could emerge.

In Indian context, list of key organiszations/institutions who are working in DRWH area have been collected (Appendix 3). Only a few of these however have done WQM. In the next phase of the work, it is proposed to cover WQ of all organisations who are working in Kerala and a few from other states for comparison.

Table 3.1: Water based disease transmission and preventive strategies

Classification	Transmission	Examples	Preventive strategies
Water-borne (water-borne diseases can also be water-washed	Disease is transmitted by ingestion	• Diarrhoeas (e.g. cholera) • Enteric fevers (e.g. typhoid) • Hepatitis A	• Improve quality of drinking water • Prevent casual use of other unimproved sources • Improve sanitation
Water-washed (water scarce)	Transmission is reduced with an increase in water quantity: • Infections of the intestinal tract • Skin or eye infections • Infections caused by lice or mites	• Diarrhoeas (e.g. amoebic dysentery) • Trachoma • Scabies	• Increase water quantity • Improve accessibility and reliability of domestic water supply • Improve hygiene • Improve sanitation
Water-based	The pathogen spends part of its life cycle in an animal which is water-based. The pathogen is transmitted by ingestion or by penetration of the skin.	• Guinea worm • Schistosomiasis	• Decrease need for contact with infected water • Control vector host populations • Improve quality of the water (for some types) • Improve sanitation (for some types)
Insect-vector	Spread by insects that breed or bite near water	• Malaria • River blindness	• Improve surface-water management • Destroy insects' breeding sites • Decrease need to visit breeding sites of insects • Use mosquito netting • Use insecticides

Table 3.3 : WHO Guidelines for Drinking Water (1984)

Parameter	Guideline value*
Colour (TCU)	15
Turbidity (NTU)	5
PH	6.5-8.5
Hardness (as $CaCO_3$)	500
Iron	0.3
Manganese	0.3
Sulphate	400
Chloride	250
Total Dissolved Solids	1000
Nitrate	10
Arsenic	0.05
Cadmium	0.005
Chromium	0.05
Cyanide	0.1
Fluoride	1.5
Lead	0.05
Mercury	0.001
Selenium	0.01
Zinc	5
F. coli/100 ml	0
T. coli/100 ml	0

* Note: All units, except pH, in mg/l unless stated otherwise

Table 3.4: WHO Guidelines for Drinking Water Constituents
Microbiological and Biological Quality

Organism	**Unit**	**Guideline value**	**Remarks**
I. MICROBIOLOGICAL QUALITY			
A. Piped water supplies			
A1 Treated water entering the distribution system			
Faecal coliforms	Number/100 ml	0	Turbidity 1 NTU: for disinfection with chlorine pH preferably 8.0: free chlorine residual 0.2-0.5 mg/litre following 30 minutes contact
A2 Untreated water entering the distribution system			
Faecal coliforms	Number/100 ml	0	
Coliform organisms	Number/100 ml	0	In 98% of samples examined throughout the year in the case of large supplies when sufficient samples are examined
Coliform organisms	Number/100 ml	3	In an occasional sample, but not in consecutive samples
A3 Water in the distribution system			
Faecal coliforms	Number/100 ml	0	
Coliform organisms	Number/100 ml	0	In 95% samples examined throughout the year in the case of large supplies when sufficient samples are examined.
Coliform organisms	Number/100 ml	3	In an occasional sample, but not in consecutive samples
B. Unpiped water supplies			
Faecal coliforms	Number/100 ml	0	
Coliform organisms	Number/100 ml	0	Should not occur repeatedly if occurrence is frequent and if sanitary protection cannot be improved an alternative source must be found if possible.
C. Bottled drinking water			
Faecal coliforms	Number/100 ml	0	Source should be free from faecal contamination
Coliform organisms	Number/100 ml	0	
D. Emergency water supplies			
Faecal coliforms failure	Number/100 ml	0	Advise public to boil water in case of to meet guideline values
Coliform organisms	Number/100 ml	0	
Enteric viruses			
II. BIOLOGICAL QUALITY			
Protozoa (pathogenic)		Do	
Helminths (pathogenic)			Do
Free living organisms (algae others)		Do	

Table 3.5: Tentative Limits for Toxic Substances in Drinking Water

Substance	Upper limit of concentration (Mg/l)	Methods of estimation
Arsenic (as As)	0.05	• Polarographic estimation • Atomic absorption spectrophotometric method • Use of Gutzeit generator
Cadmium (as Cd)	0.01	Dithizone method
Cyanide (as CN)	0.05	Can be estimated by means of a number of methods of which the following are generally in use and are equally satisfactory. • Titration with silver nitrate in dilute ammoniacal solution using diphenyl carbazide as an absorption indicator • Colorimetric method: Conversion of cyanide to either cyanogen chloride or cyanogen bromide & coupling with a suitable aromatic amino compound, such as dimodone, pyrozikine or sulfanilie acid • Colorimetric method: Yellow ammonium sulfide converts cyanide to thiocyanate in slightly alkaline solution: the thiocyanate reacts quantitatively with ferrie iron to form coloured ferric thiocyanate
Lead (as Pb)	0.1	• Polarographic estimation • Atomic absorption spectrophotometric method • Calorimetric methods
Mercury (as Hg)	0.001	• Neutron activation analysis • Atomic absorption
Selenium (as Se)	0.01	Colorimetric method using gum arabic solution, hydroxylamine hydrochloride sulphur dioxide and concentrated hydrobromic acid

Table 3.6: Specifications for Drinking Water (RGNDWM)

S.No.	Characteristics	Maximum permissible limits	Adverse effects beyond permissible limits	Alternative extended limits if no toxicity confirmed
1.	Colour (Hazen units)	10	Consumer acceptance decreases	50
2.	Odor	Unobjectionable	-	-
3.	Taste	Agreeable	-	-
4.	Turbidity (NTU)	10	Consumer acceptance decreases	25
5.	T.D.S. (mg/1)	500	• Palatability decreases • May cause g-i irritations	3000 (WHO limits: 4500)
6.	PH value	6.5 to 8.5	Mucous membrane affect	9.2
7.	Total hardness as $CaCO_3$ (mg/1)	300	Encrustation and adverse effect on domestic use	600
8.	Calcium as Ca (mg/1)	75	Do	200
9.	Magnesium as Mg (mg/1)	30	Do	100
10.	Copper as Cu (mg/1)	0.05	• Astrigent taste • Discoloration & corrosion of metalc parts	1.5
11.	Iron as Fe (mg/1)	0.3	• Taste/appearamce affect • Promotes iron bacteria	1.0
12.	Manganese as Mn (mg/1)	0.1	Taste/appearance affected	0.5
13.	Chlorides as Cl (mg/1)	250	• Taste/palatability reduces • Corrosion increases	1000
14.	Sulphates as SO (mg/1)	150	Gastro-intestinal irritations when Mg or Na present	400 (provided Mg does not exceed 30)
15.	Nitrate as NO (mg/1)	45	Methnaemoglobinemia takes place	No relaxation
16.	Fluoride as F (mg/1)	0.6-1.2	• Low fluoride are linked with dental care • Above 1.5 fluorosis	1.5
17.	Phenolic compounds as C H OH (mg/1)	0.001	Objectionable taste and odour	0.002
18.	Mercury as Hg (mg/1)	0.001	Toxicity increases	No relaxation
19.	Cadmium as Cd (mg/1)	0.01	Do	Do

SECTION – IV

WATER QUALITY MONITORING TECHNIQUES

Introduction

In the earlier chapter, parameters to be tested for WQM in DRWH were listed. Elaborate testing requires appropriate instrumentation and availability of a variety of chemicals. Further requisite skills may be called for. All this contributes to high cost of water testing. It may not be feasible to conduct such elaborate tests especially at the field levels, which may be located in remote locations. In view of this, a number of rapid testing methods have been evolved and standardized against the more elaborate testing procedures. Also in many countries, a set of tests are made available as a package in a compact field kit along with manual of instructions which can be followed easily by field level personnel. While less accurate than elaborate laboratory tests, these rapid tests are adequate to monitor whether the value of a given parameter exceeds acceptable limits. If rapid tests indicate unacceptable values for WQ, further tests and in depth studies can be recommended for immediate corrective action.

It may however be noted that basic principles involved in the rapid and elaborate tests may be the same. Hence the general principles and procedures for each of the WQ parameters are discussed below to help the user conduct the tests with an understanding of the processes involved. This will also help the user in taking proper precautions while conducting the tests.

A. TESTING OF CHEMICAL CONTAMINANTS

4.1) **Turbidity (Suspended solids)**

As the rain water falls on the roof, it may pick up fine dust particles. These will get washed down into the storage tank in the first flush. With suitable filters and appropriate mechanisms for rejecting the first flush, the water should be without suspensions. However in case the fine particles are of colloidal dimensions they will still persist and the water could thus appear turbid.

Turbidity can be measured by a Nepherometer.

Principle: This method is based on a comparison of the intensity of light scattered under the defined conditions with the intensity of light scattered by a standard reference suspension under the same conditions.

4.2) **Total Dissolved Solids (TDS)**

Water, a polar solvent has the capacity to dissolve ionic components from materials it contacts. In DRWH, as water contacts the roofs, gutters and inner walls of the storage structure, it may dissolve metallic salts and polar organic compounds if present in the environment.

Total dissolved solids can be measured by evaporating the water from an aliquot of water sample and weighing the residue.

Procedure: Measured volume of well mixed sample is filtered through glass fiber filter. It is washed with three successive 10 ml volumes of distilled water, complete drainage between washing is allowed and suction is continued for about 3 min after filtration is complete. Filtrate is then transferred to a weighed evaporating dish and is evaporated to dryness on a steam bath (if filtrate volume exceeds dish capacity successive portions are added to the same dish after evaporation). It is dried for at least 1 hour in an over at 180 ± 2^oC and cooled in a desiccator and weighed until a constant weight is obtained.

$$\text{Total dissolved solids in mg/1} = \frac{(A - B) \times 1000}{\text{Sample volume (ml)}}$$

Where,

A = weight of dried residue + dish (mg)

B = weight of dish (mg)

Ref. Richards (1954)

4.3) <u>Electrical Conductivity (EC)Measurements</u>

Electrical conductivity is commonly used for indicating the total concentration of ionic (salt) soluble constituents. It is closely related to the sum of the cations or anions as determined chemically and usually correlates closely with the total dissolved solids. It is a rapid and reasonably precise determination that does not alter or consume any of the sample. The apparatus for measuring electrical conductivity consists of an electrical resistance bridge and conductivity cell having electrodes coated with platinum black.

<u>Reagents</u>

Standard potassium chloride solutions: 0.7456 gm of dry reagent grade potassium chloride is dissolved in freshly prepared double distilled water and made to one liter. At 25^oC it gives an electrical conductivity (EC) of 1411.8×10^{-6} mhos/cm. The conductivity bridge is calibrated and cell constant is determined with the help of this solution.

<u>Procedure</u>: The measurement of EC (expressed in mmhos/cm) is adjusted for a known temperature (usually 25^oC) of the solution by setting up the knob provided for this purpose. The higher the salt concentration, the higher is the EC

Currently digital conductivity metres are also available. Just by dipping this in the water sample EC can be measured. The cost of an Indian meter of this kind is ~ Rs. 4,000. Many of the rapid testing kits have an EC meter incorporated which is calibrated to directly give the TDS.

4.4) pH

pH (the negative log 10 of hydrogen ion concentration in a solution) is a solution) is a useful parameter to indicate the presence of acidic or alkaline substances in water. The pH of water without contaminants is around 7 (neutral). If acids are present pH goes below 7 and with alkali it rises above 7. pH can be measured by colorimetric methods using various indicators. The indicators are chemical compounds which undergo change in color rapidly at a certain pH due to changes in their chemical structure. The indicators may be used in a solution and the colour change is seen using a colorimeter. For rapid tests the indicator may be mounted on paper strips.

For accurate measurement of pH, use of electrometric method employing hydrogen ion sensitive electrodes, in a pH meter is preferred.

<u>Apparatus</u>: There are number of makes and models of pH meters. Portable pH meters operated by battery are also available. The accuracy of pH measurement can vary from 0.01 to 0.1 depending on the make. Some pH meters employ two electrodes, an indicator glass

electrode, and a calomel reference electrode, while other may have a combined glass and reference electrodes. Most pH meters also have a temperature compensation systems to avoid the differences arising due to the different temperatures.

Procedure: The pH meter is calibrated using suitable buffers whose pH is known. The water sample is taken in a beaker and the glass electrode is dipped into it. Equilibrium between electrode and sample is established by stirring the sample to ensure, homogeneity and pH meter reading is read after dipping the electrode into sample for one minute.

4.5) **Estimation of Calcium and Magnesium Ions (Total Hardness)**

Hard water contains calcium and magnesium ions and estimation of these are important for determining the hardness of water. In the context of DRWH, water samples may contain these ions eluted from walls of storage tank if made of cement or lined with compounds containing calcium like lime or mortar.

Titration with EDTA (Ethylenediamine Tetra Acetate) is a common method for estimation of these ions.

Reagents

A. Sodium hydroxide (0.1 N)

B. Standard calcium solution : Weighed 1.0 gm of anhydrous calcium carbonate into a 500 ml erlenmeyer flask. A funnel was placed in the flask neck and 1+1 HCl is added until all $CaCO_3$ gets dissolved. The volume is made upto 1 liter.

C. Erichrome black T indicator – 0.5 gm of Erichrome black T in 100 g triethanolamine.2 drops of indicator is added to per 50 ml solution to be titrated.

D. EDTA (Versenate) solution (0.01 M) – 3.723 gm of disodium dihydrogen ethylene-diamine-tetra-acetate is dissolved in water and diluted to 1 liter. The solution is standardized ($CaCl_2$), using titration procedure given below using indicator (Erichrome black).

E. Buffer solution : 16.9 g ammonium chloride (NH_4Cl) is added in 143 ml conc. ammonium hydroxide. 1.25 g of magnesium salt of EDTA is then added and the volume is made to 250 ml with distilled water.

Procedure:

Titration of sample:

25 ml sample is diluted to 50 ml with distilled water. 1-2 drops of buffer solution are added (to give a pH of 10.0). 1-2 drops of indicator solution are added and the solution is titrated with standard EDTA solution, with continuous stirring till the end point is reached. (blue color)

Calculation

$$\text{Hardness as mg } CaCO_3/l = \frac{A \times B \times 100}{\text{ml sample}}$$

Where,

A = ml titration for sample

B = mg $CaCO_3$ equivalent to 1.00 ml EDTA titrant

A x B x 400.8

Calcium as mg Ca/l = ----------------------
ml sample

A = ml titrant for sample
B = mg $CaCO_3$ equivalent to 1 ml EDTA titrant at the calcium indicator end point

Magnesium as mg/l
Total hardness (as mg $CaCO_3$) -Calcium hardness (as mg $CaCO_3$/l) x 0.244

4.6) **Chloride**

Determination of chloride is important where water is brackish. Normally in DRWH, the water is not expected to have chloride. However since chlorine is also used for water treatment, the method of estimation of chloride is included herein. One of the procedures involves titration of the chloride containing sample with silver nitrate using chromate as indicator. The method is discussed below.

Reagents

a) Potassium chromate indicator solution: 50 gm K_2CrO_4 is dissolved in little distilled water. $AgNO_3$ solution was added until a definite red precipitate is formed. It is allowed to stand for 12 hrs. Then it is filtered and diluted to 1 liter with distilled water.
b) Standard silver nitrate titrate (0.0141 N): 2.395 gm $AgNO_3$ in distilled water is diluted to 1000 ml. It is standardized against 0.0141 N NaCl (1.0 ml = 500 gm Cl). It is stored in a brown bottle.
c) Standard sodium chloride (0.0141 N): 824.0 mg NaCl (dried at 140^oC) is dissolved in distilled water and diluted to 1000 ml (1.00 ml = 500 μg Cl).
d) Special reagents for removal of interference:
    1. Aluminium hydroxide suspension – 125 gm aluminium potassium sulphate of aluminium ammonium sulphate, AIK $(SO_4)_2$. $12H_2O$ or $AlNH_4(SO_4)_2$. $12H_2O$ in 1 liter distilled water. It was warmed to 60^oC and 55 ml concentrated ammonium hydroxide (NH_4OH) are added slowly with stirring. It is allowed to stand for 1 hour and transferred to a large bottle. The precipitate is washed by successive additions, with thorough mixing and decanting with distilled water, until it is freed from chloride. When freshly prepared, the suspension occupies a volume of approximately 11.
    2. Phenolphthalein indicator solution
    3. Sodium hydroxide, NaOH, 1 N.
    4. Sulphuric acid, H_2SO_4, 1 N.
    5. Hydrogen peroxide, H_2O_2, 30%.

Procedure

a) Sample preparation: Suitable portion of the sample is diluted to 100 ml. [If found coloured, 3 ml $Al(OH)_3$ is added to the sample, and the suspension formed is allowed to settle and filtered. If sulphide, sulphite or thisulphate is present, 1 ml H_2O_2 is added and stirred for 1 min.

b) Titration: Samples are directly titrated in the pH range 7 to 10. The pH of sample is adjusted to 7 to 10 with H_2SO_4 or NaOH, if it was not in this range. 1.0 ml $K_2Cr_2O_4$ indicator solution was added and titrated with $AgNO_3$ titrant to a pinkish yellow end point.

$AgNO_3$ titrant is standardized and reagent blank value was obtained by titration. Calculation is outlined below.

Calculation

$$\text{mg } Cl^-/l = \frac{(A - B) \times N \times 35450}{\text{ml sample}}$$

where,

A = ml titration for a sample
B = ml titration for blank, and
N = normality of $AgNO_3$
mg NaCl/l = (mg Cl^-/ L)x 1.65

4.7) **Nitrate**

Nitrates from decomposition of organic residues may reach ground water. Rain may normally be free of nitrate unless there is a high level of oxides of nitrogen in the atmosphere and rainwater dissolves it. The spectrophotometric method for measurement of NO^-_3 is discussed below.

Principle: Measurement of UV absorption at 220 nm enables rapid determination of NO^-_3. The NO^-_3 calibration curve follows beers law up to 11 mg/ml.

Reagent

Nitrate free water
Stock nitrate solution of KNO_3 (100 ppm) standard nitrate solution is diluted (50 ml stock solution made to 500 ml with water (10 ppm).
HCl soln (IN)

Procedure: Prepare NO^-_3 calibration standards in the range of 6-7 ppm by diluting the standard solution. Add 1 ml of HCl solution and mix thoroughly. Read absorbance against distilled water set at zero absorbance at 220 nm.

4.8) **Fluoride**

Normally fluoride is not expected to be present in rain water. Occurrence of F^- however depending on the level of industrialization and contamination has been reported under certain conditions. The method of measurement is discussed below:

Flouride (F^-) SPADNS method (spectrophotometric)

The reaction rate between flouride and ions is influenced greatly by the acidity of the reaction by increasing the proportion of acid in the reagent the reaction can be made practically instantaneous.
Reagent – Standard flouride solution of NaF (1000 ppm)
SPADNS solution dissolved 958 mg SPADNS sodium 2- (parasulfolthenylzao)- 1,8 dehydromy 3, 6 naphthalene disulfonate, the distilled H_2O and dilute to 500 ml

Zirconyl acid reagent dissolve 133 mg zirconyl chloride octohadrate, zrocl in about 25 ml distilled water. Add 350 ml Conc. HCl and dilute to 500 ml with distilled water.

Phenanthroline Method

Principle: Iron is brought into solution, reduced to the ferrous state by boiling with acid and hydroxylamine, and treated with 1,10-phenanthroline at pH 3.2 to 3.3. Three molecules of phenanthroline chelate each atom of ferrous iron to form an orange red complex. The colored solution obeys beer's law; its intensity is independent of pH from 3 to 9. A pH between 2.9 and 3.5 insures rapid color development in the presence of an excess of phemanthroline. Color standards are stable for at least 6 months.

Reagents

a) Hydrochloric acid, HCl, conc, containing less than 0.00005% iron.
b) Hydroxylamine solution: Dissolve 10 g NH_2OH HCl in 100 ml distilled water
c) Ammonium acetate buffer solution: Dissolve 250 g $NH_4C_2H_3O_2$ in 150 ml distilled. Add 700 ml conc (glacial) acetic acid. Because even a good grade of $NH_4C_2H_3O_2$ contains a significant amount of iron, prepare new reference new reference standards with each buffer preparation.
d) Sodium acetate solution: Dissolve 200 g $NaC_2H_3O_2$ $3H_2O$ in 800 ml distilled water.
e) Phenanthroline solution: Dissolve 100 mg 1,10-phenanthroline monohydrate, $C_{12}H_8N_2H_2O$, in 100 ml distilled water by stirring and heating to 80 C. Do not boil. Discard the solution if it darkness. Heating is unnecessary if 2 drops conc HCl are added to the distilled water. (Note: one milliliter of this reagent is sufficient for no more than 100 μg Fe.

Procedure

Preparation of calibration curves for samples analyzed in accordance with is below:
Range 0 to 100 μg Fe/100 ml final solution pipette 2.0, 4.0, 6.0, 8.0 and 10.0 ml standard iron solution [3 gl] into 100 ml volumetric flasks. Add 1.0 ml NH_2OH HCl solution and 1 ml sodium acetate solution to each flask. Dilute each to about 75 ml with distilled water, add 10 ml phenanthroline solution, dilute to volume, mix thoroughly and let stand for 10 min. Measure absorbance in a 5 cm cell at 510 nm against a reference blank prepared by treating distilled water with the specified amounts of all reagents except the standard iron solution.

Acid zirconyl-SPADNS reagent: Mix equal volumes of SPADNS solution and zirconyl-acid reagent.
Reference solution: Add 10 ml SPADNS solution to 100 ml distilled water. Dilute 7 ml conc HCl to 10 ml and add to the diluted SPADNS solution. The resulting solution, used for setting the instrument reference point (zero).

Procedure

Preparation of standard curve: Prepare fluoride standards in the range of 0 to 1.40 mg/l by diluting appropriate quantities of standard fluoride solution to 50 ml with distilled water. Pipet 5.00 ml each of SPADNS solution and zirconyl-acid reagent, or 10.00 ml mixed acid-zirconyl-SPADNS reagent, to each standard and mix well. Set photometer to zero absorbance with the reference solution and obtain absorbance readings of standards immediately. Plot a curve of the fluoride absorbance relationship.

Stannous Chloride Method

Principal: Molybdophosphoric acid is formed and reduced by stannous chloride to intensely colored molybdenum blue.

Reagents

1. Ammonium molybdate reagent I: Dissolve 25 g $(NH_4)_6Mo_7O_{24}$ $4H_2O$ in 175 ml distilled water. Cautiously add 280 ml conc H_2SO_4 to 400 ml distilled water. Cool, add molybdate solution, and dilute to 1l.
2. Stannous chloride reagent I: Dissolve 2.5 g fresh $SnCk_2 2H_2O$ in 100 ml glycerol. Heat in a water bath and stir with a glass rod to hasten dissolution. This reagent is stable and requires neither preservatives nor special storage.
3. Standard phosphate solution

Add with thorough mixing after each addition, 4.0 ml molybdate reagent 1 and 0.5 ml (10 drops) stannous chloride reagent 1. After 10 min, but before 12 min, using the same specific interval for all determinations, measure color photometrically at 690 nm and compare with a calibration curve, using a distilled water blank.

4.9) **Estimation of Metal Ions**

Metal ions could be eluted from the roof material. Generally toxic metal ions are not expected. The estimation of these can be done by titrimetry, atomic absorption spectrophotmetry etc. The methods are available in standard reference books.

Reference

1. Standard Methods for the examination of water and waste water (1995). 16^{th} Edn. APHA, AWWA/WPCF.

B. **TESTING FOR BACTERIAL CONTAMINANTS**

If rain water gets infected by bacteria and conditions are conducive to their growth it will become unpotable. To ensure that the drinking water satisfies public health requirements, it is necessary that samples should be examined at regular intervals for indicator micro-organisms. Pathogenic organisms are difficult to monitor as the methodology involved is time consuming and highly involved.

Any indicator bacteria selected should be closely associated with source of pathogen. It should be able to provide an accurate estimate of the number of pathogens present at the levels which pose a health risk. It should have same survival characteristics of the most resistant pathogen and be measurable by simple methods with accuracy. It should occur in greater numbers than the intestinal pathogens concerned and should be more resistant to disinfectants and natural processes than the pathogens.

The recommended bacterial indicator is coliform group of organisms. Coliform group of organisms are not pathogenic, they are aerobic, facultatively anaerobic, gram negative, non-sporulating, rod shaped bacteria, that ferment lactose with gas formation and aldehyde/acid with in 48 hours at 35^{o}C inculation. Coliform are capable of growth in presence of bile salts or other surface active agents which are cytochrome oxidase negative. Coliform belongs to family Enterbacteriaceae which includes genera *Escherichia, Klebsiella, Salmonella, Shigella, Aerobacter, Scrratia, Citrobacter* and *Proteus*.

Coliform group (total coliform) are almost always present in large number in faeces of man and other warm blooded animals. They can be detected even after dilution. Detection of thermotolerant faecal coliform particularly presence *Escherichia coli* one of the members of the coliform group is considered specific faecal pollution. However unlike many others which are not thermotolerant *E. coli* groups grow well at 44.5^{o}C, i.e. they can ferment lactose and also mannitol at elevated temperatures with the production of acid and gas and form tryptophan. Confirmed *E. coli* indicates positive reaction to methyl red test (undergoing change in colour due to pH change) failure to produce acetyl methyl carbinol (V.P. test) and failure to utilize citrate as sole source of carbon. The four biochemicals tests popularly known as IMViC test give confirmation of E. coli (Table 1).

Table 4.1: Characteristic based on IMViC pattern

Organism	Indole	Methyl Red	Voges Proskauer	Citrate
Escherichia coli	+	+	-	-
Shigella sp	+ or -	+	-	-
Citrobacter freundii	-	+	-	+
Citrobacter diversus	+	+	-	+
Klebsiella,Enterobacter & Aerobacter group	+ or -	-	+	+

The presence of faecal coliform cannot definitely identify human contamination of water systems and this has led to the introduction of supplementary indicator organisms. Another important component of human microflora is faecal streptococci. A group that includes all streptococci found in the intestine of warm blooded animals. The group `D' streptococci known as Enterococci includes *Streptococcus bovis*, Streptococcus equines and *Streptococcus* *fecalis*. Faecal Streptococcus and sulfile reducing *Clostridia* are useful in determining the origin of faecal pollution and also assessing the efficiency of water treatment process.

Ratio of faecal coliforms (FC) to faecal Streptococcus (FS) (FC-FS ratio).

Human population has a much higher ratio of FC-FS usually in excess of 4.0 whereas other warm blooded animals has FC-FS ratio less than 0.7. This kind of ratio can indicate as to whether contaminant in a water sample is of human origin or not.

Sample Collection, Storage and Transport

Samples should not be taken from leaking taps as there is possibility of external contamination. Water should run for 1 minute to ensure stagnant water is flushed from the pipes before sample is collected. It is desirable to flame the mouth of the tap before sampling.

Containers for sample should be clean, sterile, glass or autoclavable plastic bottles containing 0.1 ml of a 1.8% solution of sodium thiosulphate per 100 ml of sample bottle capacity to neutralize residual chlorine if chlorination has been done. Samples should be kept cool at 4-10^{o}C and transported to the laboratory within 6 hours of collection but never >24 hours.

Methodology for Coliform Detection

1) IMViC reaction
2) Multiple tube method or most probable number method (MPN)
3) Membrane filtration (MF) technique
4) Simple field test for detection of faecal pollution in drinking water (H_2S strip test).

1. **IMViC reaction**
1. Indole Test
   a. Reagents:
   1) Medium – Tryptophane broth
   2) Test reagent – Dissolves 5 g para-dimethyl-aminobenzaldehyde in 75 ml isoamyl (or normal amyl) alcohol. ACS grade and add 25 ml conc HCl. The reagent should be yellow. The amyl alcohol solution should have a pH value of less than 6.0.

   b. Procedure : Inoculate 5 ml portions of medium from a pure culture and incubate at 35$\pm$0.5 C for 24$\pm$2 hr. Add 0.2 to 0.3 ml test reagent and shake. Let stand for about 10 min and observe results.
   A dark red color in the amyl alcohol surface layer constitutes a positive indole test, the original color of the reagent, a negative test. An orange color probably indicates the presence of skatole.

2. Methyl Red Test
   a. Reagents:
   1) Medium: buffered glucose broth
   2) Indicator solution: Dissolve 0.1 g methyl red in 300 ml 95% ethyl alcohol and dilute to 500 ml with distilled water.

   b. Procedure: Inoculate 10 ml portions of medium from a pure culture. Incubate at 35^{o}C for 5 days. To 5 ml of the culture add 5 drops methyl red indicator solution.

Record a distinct red color as methyl red positive and a distinct yellow color as methyl red negative. Record a mixed shade as questionable and possibly indicative of incomplete culture purification.

3. Voges-Proskauer Test
   a. Reagents:
   1) Naphthol solution: Dissolve 5 g purified ∝-naphthol (melting point 92.5^oC or higher) in 100 ml absolute ethyl alcohol. When stored at 5 to 10^oC, this solution is stable for 2 week.
   3) Potassium hydroxide, 7N: Dissolve 40 kg KOH in 100 ml distilled water.
   b. Procedure: Separate 5 ml of the culture inoculated for methyl red test after 48 hr or inoculate 5 ml of salt peptone glucose medium from a pure culture and incubate for 48 hr at 35$\pm$0.5^oC. To 5 ml of culture add 3 ml naphthol solution and 1 ml KOH solution, and shake vigorously. Development of a pink to crimson color within 15 min to 1 hr constitutes a positive test.
4. Sodium Citrate Test
   a. Alternate media: Use either Koser's citrate broth or Simmons' citrate agar.
   b. Procedure:
   1) Lightly inoculate liquid medium with a straight needle, never with a pipette. Incubate at 35$\pm$0.5^oC for 72 to 96 hr. Record visible growth as positive, no growth as negative.
   2) Inoculate agar medium with straight needle, using both a stab and a streak. Incubate 48 hr at 35$\pm$0.5^oC. Record growth on the medium with (usually) a blue color as a positive reaction, record absence of growth as negative.

2. Multiple tube method or Most Probable Number Method (MPN) for standard total coliform (Table 4.2)

(1) Measured volumes of the samples of one or more dilutions are inoculated into a series of bottles or tubes containing suitable differential medium containing lactose. The tube should have inverted Durham tubes. After incubation at 35 or 37^oC for 48 hours tubes are examined for acid and gas production. Positive reaction is only presumptive as in addition to coliform other lactose fermenters also grow and produce acid and/or gas.

- This should be followed by confirmatory tests using selective differential media

- MPN method is a statistical estimate of most probable number of coliform in a given volume of sample.
- Sub-cultures made from positive tubes can be used for differentiation of coliforms.

1. Presumptive test
   Use Mac Conkey Broth in the presumptive test
   a. Procedure: Take 10 ml of Mac Conkey broth in fermentation tubes, add inverted durham tubes, plug and autoclave.
   1) Inoculate a series of fermentation tubes ("primary" fermentation tubes) with appropriate graduated quantities (multiples and submultiples of 1 ml) of sample. If 100 ml sample portions are used prewarm bottles at 35^oC. After adding sample mix thoroughly.
   2) Incubate inoculated fermentation tubes at 35$\pm$0.5^oC. After 24$\pm$2 hr shake each tube gently and examine it and if no gas has formed or been trapped in the inverted

vial, re-incubate and reexamine at the end of 48 ± 3 hr. Record presence or absence of gas formation regardless of amount at each examination of the tubes.

b. Interpretation: Formation of gas in any amount in the inner fermentation tubes or vials within 48+3 hr constitutes a positive presumptive test.

2. <u>Confirmed Test</u>

Use brilliant green lactose bile broth fermentation tubes for the confirmed test.

a. Procedure: Submit all primary fermentation tubes showing any amount of gas within 24 hr of incubation to the confirmed test. If active fermentation appears in the primary fermentation tube earlier than 24 hr preferably transfer to the confirmatory medium. If additional primary fermentation tubes show gas production at the end of 48 hr incubation, submit these to the confirmed test.

b. Procedure with brilliant green lactose bile broth: Gently shake or rotate primary fermentation tube showing gas and with a sterile metal loop, transfer one loopful of culture to a fermentation tube containing brilliant green lactose bile broth.

Incubate the inoculated brilliant green lactose bile broth tube for 48 ± 3 hr at 35 ± 0.5^{o}C. Formation of gas in any amount in the inverted vial of the brilliant green lactose bile broth fermentation tube at any time within 48 ± 3 hr constitutes a positive confirmed test.

3. <u>Completed Test</u>

Use the completed test on positive confirmed tubes to establish definitively the presence of coliform bacteria and to provide quality control data. Double confirmation into brilliant green lactose bile broth for total coliforms and EC broth for fecal coliforms may be used. Consider positive EC broth results as a positive completed test response.

a. Procedure:

1) Streak one or more eosin methylene blue plates from each tube of brilliant green lactose bile broth showing gas, as soon as possible after the appearance of gas. Incubate plates (inverted) at 35 ± 0.5^{o}C for 24 ± 2 hr.

2) The colonies developing on eosin methylene blue agar are called typical (nucleated with or without metallic sheen); atypical (opaque, unnucleated, mucoid, pink after 24 hr incubation), or negative (all others). Pick two or more colonies considered most likely to consists of organisms of the coliform group and transfer growth from each isolate to a lauryl tryptose broth fermentation tube and to a nutrient agar slant.

Incubate secondary broth tubes at 35 ± 0.5^{o}C for 24 ± 2 hr, if gas is not produced within 24 ± 2 hr reincubate and examine again at 48 ± 3 hr. Microscopically examine gram-stained preparations from those 24 hr agar slant cultures corresponding to the secondary tubes that show gas.

b. Interpretation: Formation of gas in the secondary tube of lauryl tryptose broth within 48 ± 3 hr and demonstration of gram negative, nonspore-forming, rod-shaped bacteria in the agar culture constitute a satisfactory completed test, demonstrating the presence of a member of the coliform group.

The sequence of tests for coliform for deciding on bacterial contamination in water are summarised in the flow chart.

Detection of coliform in water

Presumptive test

Inoculation of Mac Conkey Broth

Gas produced = Presumptive evidence of Coliform present

No gas = Coliform not present Examination stops here

Confirmed Test

Brilliant green lactose bile broth (BGLB) this medium inhibits the growth of Lactose fermenters other than coliform, thus gas formation in the BGLB medium constitutes a confirmed test, i.e. Coliforms present

or

Eosin-methylene blue agar (EMB) (coli-aerogenes organism produce characteristic colonies; Escherichia, small colonies, dark, almost black centres with green metallic sheen; Enterobacter; large pinkish mucoid colonies, dark centres, rarely show metallic sheen; presence of typical colonies constitutes a confirmed test, i.e., coliforms present)

Completed test

The most typical colonies are selected from EMB plate or BGLB and are inoculated into

Lactose broth (coliforms produce gas)

Agar slant (Gram stain prepared from growth, coliforms are Gram-ve, non sporulating bacilli)

Table 4.2: For most probable number (MPN) index and 95% confidence limits for various combinations of positive results when five tubes are used per dilution (10 ml, 1.0 ml, 0.1 ml)

2. **Membrane Filtration Techniques (MF)**
   Coliform organisms in water is determined by filtering known volume of the sample or appropriate dilution of it through porous cellulose acetate membrane, which is then incubated face upwards on suitable selective media in the absorption pads in the petri-dishes at 35-37^oC for 24-48 hours. Colonies that develop can be counted with the help of magnifying lens. Counts are expressed per 100 ml basis. It is usual to use 2 membranes for each sample, in order to incubate at 35-37^oC for total coliform and the other at 44.5^oC for faecal coliform.

Laboratory apparatus

Sample bottles, dilution bottles, pipettes and cylinders, containers for the culture medium, culture dishes, filteration units, filter membrances, absorbent, incubator, microscope

Procedure

Selection of sample is governed by expected bacterial density which in finished water samples will be limited only by the degree of turbidity.

Filteration of sample

Using sterile forceps, place a sterile filter over porous plate of receptacle, grid side up. Place matched funnel unit over receptacle and lock it in place. Filter sample under partial vacuum. With filter still in place, rinse funnel by filtering three 20-30 ml portions of sterile dilution water. Unlock and remove funnel, immediately remove filter with sterile forceps and place it on sterile pad or agar with a rolling motion to avoid entrapment of air. Use sterile filtration units at the beginning of each filtration series as a minimum precaution to avoid accidental contamination. A filtration series is considered to be interrupted when an interval of 30 minutes or longer elapses between sample filtrations. After such interruption, treat any further sample filtration as a new filtration series and sterilize all membrane filter holders in use. Decontaminate the equipment between filtrations by sterilization.

Enrichment technique

Place a sterile absorbent pad in the upper half of a sterile culture dish and pipette enough enrichment medium (1.8 to 2.0 ml lauryl tryplase broth) to saturate pad. Carefully remove any surplus liquid. Aseptically place filter through which the sample has been passed on pad. Incubate filter without inverting dish for 1.5 to 2 hr. at 35 ± 0.5^o C in an atmosphere of at least 90% relative humidity. Remove enrichment culture from incubator, lift filter from enrichment pad and roll out the agar surface. If the liquid medium is used, prepare final culture by removing enrichment culture from incubator & dish halves. Place a fresh sterile pad in bottom half of dish and saturate it with 1.8 to 2.0 ml. of final M-Endo medium. Transfer filter to new pad. Discard used pad with either agar on the liquid medium invert dish and incubate for 20-22 hr at 35 ± 0.5^oC.

Counting

Typtical coliform colony has a pink to dark red colour with a metallic surface sheen. The sheen area may vary in size from a small pinhead to complete coverage of colony. Count the colonies with colony counter

Calculation of coliform density:

$$\text{Total coliform colonies/100 ml} = \frac{\text{Coliform colonies counted x 100}}{\text{ml sample filtered}}$$

3. Simple field test for detection of faecal pollution in drinking water (H_2S strips)

The test is based on detection of hydrogen sulfide producing organisms in samples in water. It has been observed that coliform in drinking water is consistently associated with organisms that produce H_2S (*Salmonella, Proteus, Citrobacter* and same strains of *Klebsiella*)

Methodology: The method uses concentrated medium containing:

i)	Bacto peptone	20 g
ii)	Dipotassium hydrogen phosphate	1.5 gm
iii)	Ferric ammonium citrate	0.75 gm
iv)	Sodium thiosulphate	1.0 gm
v)	Teepol	1.0 ml
vi)	H_2O	50 ml

One ml of concentrated medium were absorbed on to 80 cm^2 folded tissue paper, which was placed in McCartney bottles sterilized and dried at 50^oC. The water samples to be screened for faecal pollution were placed in bottles up to pre-calibrated mark (20 ml) and allowed to stand at ambient temperatures (30-37^oC). Faecal pollution is indicated if the contents of the bottle turned black due to formation of iron sulfide in 12-18 hours.

H_2S producing organisms	Release H_2S + Fe	FeS
Coliforms in H_2O sample	During growth in medium that contain Ferric ammonium citrate	Black colour in the medium

The new test medium has good correlation with MPN test. The method is reliable and simple to perform.

Note: Recently UNICEF held a workshop on the efficacy of H_2S strip test and modifited methods to make it more rapid and accurate.

Tests for the faecal streptococcus group

Multiple tube technique

1. Presumptive test procedure
a. Take a series of test tubes containing 10 ml. Azide dextrose broth. Use 10 ml single strength broth for inocula of 1 ml or less and 10 ml double strength broth for 10 ml inocula
b. Incubate inoculated tubes at 35$\pm$0.5^oC. Examine each tube for turbidity at the end of 24$\pm$2 hrs. If no turbidity is present, reincubate and read against at the end of 48$\pm$3 hrs.

Confirmed test

Subject all azide dextrose broth tubes showing turbidity streak a portion of growth from each positive azide dextrose broth on a petridish containing PSE agar. Incubate the inverted dish at $35 \pm 0.5^{o}C$ for 24 ± 2 hr. Brownish black colonies with brown holes confirms the presence of *Faecal stretococci*.

Computing & recording of MPN as given in table 2.

C. TEST KITS AVAILABILITY AND DETAILS IN INDIA

For rapid testing kits have been developed by a number of Indian institutions and are being marketed. Also other countries have developed kits. Recently the Central Pollution Control Board (CPCB), Delhi and the Sriram Institute for Industrial Research, Delhi have conducted a comparative evaluation of various water testing kit packages available in India. Some manufacturers names and address are listed below . References on major reports concerning WQ monitoring are also listed.

Details of selected Water Quality Kits: Availability in India

1.	Developed by	:	Defence Laboratory, Jodhpur
	Method of Analysis	:	Qualitative, visual colour comparison
	Parameters that can be analysed	:	Fluoride, nitrate, iron, nitrite, residual chlorine, chlorides, total dissolved solids, faecal coliform
	Power Supply	:	220V AC mains or 12 V/DC battery
	Weight	:	10 kg
	Size	:	42 cm x 28 cm x 25 cm
	Components	:	Single unit with built in incubator
2.	Developed by	:	Industrial Toxicology Research Centre, Lucknow
	Method of Analysis	:	Quantitative, colorimetric & titrimetric
	Parameters that can be analysed	:	pH, fluoride, nitrate, iron, nitrate residual chlorine, chlorides, alkalinity, hardness and faecal coliform
	Power supply	:	AC mains, 20/110 volts for 1 KVA generator
	Weight	:	16 kg
	Size	:	50 cm x 35 cm x 28 cm
	Components	:	Incubator and calorimetric unit with suitcase holding chemicals (2 units)
3.	Developed by	:	National Environmental Engineering Research Institute, Nagpur
a)	Name of the kit	:	Rapid Aqua Tester
	Method of analysis	:	Colour comparison
	Parameters that can be analysed	:	pH, fluoride, iron, residual chlorine
	Power supply	:	No power required
	Weight	:	300 g
	Size	:	9.7 cm x 9.7 cm x 3.1 cm
	Components	:	Single unit
b)	Name of the kit	:	Rapid Bacteriological Tester
	Method of analysis	:	Bacteriological
	Parameters that can be analysed	:	Faecal coliform (12 hours)
	Power supply	:	230 volts AC
	Weight	:	10 kg
	Size	:	39 cm x 34 cm x 30 cm
	Components	:	Single unit
c)	Name of the kit	:	Aquazer

	Method of analysis	:	Visual colour comparison, titrimetric tablet count method, bacteriological examination
	Parameters that can be analysed	:	pH, fluoride, iron, residual chlorine, chlorides, hardness, nitrite, nitrate and faecal coliform (12 hours)
	Power supply	:	230 volts AC
	Weight	:	10 kg
	Components	:	Single unit
d)	Name of the kit	:	Titrimetric Water Analyser
	Method of analysis	:	Titrimetric tablet count method
	Parameters that can be analysed	:	Acidity, alkalinity, hardness and chlorides
	Power supply	:	No power required
	Components	:	Single unit
e)	Name of the kit	:	Mini Digital Colorimeter
	Method of analysis	:	Quantitative
	Parameters that can be analysed	:	Fluoride, iron, residual chlorine, nitrate and chromate
	Power supply	:	Single 9 volt battery and 2 1.5 volt cells
	Weight	:	400 g
	Components	:	Single unit
4.	Developed by	:	Elico Water Quality Analyser
	Method of analysis	:	Through probes
	Parameters that can be analysed	:	pH, temperature, dissolved oxygen, conductivity
	Power supply	:	Two 9 volt battery
	Weight	:	6 kg
	Size	:	Medium size VIP suitcase
	Components	:	Single unit
5.	Developed by	:	CSIO, Chandigarh (Central Scientific Instruments Organisation)
	Parameters that can be analysed	:	Turbidity, conductivity, salinity and pH
	Operated by	:	Main supply and battery
6.	Developed by	:	AIIH & PH (Calcutta) All Indian Institute of Hygiene & Public Health
	Parameters that can be analysed	:	Turbidity, pH, hardness, chloride, iron, nitrate, fluoride, residual chlorine and arsenic Bacteriological test kit with incubator is provided

INTERNATIONAL AGENCIES

SECTION – V

WATER TREATMENT IN DRWH

A Desk Review

In limited cases where water treatment has been reported for `DRWH', boiling, chlorination and use of traditional plants (e.g. *Morenga olifera* seeds, *Semacarnus anacardium* seeds, *Eletaria cardamum* seeds, *Vetiveria zizanoides* etc.) and alum are referred to for treatments of water.It is noted that often only the physical status (color, odour and tests) of water is considered before consuming it, and as long as there is no adverse effect effect, the water is taken to be acceptable.

The available data from different regions of the world are summarised below:

Africa

- In a report[5.1] by UNEP describing treatment of water using traditional methods of treatment of water using indigenous plants and natural products is described. Certain soils, such as the clay known as `clarifying earth' in the Gezira and Northern province in Sudan, produce floc in turbid water and induce sedimentation. A similar flocculation of suspended solids can be achieved by adding certain pounded or crushed plants to water. (Common practice in Sudan and the coastal region in East Africa.
- Bambrah and Haq[5.2] discussed the following physical and chemical methods used for treating stored rain water in Kenya.
  - i) Physical Disinfection
  - ii) Boiling
  - iii) ii)UV irradiation: protects the water against new contamination and can serve as a control and monitoring mechanism. (UV light disinfection is rarely applied in developing countries)
  - iv) Chemical Disinfection: Chemicals used include
  - v) Chlorine and chlorine compounds
  - vi) Iodine doses in suitable form
  - vii) Ozone

viii) Potassium permanganate (oxidant)

ix) Hydrogen peroxide (oxidant)

- Gould[5.3] described chlorination as a suitable treatment for rain water in Botswana and observed that periodic chlorination (2 mg chlorine per litre water requires ½ hour contact to be effective and application approximately every 3 months) will be adequate to combat bacteriological contamination.
- Otieno[5.4] discussed quality issues in rain water in Kenya and recommended that rainwater to be used for drinking may be disinfected by chlorination. For example, household bleach containing the active ingredient sodium hypochlorite may be used, at the rate of 1 ml/25 litres of water. Where resources and technology permit, filters could be used along with ultravoilet (UV) light to disinfect drinking water.

U.S.A.

- Fujioka et al.[5.5] described a solar powered UV-system to disinfected cistern water at (Honolulu/Hawaii). Water in the cistern tanks contain high concentrations of total bacteria as well as faecal indicator bacteria well in excess of drinking water standards. The paper describes a system which is a small, solar powered UV unit which uses gravity flow to process 1.5 litres of water per minute. This unit was shown to be effective in inactivating up to 99.9% of faecal indicator bacteria (faecal coliform, E. coli, Enterococci) and upto 99.999% of total heterotrophic bacteria present in cistern water samples.
- Fujioka et al.[5.6] also recommends a simple to do home owners test for bacteria in cistern water to indicate level of contamination. The hydrogen sulfide (H_2S) test described is a simple, reliable test that home owners can use to analyse cistern water in their own homes without the use of special equipment. This is a semi-quantitative test. The home owners are provided with a 10 ml test container and 100 ml test container to analyse each water sample. The smaller (10 ml) container is filled upto the line indicating 10 ml volume and the larger (100 ml) container to a line indicating 100 ml volume. Both containers have the appropriate dried test paper which includes all the necessary reagents. After filling the two containers with water, containers are recapped and held at ambient temperatures (23-30^{o}C). If blackening of the test paper

is observed after 24-48 hours it is taken as a positive test result for H_2S and hence the bacteria. A cistern sample which is positive in 10 ml and 100 ml sample indicates that the water is heavily contaminated with bacteria and should be disinfected. On the other hand, if the test is negative for H_2S bacteria in the 10 ml sample but positive in the 100 ml sample, a lower level of contamination is indicated.

Europe

- Joklik[5.7] described potabilization of water using ultra violet plant in Austria. A rainwater potabilization plant with a design capacity of 2000 litres of safe potable water/hour is described. The plant uses uv short wave UV-C radiation of 253.7 nm for rainwater disinfection without the use of chemicals. The rainwater is collected from the roof into a rainwater cistern and then directed to a combined filtration unit consisting of a pre-filter, a coarse filter and a fine filter for the removal of mechanical impurities and then passed to an activated carbon filter for the removal of dangerous chemicals and for taste and smell improvement. The filtered and activated carbon treated water is then proceeded to a photo reactor with a coaxilally arranged UV-C sensor and all the process data are recorded on an UV-C data logger. The disinfected water is finally passed onto a hardness increase filter and a micro dosage unit for the addition of essential minerals, vitamins and trace elements to obtain a healthy drinking water of excellent quality. Also the author has tabulated pathogenic micro-organisms in water.

Asia

- Appan[5.8] described utilization of rainfall in airports in Singapore for non-potable uses. The raw water is treated before usage. Rain water from impounding reservoir is pre-chlorinated and then dosed with alum and lime. The coagulated water is then flocculated in an upward flow sedimentation tank and the settled water is filtered in rapid sand filters.
- Appan[5.9] also reported on the water quality control in some southeast Asian countries and has listed some treatment methodologies. In some cases quality control is arbitrary and limited to few cases to diverting of first flushes and rearing of fish

within the container. Boiling, despite its limitations, is the easiest and surest way to achieve disinfection. Alternatively, simple methods of adding any halogen compounds could be practiced. Chlorine in the form of household bleach has been successfully applied to collected roof water, retaining residual levels of 0.2 mg/l.

The cheapest UV system could still be prohibitive in many developing countries. It is also recommended that, as most of the countries in the region have abundant amount of sunlight, research should be undertaken to study the possibility of using solar radiations as T. coli, F. coli & F. steeptococci have effectively been removed when exposed to sunlight in Honolulu and Thailand.

- Bo Ling[5.10], (China) discussed a novel disinfection process, termed KDF-55.

  Water in cistern tanks , contains high concentrations of total bacteria as well as faecal indicator bacteria, well in excess of drinking water standards. One simple to operate reliable and low costs disinfectiong method which can be used in the cistern water without the need for electrical power source and without changing taste of water is a kind of processing medium which is made of a very purified alloy of Cu-Zn which is called as KDF-55.

- Different water treatment and water protection methodologies in Iran are reported by Hussain et al.[5.11], and are summarised below:

  i) Biological Control: A special kind of fish known locally as Loi, Sing or Magur (cat fish) was allowed to grow in the stored water. These species ate the larva of mosquitoes and other insects. On the other hand, the fishes discharged their own excreta into the water which caused deterioration in the quality of drinking water

  ii) Chemical Treatment: Lime or alum is used to purify water. A few households in the area developed a technique to maintain the quality of stored water by treating it with about 25 g/200 litre of burnt snail shell. Some households claimed that water treated with burnt ash of snail improved taste of drinking water.

  iii) Filteration: Several types of filter elements such as a piece of cloth or mosquito netting were used to filter water. In hilly and forest areas a sand filter unit was used to filter rainwater before it was consumed. Pond water was also filtered sometimes to remove suspended particles before drinking. Sedimentation or boiling were also practiced before river or canal water was consumed.

India

- Ramani[5.12] (Madras) described various treatments of stored rainwater as follows:
  - i) A piece of Alum is tied to a rope is swirled through the water for 5-7 minutes. In 2-3 hours the flocculated mass with a mild film formation on the top of the water level along with the other foreign materials is allowed to settle. (if ferric alum is used, the duration can be reduced and better results are obtained).
  - ii) To prevent bacterial growth ,a mild dozing of chlorine powder/liq. Chlorine is given as preservative agent and the storage tank is kept closed (anaerobic). For using residual chlorine 2-3 drops of Ortho-Tolidine is used in a small quantity of water. (if color of H_2O changes to yellow, presence of residual chlorine is indicated. The water sample is then taken to be bacteria free and safe for drinking).
  - iii) $KmnO_4$ may also be used for disinfection.
- In a report[5.13] From RGNDWM, Avinashilingam Institute (Coimbatore) described rain water purification methods/treatment at household level. These include;
  - i) <u>Physical Methods</u>: Filteration through cloth, Boiling and Boiling and filtering
  - ii) <u>Chemical Methods</u>: Chlorination, Alum and Lime treatment.
- In the rainwater harvesting system designed by P.C. Sharma at SERC, Ghaziabad designed a pre filter is inbuilt at the mouth of the storage tank. Water is chlorinated as needed.

A number of compilations are available on water treatment in general . These can also be applied to DRWH. In the Indian context Vasudevan and Saxena[5.14] have listed available technologies for water treatment in the directory on Drinking Water of Rural Technologies, Volume 3 on drinking water, 1989, compiled by the authors. They have described low cost methodologies appropriate for the rural areas where there are financial and infrastructural constraints. It includes domestic filter unit, charcol water filter, filter Aid FA-5 for mobile filtration, slow and filtration plant, water filter candles, package water treatment plant, traditional .water purifying seeds, chlorine tablets for distribution and pot chlorination respectively. and Rural Energy Journal has discussed `Solar water disinfection' as treatment procedure. The details are reproduced in appendix (5A-1 – 5A-10).

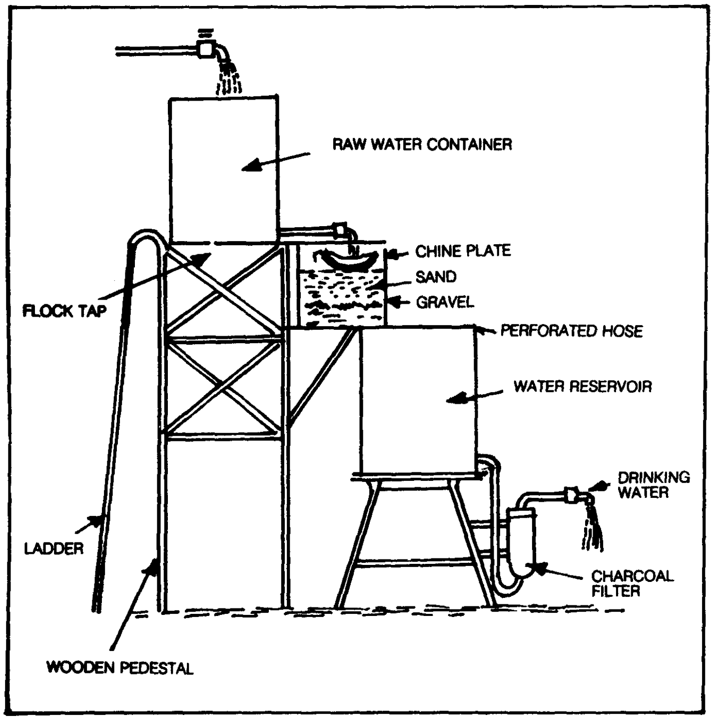
Appendix 5A-1

Drinking Water	Water Purification, Storage and Supply	DOMESTIC FILTER UNIT

Code PS 2001

CLASSIFICATION

Lab. stage	•
Prototype field tested	
Manufactured	



DOMESTIC FILTER UNIT

SCOPE

It is a simple device for purifying and disinfecting raw water for drinking purposes.

SALIENT FEATURES

The equipment provides a simple way of performing disinfection, sedimentation and filtration. It consists of three tanks namely a raw water tank, a filter and a clean water reservoir.

The unit is operated by adding half a teaspoonful of calcium hypochlorite to about 100 l of raw water in the tank, it is stirred gently for a few minutes (five minutes or so), then one spoonful of aluminium sulphate or two spoonfuls of potassium alum is added and stirred for five minutes until sediments start forming. At this point one spoonful of calcium carbonate is added and the water in the tank is stirred and the flow is drained through cock which is at the bottom.

Then the tap is opened and water flows on the swash plate in the second container until the tank is full, the outlet tap allows water to flow through a charcoal filter contained in a cylindrical vessel of about 75 cm length and 25 cm diameter (it is filled with charcoal between two layers of fibrous material such as palm fibre). Filtered water through this is collected in a clean water reservoir.

The unit can be easily fabricated in the village and would cost approximately Rs. 250/- only.

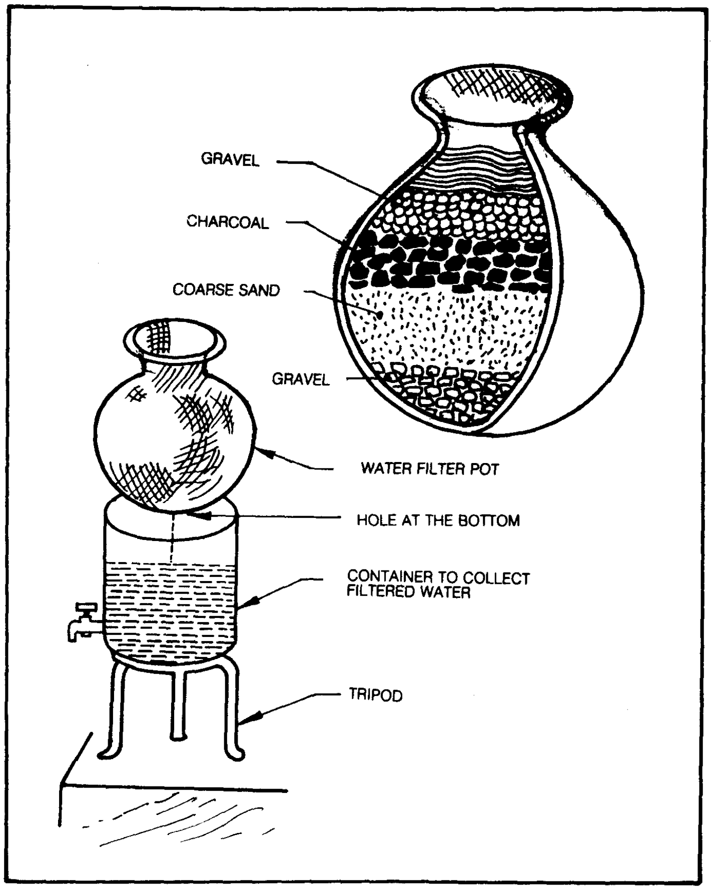
Appendix 5A-2

Drinking Water | **Water Purification, Storage and Supply** | **CHARCOAL WATER FILTER**



CHARCOAL WATER FILTER

Code PS 2002

CLASSIFICATION

Lab. stage	
Prototype field tested	
Manufactured/In use	●

SCOPE

It is an effective technique for the removal of solids, suspended materials and other harmful bacteria. Suitable for adoption at the family level.

SALIENT FEATURES

It consists of a clay pot fitted with a tap at the bottom. Layers of washed gravel, coarse sand, charcoal and another thin layer of gravel again are piled respectively upto 2/3rd of pot. Lowermost layer of gravel removes dust and dirt and the uppermost layer of gravel prevents the charcoal pieces from floating and keeps them stationary. It is advisable to add a few drops of chlorine solution (5-25 concentration) to a jug of filtered water as a disinfectant.

SPECIFICATIONS

Diametre of clay pot	42 cms
Height of clay pot	100 cm
Thickness of lowermost gravel layer	25 cm
Thickness of coarse sand layer	25 cm
Thickness of charcoal layer	15 cm
Thickness of uppermost layer	5 to 10 cm

PRECAUTIONS IN USE

The filter requires cleaning or renewal of the beds when these become clogged. To avoid frequent washing larger clay pots (200 l) can be used.

FIELD APPLICATION

It is being used in rural areas of Maharashtra.

Appendix 5A-3

Drinking Water | **Water Purification, Storage and Supply** | **FILTER AID FA-5 FOR MOBILE FILTRATION**

Code PS 2003

CLASSIFICATION

Lab. stage	
Prototype field tested	●
Manufactured	

SCOPE

Pressure filtration through precoat filters is very useful for water filtration on a small scale.

SALIENT FEATURES

The filter aid FA-5 is made from wood charcoal powder of very fine grit (50-100 μm). Raw water having turbidity upto 125 formazin units can be filtered through it without any chemical treatment. With a raw water turbidity of 20-40 FU, upto two cubic meter of filtered water can be obtained from 0.46 m^2 septum area while using 1075 $\pm$ 10 g of FA-5 per square meter septum area. The filter aid could be reused particularly at turbidity levels of less than 60 FU, 3-4 times.

The estimated cost of FA-5 is about Rs. 5/- per kg. and cost of filtration is about 50 paise per cubic meter.

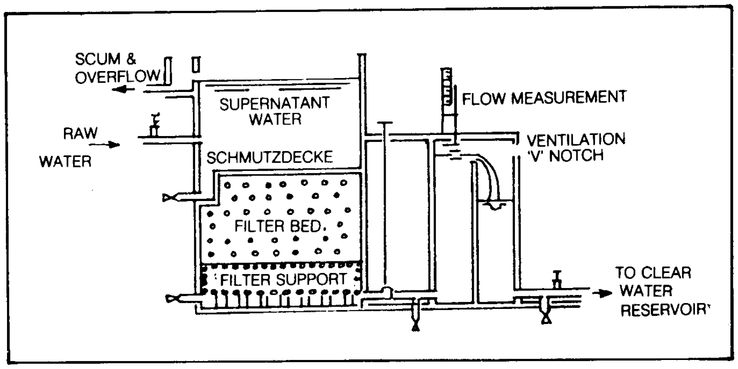
Appendix 5A-4

Drinking Water

Water Purification, Storage and Supply

SLOW SAND FILTRATION PLANT

Code PS 2004



SLOW SAND FILTRATION PLANT

CLASSIFICATION

Lab. stage	
Prototype field tested	
Manufactured/In use	●

SCOPE

It is a simple and economical treatment plant, which does not require any chemicals. It has an edge over rapid gravity and high rate type filters.

SALIENT FEATURES

Slow sand filtration is a simple method for purifying polluted surface waters, especially for rural and small community water supplies. It provides a single step treatment for surface waters of low turbidity (20 NTU). It also improves simultaneously the physical, chemical and bacteriological quality of raw water. For surface waters of high turbidity suitable pretreatment steps such as an infiltration system, sedimentation tanks or lagoons, horizontal flow roughing filtration etc. are required.

The filter unit consists of large size open watertight tanks 2.5–3 m deep (built in masonary/RCC) and filled with fine grade sand (0.25–0.30 mm E.S.) overlaying layers of gravel. Raw water is distributed gently over the top of the filter bed without addition of any chemical, and clean filtered water is collected by a system of under drains constructed at the bottom of the filter.

The process of purification of water by slow and filtration is as follows:

Water passes slowly through the filter bed at a rate of 0.1–0.2 m/hour. Its quality gets improved considerably during this passage due to removal of impurities and reduction in the number of micro-organisms (bacteria, viruses, cysts etc.) Soon after the start of the process a biological film or filter skin forms on the surface of the sandbed, which contains a wide variety of biologically active micro-organisms. These break down organic matter, including bacteria and viruses in water and convert it into water, carbon di-oxide and harmless inorganic salts. At the same time, a great deal of suspended inorganic matter is retained by straining. The continuous straining process gradually increase the resistances in the filter skin.

SPECIFICATIONS

Initial depth of filter bed	0.8–1.21m
Number of filter beds	minimum two
Minimum depth of sand before resanding	0.5 m
Depth of underdrains	0.2-0.4 m
Sepcification of filter	effective diameter 0.15–0.35 mm, uniformity coefficient 5
Specification for sand support Coarse sand gravel	 1-1.4-100 mm deep 4-5.6–100 mm deep 16-23–100 mm deep
Rate of filtration	0.1–0.3 m/hour
Period of operation	24 hours capacity 8000 m^3/day

PRECAUTIONS IN USE

After about 1–3 months the resistance in the filter skin becomes high enough to decrease the capacity of the plant for filtration. Hence cleaning of the filterbed by scraping off the top 2 cm of sand including filter skin, must be taken up periodically.

FIELD APPLICATION

These plants have been constructed in villages of Punjab, Haryana, Uttar Pradesh, Andhra Pradesh and Tamil Nadu. Demonstration is available at National Environmental Engineering Research Institute, Nagpur.

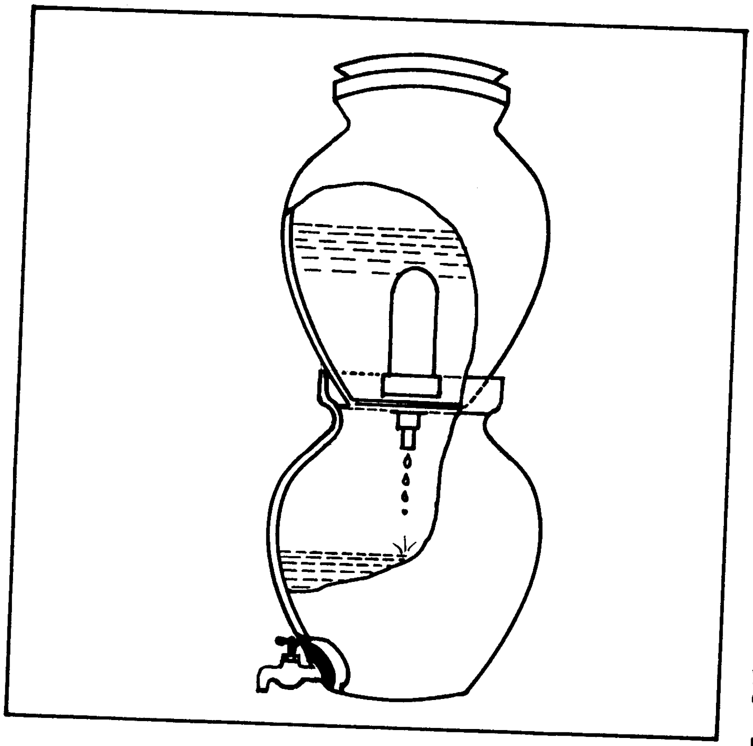
WATER FILTER CANDLES



Code PS 2005

CLASSIFICATION

Lab. stage

Prototype field tested

Manufactured •

SCOPE

This is an inexpensive way of getting potable water in the house. The filter candle can be fitted in any type of container and can remove all suspended impurities including harmful bacteria.

SALIENT FEATURES

The water filter candles are manufactured from non plastic materials like quartz and felspar, which are ground to the required fineness in a ball mill and mixed with china clay, plastic clay and some organic combustible materials in required proportions. A casting slop is prepared by adding the required quantity of electrolytes. Candles are made by the usual casting process with plaster of paris moulds. These are finished and baked at a suitable temperature. Candles are then given a special chemical treatment so that they could give bacteria free water. The life of a candle is generally 2–3 years and can be installed in any domestic container.

PRECAUTIONS IN USE

The candle should be handled carefully as it is easily breakable. After long use the surface should be cleared off the mud coating, with the help of a knife or blade periodically.

Appendix 5A-6

Drinking Water

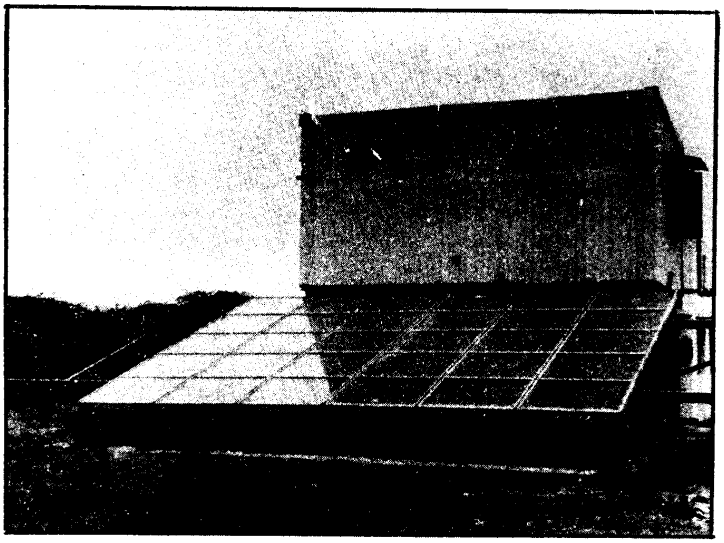
Water Purification, Storage and Supply

PACKAGE WATER TREATMENT PLANT

Code PS 2006

CLASSIFICATION

Lab. stage	
Prototype field tested	●
Manufactured	



SCOPE

This is a compact plant for providing safe drinking water in rural areas.

SALIENT FEATURES

The package plant consists of units for chemical coagulation, sedimentation and filtration. There are three concentric cylindrical compartments, the inner most is the flocculator and central compartment is a hopper bottom sedimentation basin. The flocculator is equipped with paddles. The alum solution is fed by a constant head gravity device, the flocculated and settled water is filtered. A bleaching powder solution is added to the flocculated water before it flows into the sedimentation basin.

The plant produces clean water with less than 2 NTU turbidity from raw water having turbidity upto 400 NTU. The plant can supply safe drinking water to small communities. The alum required is about 7–20 mg/l.

The advantages of the system are that it is easy to operate, maintain and does not need sophisticated mechanical equipment. The units can be pre-fabricated and assembled in the villages.

PRE-REQUISITE FOR ADOPTION

A short training in maintenance and operation is required.

PRECAUTIONS IN USE

Periodic maintenance is required.

FIELD APPLICATION

Evaluation studies on the equipment are carried out in villages of Nagpur district.

Appendix 5A-7

Drinking Water	Water Purification, Storage and Supply	TRADITIONAL WATER PURIFYING SEEDS

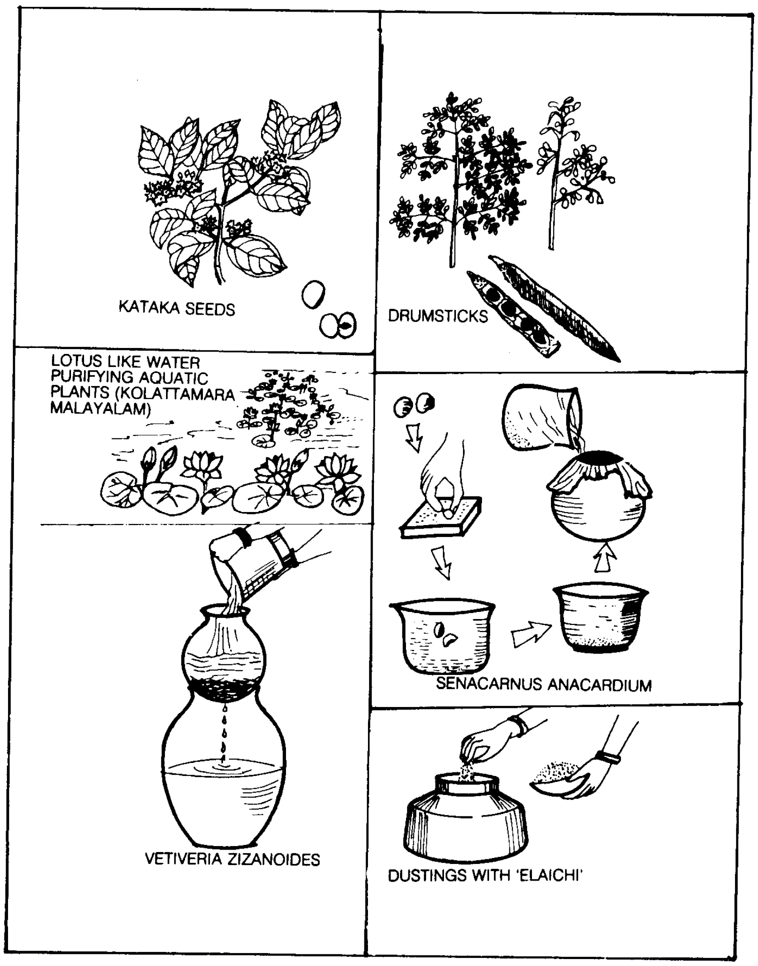
Code PS 2007

CLASSIFICATION

Lab. stage

Prototype field tested •

Manufactured



SCOPE

Good potable water can be had by using some purifying seeds.

SALIENT FEATURES

Many local seeds are used as natural coagulants for treating muddy water. Eg. Kataka Seeds (Strychanos potatorum). A dose of 1.5 mg of seed extract per litre of water is used (seed extract is prepared from a thick paste of crushed seeds with clean water). The water is stirred for 3–5 minutes after putting the seed extract, and it is then treated with 10–15 mg/l of alum. This treatment reduces the turbidity to safe limits.

Similarly, drumsticks (Morenga olifera) seeds are crushed and the powder is mixed with a small quantity of purified water in a glass and stirred vigorously for 5 minutes. The suspension is used for treating turbid water. Generally 30 seeds are required for treating 40 l of raw water.

Seeds of Bhela (Semacarnus anacardium) are rubbed on stone and made into a thick paste, this can be added to turbid water for treatment.

Sometimes coagulants like plant ashes, earth from termite hills, paddy husk or crushed seed of Elaichi (Eletaria cardamum) is dusted on water surface to treat turbidity.

Wiry roots of the rhizome from Ramaccham (Vetiveria Zizanoides) are laid in a pitcher with small holes in the bottom and the pitcher is used as a filter.

Some aquatic plants like Kolattamara may be introduced in the ponds or wells. These plants check the pollution created by animal wastes.

Appendix 5A-8

Drinking Water

Water Purification, Storage and Supply

CHLORINE TABLETS FOR DISTRIBUTION

Code PS 2008

CLASSIFICATION

Lab. stage	
Prototype field tested	
Manufactured	●

CHLORINE TABLETS

SCOPE

Water in rural areas can be made safe for drinking by addition of chlorine tablets.

SALIENT FEATURES

The chlorine tablets are compounded with normal harmless salts and chemicals. For quick dissipation, powdering of the tablets before addition to the water is recommended. For uniform distribution water, slowly stirred about 30 minutes are allowed after administrating the tablet, so that complete disinfection takes place. The shelf life of tablet, stored in a dark place is about two years.

SPECIFICATIONS

Chlorine tablets are available in different sizes and conform to IS: 9825–1981

Weight of a tablet (in gm)	Strength of chlorine (per tablet)(in mg)	Capacity to treat water (in litre)	Packing (Tablets)
5.0	600	550	500
2.5	300	300	1000
0.5	30	25	1000
0.25	5	5	1000

Note: A packet of 1000 tablets of 0.25 gm costs approx. Rs. 80/-

PRECAUTIONS IN USE

Water should be filtered or cleaned and should not have much suspended solids and turbidity.

FIELD APPLICATION

Widely used in villages in India.

CONTACT AGENCY

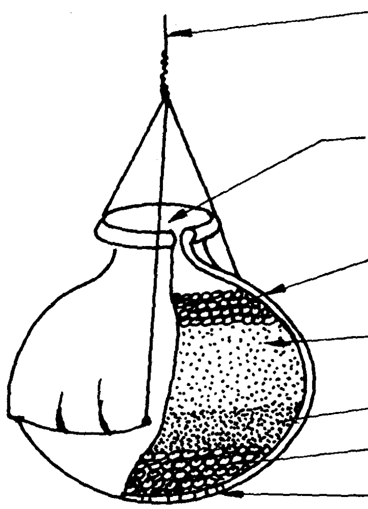
Director
National Environmental Engineering Research Institute
Nehru Marg
Nagpur-440 020

Appendix 5A-9

Code PS 2009

CLASSIFICATION

Lab. stage
Prototype field tested
Manufactured •



SCOPE

It is an inexpensive technique for continuous disinfection of water in open wells.

SALIENT FEATURES

It consists of a plastic pot of 5 l capacity, filled with 2.0–2.5 cm size gravel to a height of 5 cm from bottom. A mixture of bleaching powder and coarse sand (1:4 by weight) is placed on top of the gravel to about an equal height. Again an equal layer of gravel is put and the pot is covered. Two half centimetre holes are made in the cover, and is put in a stout wire cage and is lowered in the centre of the well which is to be disinfected. The length of the rope is so adjusted that the pot is kept submerged in water to a depth of about 1 m. The chlorine from the bleaching power oozes out slowly maintaining a residual concentration of about 0.2–0.5 mg/l for a period of about a week (when the draw off rate of water from well is about 1200 l/day. The process is simple and can be operated by villagers themselves.

PRECAUTIONS IN USE

1 Care should be taken to keep the surroundings of the well to be clean, disinfected and avoid contamination of water through spillage or seepage of used water.

2 Repeat fillings of the pot are required periodically, generally when the residual chlorine is about 0.005–0.002 g/l (it can be estimated by a chloroscope). Otherwise pot may be recharged at intervals of 7–10 days.

FIELD APPLICATION

Being used in a number of villages in Maharashtra, Uttar Pradesh, Madhya Pradesh, Andhra Pradesh, Tamil Nadu etc.

CONTACT AGENCY

Appendix 5A-10

SOLAR WATER DISINFECTION

Putting solar energy to its simplest of uses, for water disinfection, has caught on in several countries. In fact, it is one technique that must score over the more costly ones as potable water in most developing countries need treatment before it is consumed. Interestingly, nature has bestowed such countries with adequate sunshine during most part of the year.

Solar Water Disinfection (SODIS) technique has been perfected. Dissemination of SODIS is not a technological problem, but rather a question of marketing and dissemination of information. Adequate information and controlled demonstration are necessary for large-scale SODIS use. It is the volume of water versus the exposure to solar radiation that needs to be conveyed to the masses.

Yayasan Dian Desa, an NGO in Indonesia, introduced SODIS in the initial phase to 29 families only. However, at the end of the two-year official project phase in 1998, this number increased tenfold to 330 participating households. But wherever government institutions were involved in SODIS dissemination, the impact was far from desirable.

The objective of the SODIS demonstration projects, conducted by local institutions in seven different countries, was to study the socio-cultural acceptance and affordability of this treatment option. The recently carried out survey in Colombia, Bolivia, Burkina Faso, Togo, Indonesia, Thailand and China revealed that an average of 84 per cent of the users will certainly continue to use SODIS after conclusion of the project, and about 13 per cent consider using it is in future. Only 3 per cent thought otherwise because they were presumably not affected by the present water quality.

The most interesting part of the project was the preference of local people for reusing plastic bottles for this purpose – a waste product of the soft drinks industry. An average of 66 per cent of users favour SODIS plastic bottles as these are easy to handle, sturdy and durable. With bottles being available in plenty, replacement of broken bottles is not a problem. The project, which was implemented by the Swiss Federal Institute for Environmental Science and Technology, is now negotiating with the local plastic bottle industry for a joint venture with the SODIS project.

SECTION VI

SCOPE OF FURTHER WORK

Based on the extensive literature review and survey data reported herein, the following work elements have been identified for further action:

1. A number of test kits are available in India and abroad for rapid testing of water samples. There have been modifications and improvements on bacteriological and other tests for water contaminants. In India some institutes/organizations like UNICEF, RGNDWM, CPCB, Sriram Institute for Industrial Research and CAPART have made comparative evaluation of water testing kits. Information from all these agencies will be pooled. The Indian partners will also buy some of these kits and test them. (Already some work has been initiated in this direction). Based on this, recommendations will be made on the choice of kits for rapid testing and most suitable methods for laboratory testing of water samples, specifically in context of DRWH.

2. A questionnaire for collecting field level data on WQM has already been sent to all partners. Each partner is requested to collect available data and also gets sample survey done with regard to WQM in their respective areas of work.

   The Indian partners have already compiled available WQM data based on literature survey and personal interaction and have shown that there is paucity of authentic and accurate information in this regard. They have collected names and addresses of institutes/organisations in India who have put up DRWH in different parts of the country. DRWH systems will be tested with the help of water form some of these institutions. Special attention will be paid to existing units in Kerala and nearby states. A thorough study will be made in these places in collaboration with Sh. P.K. Sivanandan and Mrs. V.K. Sulochana.

3. The Indian partners are to collaborate with Warwick University on storage structures. It has been noted that extensive work has been done by Dr. P.C. Sharma (SERC, Ghaziabad) in this regard. They have essentially used ferro-cement storage tanks of capacity from 600-25000 litre. The shape is cylindrical and the DRWH has inbuilt first flush rejection and filtration facility. To gain from their experience, a training programme is being organised on ferro-cement technology for building some model structures at I.I.T., Delhi. The Indian partners are also working on computer modelling of storage systems.

4. Various parameters contributing to deterioration of water quality have already been identified. WQM has to be related to different roofing materials. (Research has been initiated by consctucting small sheds with different roofing material. New DRWH designs suggested by University of Warwick will be field tested). By inoculation of E. coli and other bacterial strains in water samples and observing their shelf life in aerobic and anaerobic conditions, data will be generated for DRWH designs.

5. Water treatments by sunlight (UV), chlorination and slow sand filter will be studied further.

6. Studies on mosquito breeding will be initiated. To begin with a review will be made and will be submitted under the **Milestone 2: Report C2.**

Milestone 2: Report C2

EUROPEAN COMMISSION

"DRWH AND INSECT VECTORS: A LITERATURE REVIEW"

Milestone 2: Report C2 of the project

Section I: Mosquito - The Major Disease Vector

1.1 Introduction

The health implications of widespread use of DRWH are divided into two aspects , namely;

a) Concerns regarding water quality (WQ) and possible direct health implications due to contaminants.

b) Insect vector breeding related to water storage and health implications arising out of it.

A literature review on DRWH- WQ has been presented in milestone report C1. The current report C2 is on the second aspect.

A review of the literature indicates that mosquito is the major insect vector which needs to be considered in the context of DRWH especially in humid tropics. The current review hence deals essentially with mosquito breeding and related diseases. Since designing for mosquito control requires an understanding of breeding habits, life cycle and behavioral patterns of mosquitoes as well as modes of disease transmission, these are discussed below.

1.2 Mosquito borne Diseases

Mosquitoes belong to the Class - Insecta, Order -Diptera and Family - Culicidae. They are thin brown, sized 6.4-12.7 mm, long legged winged insects; adults have three pairs of long, slender legs, and elongate 'beak' or piercing proboscis. Most mosquitoes remain close to the lake, pond or clogged gutter. Rainy season provides plenty of breeding places for them. Breeding of mosquito depends on various factors which include temperature, relative humidity and rainfall pattern. While certain characteristics are common to all mosquitoes, there are differences among different genus and species. Habitat and climate conditions determine the dominance of a particular species in any given area. Larval requirements can also be quite specific to the species. The number of mosquito species under 4 major genus are listed in table 1 along with the number of species which are major disease vectors.

Table 1: Distribution of Mosquito species

Genus	World		India	
	No. of Species	**Major Vector**	**No. of Species**	**Major Vector**
Anopheles	422	60	58	6
Aedes	888	25	111	1
Culex	715	12	57	3
Mansonia	23	7	4	1

Anopheles, *Aedes* and *Culex* are the most common genus and are known to cause various diseases. The major diseases caused by these various species belonging to the sub-family: Anophelinae (Anopheles) and Culicine (Culex, Aedes) are shown in fig. below, and their mode of transmission is discussed briefly.

Diseases caused by mosquitoes

Protozoan disease → Malaria

Filarial disease → Heart worm

Viral disease →
- Yellow fever
- Dengue fever
- Encephalitis

(a) Malaria: caused by protozoan parasites of the genus Plasmodium

- *P. falciparum* - cause most wide spread and dangerous form of malaria
- *P. vivax*
- *P. ovale*
- *P. malariae*

Parasites are transmitted from one person to another person by female *Anopheles* mosquito (males do not transmit the disease as they feed only on plant juices). Parasites develop in the gut of the mosquito and are passed on through the saliva of an infective mosquito, each time it takes a new blood meal. The parasites are carried by the blood stream to the victim's liver, where they invade the cells and multiply. After 9-16 days they return to blood and penetrate the RBC where they multiply again, progressively breaking down RBC. The infected individual is affected by bouts of fever and anaemia. Anopheline species in selected areas of India are listed below.

Major Vector	**Zone of Influence**
An. culicifacies (rural vector)	Vector of rural malaria in the north, south & central India. All over India except north-east
An. stephensi (urban vector)	All towns except north-east, rural areas of arid/semi-arid zone except in the north
An. minimus (foot hill vector)	North-east states, north West Bengal
An. fluviatilis (foot hill vector)	Foot hills all along the Himalayan range, seepages in irrigation channel
An. dirus (forested areas)	Deep forests in north-east region
An. sundaicus (coastal areas)	Andaman & Nicobar Islands

Anopheline vectors related to various countries in the world are available in the book entitled "The anophelines of India", by T. Ramachandra Rao, ICMR, New Delhi (1981).

b) Lymphatic filariasis

Infection of the human lymphatic system by filarial nematodes (round worms) is vectored by mosquitoes. Humans serve as the reservoir of this disease. Mosquitoes taking a blood meal ingest micro-filaria (larval stage) which are present in the blood. There are many mosquitoes species which act as vectors for the different species of filarial nematodes e.g.

- *Wuchereria bancrofti*: vectors are - *Culex quinquefasciatus*, *Aedes gambiae*, *Aedes polynesiensis* etc.
- *Brugia malayi*: is vectored by *Anophelus barbirostris*, several species of *Aedes* & *Monsonia*.

Heart worm disease: found in dogs and related canines is caused by a filarial nematode (a large thread like round worm), *Dirofilaria immitis*. The adult worms live in the right side of the heart (right ventricle) and adjacent blood vessels (pulmonary arteries) and because of their location are commonly "dog heart worms".

c) Yellow fever

This viral disease is transmitted to man by a specific mosquito, *Aedes aegypti*. One gets yellow fever on being bitten by infected *Aedes* mosquito which injects yellow fever virus through the bite.

d) Dengue

Dengue is caused by an RNA flavivirus exhibiting many stereotypes. *Aedes aegypti* is the main vector of dengue. It is a container breeder adapted to urban life. As people move away from the proximity of natural water and start to sequester water in containers, this mosquito finds a good breeding ground. *A. aegypti* transmits dengue via bite only. A mosquito feeding on a person, who is in the 1st-5th day of the disease symptoms, can vector the disease to another person. The dengue virus does not affect the mosquito in any way.

(e) Encephalitis

i) Eastern equine encephalitis (EEE): The EEE virus is maintained in enzootic bird- mosquito cycles centered around hardwood. Passerine birds in and around these swamps serve as reservoirs for the virus. Mosquitoes, especially *Culiseta melanura* feed on these infected birds thereby amplifying the amount of virus. (*Aedes sollicitans* and *Coquillitidia perturbans* - mosquitoes are referred to as bridge vectors due to their ability to bridge the gap between birds and mammals and carry the virus out of bird mosquito cycle and introduce it to mammals.

ii) St. louis encephalitis (SLE): is a mosquito borne viral infection. The virus is known to occur in natural enzootic bird mosquito cycles. The mosquito species responsible for transmitting the infection is the common house mosquito *Culex pipiens*. Occassionally, these mosquitoes will feed on a variety of mammals, including humans, thereby, transmission of the virus can occur through infected mosquitoes that which had previously fed on infected birds. *Culex pipiens* breeds in stagnant water that collects in a variety of places, including catch basins, dis-repaired pools, buckets and other containers, and road side ditches. The virus is thought to enter new areas through migrating birds, because these mosquitoes do not normally fly very far from their breeding sources.

iii) West Nile encephalitis (WNF): is transmitted through a mosquito borne flavi virus. It is found in Africa, Europe and Asia. Typically, this virus causes clinical disease in only a small percent of humans infected. A number of mosquito species have been shown to transmit WNF, the most notable belonging to the genus *Culex* and *Aedes*.

1.3 Characteristics of Mosquito species

For prevention and control of mosquitoes, it is important to know their general morphology/ physiology and other general features and variations among different species.

Life cycle

Adult female (only) mosquitoes seek a blood meal and produce a batch of eggs/individual eggs. Some mosquitoes lay eggs on the sides of tree holes or discarded containers, or in depressions in the ground that can hold water. The eggs can lay dormant for several years and hatch when they are flooded by rainfall. Several flooding and drying cycles are usually required to hatch all the eggs laid by a particular mosquito. Other mosquitoes lay eggs directly on the surface of water.

The life cycle from the stages of eggs to larvae to adults is depicted in Fig. 1. The eggs are often attached to one another to form a raft. The individual eggs or rafts float on water. They hatch in 24-28 hours releasing larvae that are commonly called 'wrigglers'. Larvae can be often seen wriggling up and down from the surface of water.The larval stage is always aquatic and they shuttle from the sub-surface to obtain oxygen through a snorkel-like breathing apparatus. Generally, the larvae feed on micro-organisms and organic material in water. In about 7-10 days after the eggs hatch, larvae (which go through 4 instars or developmental stages) change to the pupal or 'tumbler' stage in preparation for adult life. The pupal stage does not feed but unlike most insect pupae it is extremely active. The adult emerges from the pupal case using air pressure and assumes a terrestrial existence. Male mosquitoes mate with females one to two days after they emerge. A few days after emerging from water, female mosquitoes begin to seek an animal to feed on. Males do not bite, but feed on plant juices. Mosquitoes can travel a mile or more from their breeding spot to find a meal.

The differences in the different stages of life cycle between various species of mosquitoes is important for DRWH design. All mosquitoes go through the stages of egg-larvae-pupae-adult. The egg and pupae are in water, but once the head develops, the adult goes in the air. However notable differences are seen among various genus. These details and differences are summarised in table 2 and further schematically presented in figures 2 and 3.

Conclusions

From the above review it is clearly seen that all mosquitoes have one key requisite; they need water to complete their life cycle. Since DRWH involves water collection and storage, there is a potential for mosquito breeding. All the available literature pertaining to the aspects of mosquito breeding and control with reference to DRWH are compiled in the subsequent section-II: 'DRWH design and insect breeding'.

Under the project, steps have been taken to examine closely the various measures which are to be taken for the prevention of mosquito breeding and control in DRWH system. These are presented in section-III.

Table 2: Characteristics of major mosquito species

PARAMETERS	***ANOPHELES***	***AEDES***	***CULEX***
Sub-family:	Anophelinae	Culicine	Culicine
Life span	7-10 days (male) 4-5 weeks (female)	Average of 20-30 days Females deposit ~ 4 batches of eggs	-
Breeding site	River margins, river bed pools, canal, seepage from water from canal/dam, rainwater (burrow/pits) Low lying grounds, hoof marks & wheel ruts, rice fields, wells, ponds, brackish water pools	Containers, discarded tins, empty pots, broken bottles, coconut shells, artificial collection (of waters) e.g. coolers, tyres (discarded)	Domestic & peridomestic sources such as cesspools, open ditches, sewage and waste water
EGGS	Laid singly (has lateral floats)	Laid singly, no floats, breed in clean/unpolluted water (man made/artificial containers)	Clusters/rafts of 100-250 eggs, no floats
Viability	1-2 days at normal temperature. May be extended upto 1 week in winters	If dried under natural conditions, are viable for 6 months or longer	~ 2-3 days
LARVAE	(yellowish, green/ grey) remain parallel to surface of water, no siphon (breathing tube)	Remain vertically hanging to water surface, has a siphon (breathing tube)	Remain vertically hanging to water surface, has a siphon
No. of Instar & size			
I Instar	< 1 mm	-	-
II Instar	1-2 mm	-	-
III Instar	4-5 mm	5 - 10 mm	-
IV Instar	5-7.5 mm	~ 10 mm	-
To what water depths it can reach	~ upto 1 m	Few meters	
Emergence	7-10 days normally	7-10 days	-

PARAMETERS	***ANOPHELES***	***AEDES***	***CULEX***
Sub-family:	Anophelinae	Culicine	Culicine
ADULT Size	~ 0.5 cm	0.4-0.5 cm	~ 0.5-0.9 cm
Color	Grey, rest at 45o angle to surface	Black with white patches on the legs, rests parallel to surface	Dark grey, rests parallel to surface
Sitting posture Resting habits	• Body parallel to resting surface. • In cattle sheds, under bushes & in tree holes, an indicator of outdoor resting	-	-
Eating habits i) (male) ii) (female)	 Nector/fruit juices Haematophagus	 Nector/plant juices Haematophagus	 Nector/plant juices Haematophagus
Biting habits/time	Both indoor/outdoor Through out night but peak biting occurs between 19 and 4 hrs. Predominantly zoophilic	Mostly indoor than out doors Diurnal, day biters with 2 peaks of biting (1st at the dawn after the sunrise and 2nd at dusk before sun set)	Both indoor/outdoor From dawn to dusk
Flight range	1-3 km	50 -200 m	1-2 km
ADULT DENSITY (needed to maintain transmission)	1 infective bite	No estimate of adult density is known for transmission possibly one infective bite	Usually very high density is required Needs several infective bites for transmission
Diseases caused	Malaria Filaria	• Yellow fever • Dengue • DHF • Filaria • Chikungunya fever	• Ban croftian filarias • Japanese encephalitis • West nile fever • Viral arthrites • Epidemic/polyarthritis

Proboscis and body in two axes

Section -II: DRWH and Mosquito Breeding

It is known that any water source is a potential ground for breeding of mosquito and hence adequate precaution for mosquito control must be taken in designing DRWH. Available reports on this aspect are chronologically presented below.

* One of the first references available is from engineering construction, malaria control bulletin. Though not in the context of DRWH, the authors describe a mosquito proof domestic cistern, with protection of the opening from entry of mosquitoes. [(Health Bulletin No. 32 (Malaria Incidental to Engineering Construction) (see Appendix-1)].
* Waller (1989) in a study on RWCS in Nova Scotia, Canada, and Bermuda, asserts, that if the cistern surface is not covered, open storage may provide a breeding place for mosquitoes, which may act as vectors for diseases including haemorrahagic fever. Exposure to sunlight may promote algal growth. He recommends disinfection of cistern water using UV light including occasional addition of chlorine. Filtration devices have been used in some systems, but these should be properly constructed, designed and maintained.
* In a discussion on how mosquito breeding can be prevented, Noriyuki Fukano (1994) has suggested installation of insect -proof mosquito nets or other insect proof devices in the vent routes (drain pipes, overflow pipes etc.). If tank water is continuously consumed and replenished, no batch of water would stay in storage for a long time. Therefore, even if mosquito enters into the tank and spawns eggs, there is virtually no likelihood of mosquito proliferation. However this is not always the case in rain water storage. Also mosquitoes breed easily in rain water drainage pits. As rain water from roofs and the ground surface drain into sewers many larvae accumulate. To change conventional rain water drainage pits to ones made of permeable matter is a good solution to avoid mosquito problems, even if some cost is involved.
* Commenting on prevention of mosquito breeding, Appan (1994) recommended that a mosquito proof device has to be installed between the filter and the rain water storage tank. He presented data on the use of simple and inexpensive roof water collection systems in some South East Asian countries. Collected samples in most locations were positive for Total and Faecal Coliform. It is proposed that collected roof water be boiled, disinfected with household bleach or subjected to radiations from sunligh. In a certain RWH systems in Indonesia ,fishes are being reared to prevent mosquito breeding in tanks .

* According to Daulat et al. (1997) sometimes the water in the container becomes contaminated by toads, frogs, mosquitoes, cockroaches and rats. He suggested that the lid of the containers should be kept closed at all times or polyethylene sheet may be used to close the mouth of the container to prevent breeding of mosquito and other insects. Periodic cleaning is needed.
* Bambrah & Haq (1997) pointed out that a tight cover ensures dark storage conditions preventing growth of algae and breeding of mosquito. Open containers or storage ponds are generally unsuitable for storing drinking water.
* Hartung in his study at Rwanda (1999) suggests that the tank should be tightly closed to prevent mosquito breeding in RWH tanks. He is of the opinion that water in the tanks should not be exposed to direct sunlight in order to avoid algal growth.
* Gould's (1999) in the chapter on `Rainwater Quality Issues' has highlighted `Mosquito breeding and control. The relevant details are presented in Appendix 2.
* Malaria Research Centre is an apex body in India working on the prevention and control of mosquito and malaria. Details on how mosquito can be prevented by physical, chemical and biological methods are summarized in table 2. Some of these methods may prove useful in designing DRWH.

Table 2 General measures for Mosquito Control *

CONTROL MEASURES	*ANOPHELES*	*AEDES*	*CULEX*
Physical	Adults: House screening and mosquito nets (1.5 mm size or 25/26 mesh holes). Recommended doses for impregnation are: Permethrin: 0.2-0.5 gm/sq. m Deltamethrin: 0.025 gm/sq. m Cyfluthrin: 0.05 gm/sq. m Larvae: oiling and environmental management	Environmental management Container management • Elimination of breeding sites • Preventive measures for breeding in containers	Environmental sanitation Mosquito proofing
Chemical	Larvicides: abate (temophos) & chloropyriphos Adulticides: pyrethrins, Spraying and residual insecticides, repellants are also used for personal protection	Chemical larviciding: 1% temephos (Abate) granules @ 0.1 g/l Focal sprays (Pyrethrins-0.1 %) Insecticide treated curtains/nets Thermal fogging ULV	Chemical larviciding: Temephos, Fenthos, Chlorophyriphos etc. ULV thermalfogging
Biological	• Larvivorous fishes (*Gambusia affinis, Lebister reticulatus*) • Invertibrate predators Microbial insecticides: Bti (*Bacillus thuringiensis*) & B.S (*Bacillus sphareicus*)	• Larvivorous fishes • Bti (*Bacillus thuringiensis*) • Invertebrate predators such as mesocyclops	• Larvivorous fishes (*Poecilia reticulata*) and *Oreochromis mossambicus* (Peters) control breeding in cow dung pits. • Bti (*Bacillus thuringiensis*) & B.S (*Bacillus sphareicus*)

* These are general control measures. Not all of these could be considered safe for DRWH

Mosquito breeding and control

The three main groups of mosquitoes and their associated diseases are *Aedes* associated with dengue and yellow fever, *Anopheles* with malaria and *Culex* with filariasis and extreme nuisance. Larvae from members of all three groups may be found in tanks containing stored rainwater, especially in tropical regions. It is the *Aedes* group, and particularly *Aedes aegypti*, the vector responsible for transmission of dengue and yellow fever, which is most commonly found in water storage containers both large and small in and around the house. While evidence suggests that covering containers can significantly reduce the prevalence of mosquito larvae in the water, it is difficult to prevent the problem completely.

In a survey of 150 households in three villages in Khon Kaen Province, Thailand, *Aedes* mosquito larvae were present at all households. They were found in 95 per cent of small indoor clay storage containers, in 32 per cent of all rainwater jars and 4 per cent of rainwater tanks (Chareonsook et al., 1985). Hewison and Tunyavanich (1990) reported that villagers complained of increased mosquito infestation in north-east Thailand following the widespread introduction of ferrocement water jars. While this may have been due to the increased availability and presence of water in the village, it also seemed to be much worse where containers were not covered. To reduce the problem significantly it was recommended that all containers, large and small, and both inside and outside the house, must be covered and screened with some form of mesh. In Queensland, Australia, a survey of 1349 premises revealed that rainwater tanks provided important breeding sites for immature *Aedes aegypti* mosquito larvae (Tun-Lin et al., 1995). A study conducted in two villages in southeast Nigeria, where all households use rainwater stored in earthen ware pots around the house, revealed the widespread presence of *Aedes aegypti* mosquito larvae. In this case, the vector was associated with the transmission of yellow fever, and between 53 and 76 containers per 100 households were found to be infested during the wet season (Bang et al., 1981).

Various approaches to mosquito control can be used. The addition of small amounts of domestic kerosene (5ml per 1000 litres) works well, but can give the water an unpleasant taste and may not be suitable for tanks lined with plastic. [Note: Commercial or industrial kerosene should *not* be used]. Various forms of biological control, such as keeping fish and dragonfly larvae in the tanks to consume mosquito larvae, have also been tried with some success (Skinner, 1990; Corbet, 1986). While biological control may be a useful and effective tool at specific locations over limited time periods, the best guarantee against preventing mosquitoes from laying eggs in rainwater jars, tanks or other water storage containers is to make sure they are inaccessible. To exclude mosquitoes, containers must be tightly covered and any openings properly screened with fine nylon or metallic mesh. Nevertheless, regular inspection is also essential to alert users to potential problems and should prompt immediate action when necessary. Leaving rainwater tanks, jars and in-house water storage containers unscreened or uncovered in areas where malaria, dengue or yellow fever are endemic is to court danger.

Section III: Designing of Mosquito Control in DRWH

Based on the literature review, it is seen that mosquito control measures have to be applied at all stages of the mosquito life cycle, with suitable ovicidal, larvicidal and adulticidal interventions. (see Figure 4). The preventive measures with regard to DRWH may be divided into three groups:

i) Prevention of mosquito breeding in the surroundings.

- Appropriate physical, chemical and biological means of control can be used.
- Plants which repel mosquitoes can be grown around the DRWH site.
- If there are depressions in the surrounding B.S., BTI, larvivorous fishes, aquatic plants, plant extracts (oil layer), kerosene oil etc. can be used. Some of the well tested chemicals may also be used.

ii) Prevention of mosquito breeding in the DRWH system.

- Avoid all the factors which result in attracting mosquitoes.
- Tightly closed lids may be provided to the water storage system, so that there are no openings for the entry of mosquitoes.
- Screen may be used (with hole size less than 1 mm) to bar entry of mosquito larvae.
- Filter should be disinfected (eg. with household bleach).
- No stagnating water should be allowed around the DRWH site.
- Gutter leading to the storage should have a free flow of water.

iii) If inspite of the above, eggs or larvae have entered DRWH, various ovicidal and larvicidal measures have to be considered.

- The measures practiced for killing bacteria may result in dying of mosquito eggs and larvaee. These include high temperature, boiling and use of botanicals.
- Algal bloom both promote or discourage mosquito larvae depending on certain conditions.
- Measures for protection from mosquito biting should be undertaken.

Suggestions for further work

Some of the above ideas on mosquito control are being evaluated on an experimental scale under the project. Following environmental friendly mosquito control measures for preventing the entry of eggs, larvae and adult mosquitoes are being integrated in DRWH design:

- Prevention of breeding in the surroundings using certain aquatic and terrestrial plants which deter mosquitoes. In this context use of certain plants and extracts used traditionally in mosquito control would be examined.
- Screening of the entry points by mesh / nylon of appropriate mesh size (size of holes<1mm).
- Filter and filter treated with bleaching powder, at the entry point for water storage.
- Use of food grade plastic sheet/beads and botanical extracts for topping the water and prevent development of mosquito larvae.

C-3 Report by IIT Delhi, July 2000

WATER QUALITY IN DOMESTIC ROOFWATER HARVESTING SYSTEMS (DRWH)

ABSTRACT

The biological and chemical quality of water samples from experimental DRWH set up at IITD, New Delhi were analysed. Data reported in the literature on DRWH water quality were compiled by world region.

Based on experimental and compiled data it is seen that physico-chemical quality of water is generally acceptable and this can be easily monitored using field kits.

As for biological quality, there is a need for further discussions at global levels, on the indicator bacteria used for testing rain water. Under the current project, water quality from different types of experimental DRWH systems was tested by rapid field tests and compared with lab tests by standard procedures. H2S strip test is suitable at field level for detection of high level bacterial contamination. In 70% of the samples tested the bacterial content exceeded the potability standards. Avoiding the first 2 mm of rain as first flush was found to reduce contamination. It appears advisable to treat the water from DRWH before drinking.

Bacterial growth and decline, kinetics of bacterial decay, conditions for algal growth in water stored in DRWH, are also under study and preliminary results are reported herein.

CONTENTS

1 INTRODUCTION

1.1 Background

The sub-programme under the project on DRWH, namely, "Health issues related to DRWH" is led by I.I.T., Delhi. The focus is on the following issues:
1) To see if the quality of water in DRWH storage meets potable water standards.
2) To study various design parameters which influence the quality of water.
3) Suggest modifications and practices to be introduced to make the quality of water acceptable.
4) Suggest design modifications and practices needed for insect/mosquito control.

Early in the current year the C-2 report on "DRWH and insect vectors: A literature review" was submitted.

The following activities were taken up with respect to water quality:
a) The review of literature on "Water Quality in DRWH systems" was updated.
b) The efficacy of various measurement techniques for determining water quality was experimentally examined. The results for different types of tests were correlated.
c) DRWH systems with different design modifications were set up and water quality was monitored and related to design aspects.

The results of water quality tests are presented in this report (C-1). The water quality in DRWH as reported by different researchers from different countries is also recorded. Some additions and modifications have been made to this report based on additional information obtained in the current year. Experimental facilities were set up for rapid and in depth analysis of inorganic, organic and biological contaminants in water.

1.2 Water quality in DRWH

As seen from the literature survey the percentage of DRWH samples which meet potability standards vary from 10-70% in terms of bacterial quality. Thus in the worst case 90% of the samples do not meet the standards (Appendix I). Clearly in no case 100% of the samples were found to meet bacteriological standards. On the other hand chemical quality of DRWH samples were acceptable in majority of cases except in the of first flush, and also when toxic metals or chemicals from roof or the atmosphere, was there.

Hence, DRWH would be especially useful where the ground water is highly contaminated by chemicals such as arsenic, fluoride or other chemical contaminants, but the bacteriological quality would still require monitoring. In this context rain water harvested from the roof directly would indeed be a valuable source. It is relatively easy to eliminate bacterial contamination by boiling, but elimination of dissolved chemicals even in small concentrations is quite costly.

Under the project it was proposed to systematically test the biological quality of water from different DRWH systems, using different measurement techniques, and look for correlations. Among bacteriological contaminants, total and faecal coliform, faecal streptococci and E. coli are used as indicator bacteria for faecal contamination. H_2S producing bacteria can also be monitored. Details on H_2S strip tests, MPN and other standard methods were presented in Report C-1. In addition the following tests which are useful in the detection of biological contamination are available. Details of these are appended to report C-1:
i) Coliphage detection test
ii) β Galactosidase/enzymatic test
iii) Viral detection in water

The biological quality has to be tested immediately after sampling. In this regard rapid tests are very useful. Different authors have used different tests as were described in the Report C-1. Of these, the H_2S strip test is considered promising. In the present study, water quality as measured by the H_2S test was compared with results obtained by laboratory MPN method/plate count method. Based on this the reliability of the rapid test was examined.

1.3 WQ measurements in experimental DRWH systems

Various design parameters have been identified as contributing to the contamination of rain water. Specifically the effect of the following needs attention:

i) whether there is first flush diversion.
ii) the types of roof, gutter, tank, filter
iii) the nature of the roof's surroundings: e.g. overhanging trees, accumulation of leaves, animal and bird droppings

Five DRWH systems with varying design features were constructed on the I.I.T., Delhi Campus. The salient features of these systems are shown in Table 1.

2 BIOLOGICAL QUALITY OF WATER SAMPLES

2.1 Indicator bacteria and correlations between tests using them

It may be noted that the H_2S producing bacteria like *Clostridia perfringens* are normally present in faeces. Though in much smaller number as compared to *E. coli*, they can survive in water longer than coliform bacteria. The H_2S strip test depends on their presence. Although the H_2S strips have a good shelf life, it was noted that, while freshly prepared strips become black in 24 hrs in the presence of H_2S producing bacteria, in the case of shelf-stored strips an incubation of 48 hrs may be needed. Hence, while establishing a correlation between the results of H_2S strip tests and MPN tests, a time period of 48 hrs was chosen.

The ratio of faecal coliform to faecal streptococci gives an idea of the source of faecal contamination. If FC:FS < 1, it suggests that the contamination is of non-human origin i.e. animals and birds. But if FC:FS > 4, it is implied that faecal contamination may be of human origin, which could also be secondary. Primary contamination by human excreta may however be ruled out where the roof is inaccessible to humans. It may be noted that in stored water samples, streptococci can produce enough lactic acid and other organic acids from sugar fermentation that their medium becomes acidic and their growth is inhibited. This may lead to faster reduction in streptococci as compared to coliform, thus raising the FC:FS ratio for the stored sample above that in the fresh sample. Hence the time elapsed between water contamination and testing becomes crucial.

Water samples from each of the tanks were analysed at different times to see the water quality, with or without intermittent rains. The samples were drawn in sterilised bottles and tested for potability. A total of 54 samples were analysed. The results are compiled in tables 2A, 2B, 2C, 2D and 2E respectively for tanks MAA, MAP, BLC, BLT and MIC (the tank features are shown in table 1). Table 2F shows some rainfall data. The data for the first flush samples are shown in table 3A. As expected, the bacterial count in the first flush was very high.

H_2S strip test is an excellent test suitable for field level as it is easy, cheap and the villagers can see the black colour. MPN test is quantitative as it gives the most probable count of bacteria. The correlation between rapid H_2S strip test and various MPN test was examined (tables 3B-3F).

P_1 signifies a positive correlation when both the tests give negative results i.e. bacterial count below limits specified.
P_2 is a positive correlation when both the tests give positive results i.e. indicate bacterial counts above the limits specified.
N_1 signifies a situation where strip test does not give black colour in 48 hrs but MPN shows a bacterial count.
N_2 is signifies a situation where H_2S strip test gives black colour in 48 hrs but MPN does not give a bacterial count.
Thus N_1 and N_2 stand for negative correlation between the two tests.

Out of the total different samples analysed, 65-75% gave a positive correlation ($P=P_1+P_2$) between MPN and H_2S strip tests; the correlation is slightly lower where an MPN-FS test is used than when MPN-FC or MPN-TC is used. The correlation is generally higher at low levels of bacterial contamination, i.e. in most cases $P_2>P_1$.

In the remaining (35-25%) cases ($N_1 + N_2$), the two tests did not correlate (table 3B). Out of these 15-25% gave positive results for MPN but negative ones for the H_2S strip test (N_1) and ~15% gave negative results for MPN test but positive ones for H_2S (N_2). In other words in ~20% of cases even though the H_2S test shows that the water is potable this is really not so in terms of MPN. This negative correlation is more pronounced when bacterial counts are low. Roger Fujioka has evolved an MPN test based on H_2S strip method under the project. We will also evolve a MPN test based on H_2S and study the correlation with MPN for other bacteria.

Out of the water samples tested on the current project, only 13% of the samples met WHO standards for all the three indicator bacteria as well as H_2S test, and at best 25-30% samples met the relaxed standards (Table 3F). In a report (see idrc.ca/library document 008918) from International Development Research Centre (IDRC), the H_2S strip test and MPN tests with regards to total coliform and faecal coliform have been compared. The samples analysed in this report included rain water, shallow well water, pond water and deep well water. About 39% of the rain water samples were found to meet the potability standards, while for shallow well and deep well the potable samples were 3.4 and 83.3% respectively. Thus rain water was much better than shallow well water, whereas deep well water was the best. It is noted that contamination in case of rain water may be due to birds and rats. In this report correlations between H_2S and MPN tests are also presented. This varies with the type of water, i.e. shallow-well, deep-well or rain water, reflecting perhaps on the differences in the bacterial consortia present in the sample. Further work is needed in this direction.

2.2 Correlation between turbidity and number of bacteria

Pure E. coli was inoculated in 1,000 ml of sterile water and serial dilution of it was performed, as indicated in Table 4A. Each of the diluted samples (standard samples) and rain water samples were spread plated on nutrient agar plates and incubated at 35°C for 24 hrs. The number of colonies were counted in a cell counter. For the same samples turbidity was measured in a nephelometer.

As seen from the table, a rainwater sample with a low NTU of 1 had 1.632×10^6 bacterial colonies, whereas sterile water with a NTU of 1.5 had no colonies. This is because suspended colloidal particles and organic matter, contribute to turbidity besides bacteria. If turbidity was only due to bacteria even at 5 NTU the bacterial count could be greater than 3×10^7.

2.3 Decay rate of total coliform, faecal coliform and faecal streptococci in water samples stored in the tanks and in PET bottles

Three tanks were chosen from different locations having different number of initial bacterial count.

i) MIC, a cement tank with high bacterial count.

ii) BLT, a segmented cement tank at Institutional Area with high bacterial count.
iii) BLC, a cement tank at the Institutional Area with low bacterial count.
1,000 ml of samples were drawn from each into sterilised bottles.

66.6 ml of the sample was subjected to MPN test for detecting the presence of coliform group of bacteria and streptococci. The procedure was repeated everyday to observe the fall of bacteria with respect to time period. The results are shown in Tables 5A, 5B and 5C for MIC, BLT and BLC respectively. A decay rate curve was plotted between the time period (in days) and the MPN. It was observed that the total coliform and faecal coliform count fell in 20-25 days and faecal streptococcus fell in about 10-16 days. Therefore, on an average, the bacteria decay in 10-25 days of storage.

2.4 Decay rate of bacteria in the presence and absence of nutrients (Isolation of pure strains from rain water samples)

(a) Decay of faecal coliforms

Isolation of E. coli from rain water

33.3 ml of rain water was subjected to the MPN test to detect the presence of coliform in MacConkey Broth for 48 hrs at 35^{o}C in the incubator. The tube with maximum growth was taken and presence of *E. coli* was confirmed by inoculating a loop full of bacteria into the Brillinat Green Lactose Bile Broth and further grown at 35^{o}C for 24 hrs. From the BGLB tube 2 loops-full of bacteria was spread plated and streaked onto a series of nutrient agar plates and allowed to grow at 35^{o}C for 24 hrs.

The growth of 2 types of colonies typical (nucleated with or without blue green metallic sheen) and atypical (opaque, un-nucleated, mucoid, pink) were observed. From each of these plates one or more well isolated *E. coli* colonies were picked up and transferred to series of nutrient agar and Eosin methylene blue agar plates to grow separate typical and atypical colonies at 35^{o}C for 24 hrs. The process was repeated for a few generations to obtain a pure strain of *E. coli* and the presence was confirmed by performing MRVP test.

Inoculation of the pure strain of E. coli into samples with different nutrient level

Six loop fills each of the pure strain was first dissolved in 1 ml of sterile water and made up to a volume of 5 ml. This 5 ml of pure strain of *E. coli* was transferred into 1,000 ml each of (1) double distilled, sterile water, (2) rain water samples which was boiled to kill the micro-organisms and (3) rain water which was not boiled. Each of these samples were immediately subjected to MPN test and again at an interval of 4 hrs and subsequently every day to observe the bacterial decay rate with respect to nutrient availability. The data are shown in table 6A and 6B. It is observed that in complete absence of nutrient i.e. in sterilised water, the coliform bacteria survived for about 10-11 days. But in the presence of limited nutrition, the coliform bacteria decayed in 20-25 days.

(b) Decay of faecal streptococci

Isolation of faecal streptococcus from rain water sample

33.3 ml of rain water was subjected to MPN test to detect the presence of streptococcus by growing in Azide Dextrose Broth for 48 hrs at 35^{o}C in the incubator. The tube with maximum growth was taken and a loop full of bacteria was transferred on to the PSE (Pfizer Selective Enterococcus) agar plates at 35^{o}C for 24 hrs. A loop full of growth was used for generations in several plates of PSE agar to obtain a pure strain.

Inoculation of pure strain of streptococcus into samples with different nutrient levels

Six loop fulls each of the pure strain was first dissolved in 1 ml of sterile water and the volume was made to 5 ml. This was transferred into 100 ml each of (1) double distilled, sterile water (2) rain water after boiling to kill the micro-organisms and (3) rain water without subjecting to boiling.

Each of these samples were immediately subjected to MPN and again at an interval of 4 hrs and subsequently everyday to observe the bacterial decay rate with respect to nutrient availability. In case of the faecal streptococci the experiments indicated that in the total absence of nutrient i.e. in sterilised water, the streptococci count fell within 2 days. But in the presence of limited nutrition the streptococci count fell over 17-20 days approximately. The data are presented in Table 6.

(c) Decay rate constant

As discussed earlier the coliform group of bacteria decays at a slower rate as compared to the faecal streptococcus. It has been reported that the faecal streptococci when provided with sufficient nutrition grow abundantly and in this process the streptococci release toxins which inhibit the growth of their own kind. As a result, the decay rate of streptococci is much faster than the coliform group.

When the decay rate was studied for the same group of bacterium in the total absence of nutrient it was observed that due to self generated toxicity the streptococci count falls rapidly but the coliform group survive. In the presence of limited nutrition, both the bacteria fell at a slower rate as compared to the rate of decay in the total absence of nutrition. This trend was seen even on boiling the water and inoculating pure culture, the dissolved solids (nutrients) are not eliminated by boiling. The decay rate constant (often expressed as the generation/hour) was calculated.

In our experiments, the fall of bacteria under different conditions was studied and the decay was noted in (i) 1,000 ml of sterile water (ii) a sample of stored rain water from the storage tank MAP (iii) a sample of the same rain water, which was boiled to eliminate the existing bacteria (see table 6A & 6B). A graph was plotted between number of days (time period) and number of cells (MPN count). The rate constant/decay constant was found to approximately -1 generation/ day (see table 6C).

2.5 Testing for heterogeneity of the samples with respect to bacterial distribution

The following test was performed to see the distribution of bacteria on storage. Two types of samples were taken as described below:

i) Sample was kept standing for 24 hrs and water drawn from different heights/levels of the bottle.
ii) Sample was shaken vigorously and water drawn in triplets.

1,000 ml of rain water was collected and stored in two PET bottles up to a height of 18 cm in each case. Markings were made at distances 1 cm (L3), 8 cm (L2) and 16 cm (L1) respectively from the base. One of the bottle was kept standing. A 50 ml sample was withdrawn from different levels and taken into separate sterilised bottles. The second bottle of rain water sample was vigorously shaken and samples were randomly drawn from the PET bottle in triplets to observe the distribution of bacteria. All the samples drawn were subjected to the standard methods of MPN test and H_2S strip rapid test. The results are shown in table 7.

It was seen that on mixing the water by shaking, an average count of TC (46), FC (240) and FS (0) was seen. On the other hand on allowing the water to stand, there is a gradation in bacterial counts with more bacteria at the lower level closer to the base. But the gradation was not linear with depth. Further work is needed in this direction.

2.6 Water treatment methods

Since, it was observed that rainwater was found potable only 30% of times even with relaxed standards, the following physical treatments methods were applied to bring it to potable standards:

i) Heating the water at 100^oC or 60^oC
ii) Exposing the transparent storage bottles to sunlight and UV.

Rain water with a TC count of 1,000 and FC count of 240 from BLT-78 was used for the experiments for 15 minutes (table 8A). To see the effect of duration of heating, rainwater from the storage tank BLC was taken in 12 (200 ml each) sterile conical flask and subjected to different heating conditions i.e. boiling at 100^oC for 1, 5, 15 and 20 minutes and heating at 60^oC for 1, 5, 10, 15 and 20 minutes. Simultaneously, control was also taken where no heating was carried out. The water samples were subjected to H_2S strip test and MPN test for total coliform, faecal coliform and faecal streptococcus. The results (Table 8B & 8C) show that boiling even for one minute is sufficient to eliminate total coliform, faecal coliform and faecal streptococcus. The H_2S strip test which gave black colour in 24 hrs when no treatment was done, did not give black colour when the rainwater was boiled for one minutes. Heating at 60^oC for 1 minute eliminated total coliform and faecal coliform but faecal streptococci survived and were eliminated only on heating for 15 minutes. However, H_2S strip did not give black colour after 1 minute of heating at 60^oC.

In another treatment method the storage bottles were exposed to sunlight under different conditions. The samples from storage tank MAA was drawn 3.3.2000 and 11.4.2000 in sterile bottles of volume 200 ml, were kept in sun over for 16 hours over two days under the following three conditions. (a) covering the bottles totally with carbon paper, (b) covering them partially by carbon paper and (c) bottles were left totally transparent without any covering (d) Bottles kept inside with no treatment of sunlight were used as control.

The water samples were subjected to standard H_2S strip test and MPN test for total coliform, faecal coliform and faecal streptococcus. It was observed that covering the bottles partially with carbon gave good results (table 10) as it eliminated total coliform, faecal coliform and faecal streptococcus for both the samples drawn on 3rd March and 11th April. H_2S strip also gave negative test in these cases. In water samples from the bottle which was totally covered with black carbon in one case, the H_2S strip became black in 24 hrs. and TC, FC and FS persisted. In this case the temperature was only 27^oC. In the second case, the temperature in the bottle reached 45^oC. The H_2S strip gave negative result and only faecal streptococcus was seen. Transparent bottles showed better results than totally covered bottle. Thus the effect of sunlight depends on two parameters (a) heating and rise in temperature due to this and (b) exposure to UV rays. Partially covered bottles get heated and also receive UV rays of the sun, whereas the totally covered bottles get heated more but UV rays are blocked. SODIS (Solar Water Disinfection) has also been reported in the literature. Water is disinfected by radiation and by solar thermal water treatment by exposing small to full sunlight for 5 hrs or for 2 consecutive days even with 50% cloudy sky.

2.7 Algal growth in rainwater samples

It was observed that rainwater samples stored over a period of 3-6 months in transparent PET bottles and glass bottles, and exposed to sunlight supported algae growth, when sufficient nutrition was available. On the other hand sterile water (autoclaved) kept in transparent glass/PET bottles as control had no algal growth. Samples subjected to boiling were also devoid of any algal growth. When sample bottles were completely blackened by carbon paper there was no algal growth. The data are reported in Table 9. Thus both sunlight and nutrients are needed for algae to grow. To prevent algal infestation, the tanks must be kept closed without exposure to sunlight.

3 CHEMICAL QUALITY OF WATER SAMPLES

The essential chemical characteristics such as pH, EC (electrical conductivity) TDS (Total Dissolved Solids), TH (total hardness) and content of Ca^{+2}, Na^{+1}, NO^{-}_{3} and Cl^{-} are reported for storage tanks labelled MAP, MIC, BLC and BLT and MAA respectively (tables 12A, 12B, 12C, 12D, 12E). These were measured by rapid method in kits and also detailed analysis was undertaken – see Tables 12A-12D. The two data are compared. Essentially the chemical water quality was acceptable. In all the cases no significant differences could be seen with material and design changes in roof, gutter and storage type.

Specifically the following conclusions were reached concerning the chemical/physical quality of stored roofwater:

- It was be seen that the collected samples were generally clear without colour. Only a few samples had a yellowish hue when contaminated due to leaves from overhanging trees. Odour and taste wise also the water samples were acceptable.
- The pH range of water samples measured by a pH meter was in the range 7-8.5 and the values obtained by rapid testing kit was also in range 7-8. Thus the pH was well within the acceptable limits.
- Chloride and total hardness measured by laboratory method and by testing kits were in agreement. The values were below limits allowed for potability within the experimental error.
- The TDS and all other cations/anions concentrations were within acceptable limits.
- On storage in ferrocement tanks, no significant change in TH/TDS/pH was observed.
- Out of five DRWH, only in one case, the first flush showed a high TDS/TH value. In the other cases, even the first flush had acceptable TDS.

Note: Detailed procedures for using laboratory and rapid tests are described in report C-1.

4 SUMMARY AND CONCLUSIONS

Analysis of literature data available on the quality of water stored in DRWH systems, field level survey as well as experimental work done under the current project, indicate the following:

1) Generally, the physico-chemical quality of water in terms of colour, odour and taste, pH, total dissolved solids (TDS) and total hardness (TH), meet the prescribed standards. Occasionally pH has been reported to be low (acidic) or high (alkaline).
2) Toxic metal ions and toxic chemicals are reported only in rare cases and may arise from material used for the roof or atmospheric pollutants adsorbed on dust.
3) Most of the material used for storage tanks e.g. cement, iron, wood and plastics do not negatively affect the physico-chemical quality, with a few exceptions.
4) The physico-chemical parameters can be tested easily by using available field kits.

On the other hand, the main problem with the quality of stored water in DRWH lies with its bacteriological quality. The following are the main issues:

1) Total coliform (TC), faecal coliform (FC) and faecal streptoccocus (FS) are used as indicators of faecal contamination. Total coliform test is rendered difficult in the presence of large counts of other bacteria. Hence, E. coli is considered a better indicator. All the bacteria can be quantified at the lab level by the most probable number (MNP) method and plating in specific media after micro filtration and counting the colonies. It is not easy to perform these tests at the field level. The rapid tests available at field level are essentially useful for indicating the presence/absence of bacteria. The H_2S strip test based on production of H_2S by sulphur reducing bacteria such as *Clostridum perfringens* is considered most useful as it correlates well with plate count or MNP test for faecal coliform.

2) Dust from the soil, and droppings of birds and animals can also be the source of contamination by the above bacteria. Thus, the indicator bacteria need not necessarily be of human origin. It is reported that faecal streptococcus is more in bird/animal dropping. Thus if FC/FS ratio less than 1, contamination may be of non-human origin, and if FC/FS is greater than 4, then contamination may be of human origin. However, it may be noted that on storing rainwater, FC & FS counts fall at different rates. As FS counts fall faster, FC/FS ratio may increase with storage.
3) In any case where first flush eliminating devices are absent, all the indicator bacteria are generally present in water samples in numbers beyond what is acceptable by any standards. First flush is invariably contaminated. Since bird dropping and dust particles do not depend on roof type, it is difficult to categorically state whether any one type of roof is better than the other. However, experiments under the current project show that contamination from brick tiled roof was more than with other kind roof, like plastic, metallic and asbestos roof. Also it is possible that a rough surface may carry more dust and thus cause greater contamination. Higher temperature reached by a metallic roof due to solar heating may lead to reduction in bacteria. However, it is difficult to rely on such issues in designing for water quality.
4) The same goes for the gutter materials. From the health point of view it is important to clean the gutter from time to time and ensure that water does not stagnate. This leads mosquito breeding.
5) Tree hanging in the vicinity, definitely enhances the possibility of contamination due to increased access of the roof to birds and animals. Also leaves contribute to organic loading of the water samples, which in turn act as nutrient for bacterial growth.
6) On storage, generally due to limitation of nutrients, bacterial count falls. Different indicator bacteria under study decay over 7-20 days depending on the initial amount of bacteria, nutrient availability and other storage conditions.
7) Increase of temperature due to sun's heat or exposure to UV radiation of sun, reduces and ultimately eliminates bacteria. However, exposure to sunlight in the presence of nutrients can lead to algal growth, especially when the storage is open.
8) Mosquito breeding generally occurs if mosquitoes are already available in the vicinity of storage. Water quality deteriorates with the breeding of mosquito. The only way to prevent mosquito in the tank is by covering the openings by appropriate screens. The holes in the mesh should be small enough not only for preventing access to mosquitoes, but also to mosquito eggs which could be washed off.

Thus the basic conclusion from the study, substantiated by actual experimentation under the project are that DRWH must be designed, taking the following into consideration:

i) Convenient first flush device must be integrated.
ii) Storage must be tightly lidded and all entry points must be closed by a mesh to prevent entry of mosquitoes and eggs.
iii) It is preferable to allow the water to stand for some time before drawing. The bacterial count is more at the bottom. Hence the water drawn may be from a higher level, e.g. with drawing water from an over flow system may be useful. The sediments accumulated may be removed from time to time. Thus, instead of one tank of large capacity, more tanks in a series may be used, but increase in total cost has to be considered.
iv) Some rapid testing methods like H_2S test methods are useful in the field for indicating presence of biological contamination. However even, when the indicator tests are negative, it is preferable that some treatment is given for elimination of bacteria, before drinking the water. The safest methods of treatment are exposure to UV & boiling. From the angle of design parameters, a slow sand filter at inlet or outlet could be used. It would be easier to use such a filter at the outlet. However, the sand filter should be maintained properly and kept clean.

5 FURTHER WORK PROPOSED

Further research is in progress under the project to determine the following:

1) What really constitutes the first flush i.e. how much water is needed for the roof to be completely washed clean so that the subsequent precipitation of rain is clear. The design and usefulness of first flush eliminating devices integrated with DRWH, will also be examined.
2) Whether storage will lead to total elimination of bacteria in the absence of nutrients in the rain, and render the water potable. It must be noted that bacterial decay patterns vary for different pathogens and indicator bacteria. Also, so far separate tests are not being conducted for virus in water. The absence of indicator bacteria is taken to signify the absence of human contamination including human viral contamination.
3) Further studies will be conducted on settling pattern of bacteria on storage, for deciding on suitable design inputs.

Acknowledgement

The P.I. would like to thank Dr. Roger S. Fujioka, Water Research Centre and the School of Public Health, University of Hawaii, Honolulu, Hawaii, USA, for helpful discussions with regard to water quality measurements techniques, and correlating design parameters with water quality.

(b) Chemical Quality

Tanzania	Mayo & Mahuri	Samples from rain water cisters	pH, total hardness turbidity & colour were analysed	A.W. Mayo & D.A. Mashauri. Rainwater harvesting for domestic use in Tanzania. A case study. Universityof Dar es salaam staff houses. Water International 16 (1991), pp 2-8.	• pH range was 9.3-11.7 & was above standard limits • About 54% of consumers raised objections over taste of water

A2 N. AMERICA

(a) Biological Quality

USA	Roger S. Fujioka and Robert D. Chim	18 cistern systems 36 samples	First flush was not eliminated. FC was recorded in 34 out of 36 samples. FS were present in 16 of the 18 cistern. Chemical quality was also examined and was acceptable.	The microbiological quality of cistern waters in tantallis area of Honolulu Haiwa. Proceedings of the 3rd International conference on 'Rain water cisterm', Jan. 14-16, 1987, Khon Kaen, Thailand	More FS than FC indicating contamination is by birds rather than humans. Bacterial count was reduced in transit from storage tank to the bucket. Turbidity did not always correlate with indicator bacteria.
USA	Roger S. Fujioka, S.G. Insena and Robert D. Chim	15 cistern systems 28 water samples	Significant fraction of faecal coliform recovered from water sample is E. coli. Chemical quality was acceptable.	'The bacterial content of cistern water in Hawai'. Proceedings of Int. conference on rain water system, 1991, Taiwan.	Natural sunlight is an effective disinfectant. Indicator bacteria was not off the roof. Faecal indicator bacteria are present in soil house in to the roofs.
USA	E.W. Faisst and Roger S. Fujioka	Water samples from corrugated metal roof into four 55 gallon plastic cistern samples. 16 samples were analysed over an8 month period.		'Assessment of four rain water catchment designs on cistern water quality'. International Conference, 1994 proceedings of the 6th International Conference on rain water catchment system, Nairobi. Kenya, 1-6 April, 1993	H_2S strip test correlated with FC as compared to TC after a 24 hr incubation. H_2S producing bacteria are more likely to be found in cisterns with sediment build up sand/charcoal/gravel filter reduced bacteria, but still some samples did not meet US standards. The algae film inside cistern was indicated high nutrient level.

A3 S.E. ASIA

(a) Biological Quality

South-East Asia

Thailand	Komol Sivaborrorn	503 were analysed. Out of this 54 were rain water samples.	Bacteriological quality analysis was conducted by different methods	Final technical report submitted to ITRC on development of simple tests for bacteriological quality of drinking water (WQ) control for south east asia. Available on the web.	• H_2S strip test is an excellent test for it is easy, cheap & villagers can see the black colour. • β-galactosud showed good results. The method can be modified to use in the field. • Coliphage test was not so effective. • Out of 54 samples tested positive for coli, faecal coliform, E. coli counts.
Thailand	Appan	709 samples were collected from tiled roofs & gutters, containers located in homes, jars and the point of consumption		A. Appan, Roof water collection systems in some southeast Asian countries: Status and water quality levels. The Journal Royal Society of Health. October, 97, Vol. 117 No. 5, pages 319-323.	• More than 76% of the samples had values exceeding WHO standard • Samples other than those collected from the container showed an FC/ FS ratio of less than one. Possibly 79%-82% of the contamination could have emanated from animal droppings.
Phillipines	Appan	25 ferrocement tanks	24% of total samples had F. coli exceeding WHO guideline limit		
Malaysia	Appan	72 samples from 2 types of roofs in West Malaysia	F. coli values far exceeded the WHO value		
Singapore			• TC & FC values exceed guideline value		•
China	Xijing et al.	Total coliform become fewer in rain water contained in concrete cellais with tile surfaces			
Japan	Kita & Kitamura			Ichiro Kita and Kunihiko Kitamura. Fluctuation of the quality of container stored rainwater during storage. 7th International RWCS, Conference, June 21-25, 1995, Beijing, China, page 27-32.	• Results of coliform group of bacteria were positive throughout the periods.

(b) Chemical Quality

Thailand	Appan		Physico-chemical parameters performed were (pH, colour, turbidity, iron, manganese, lead & cadmium) More than 83% of the samples were satisfactory. However 43% of the samples exceedes the allowable limits of lead	A. Appan, Roof water collection systems in some southeast Asian countries: Status and water quality levels. The Journal Royal Society of Health. October, 97, Vol. 117 No. 5, pages 319-323.	

Indonesia	Appan				• Fish rearing within the tanks was tried.
Malaysia		72 samples were collected from 2 types of roofs in West Malaysia	pH value of rain water samples had a tendency to lie towards lower range of the guideline values		
Khon Kaen		709 samples were collected from tiled roofs & gutters containers located in homes, jars & the point of consumption	Only manganese (2-20% of the samples) and zinc (4-26% of samples) did not meet the guidelines levels		
Singapore		Roof water quality was monitored from a high rise building in Nanyange Tech. University for 6 years from May, 1989.	The values appear to be acceptable in all the physico-chemical parameters except pH which is low. Earlier field investigations have also shown that during January 1974 to July 1983, the range of pH in 11 monitoring stations distributed throughout Singapore was 4.8-5.5.		
China	Bo-ling		The alternative water source (rain water) which had normal fluoride levels was adopted to control fluoride endemics		
Japan	Tachi-Kawa		Metals (Fe, Zn, Pb) concentrations exceeded the standards in a study of rain water collected from roof tops		
Japan	Chiyuda Cets		1st flush of rain water after a 11 day dry spell was analysed. Physico-chemical (Fe, Cd, Cr, Cu, Mn, Ni, Pb, Zn) parameters are tabulated		• Initial rain fall upto 1.5 mm shows that the concentration of pollutants had accumulated on the roof for a 11 day dry spell
Japan	Nariyuki Inkano				• Tokyo International Rain Water Utilization Conference, Sumida city, Summer, 94, page 9-11. • Metals in rainwater in Tachikawa Saiwai-Cho Housing Complex • Quality of first flash of rainwater (Aug.-Sept., 86). • Prevention of mosquito breeding.
Japan	Kitamura		Stored rain water pH were almost constant except for the last 3 weeks duration Turbidity varied during first two weeks Ammonia nitrogen varied, decreasing on storage, which was probably caused by the bacterial activities	Kunihiko Kitamura, Ichiro Kita and Isao Minami. The effects of storage on rain water quality. Proceedings of the 8th International Conference on RWCS, April 25-29, 1997, Tehran, Iran, page 590-595.	• Bird dropping and insect caracasses were found in collected rain water (a sanitary problem)

A4 S & W ASIA

(a) Biological Quality

Srilanka	Heijen & Mansur			Han Heignen and U. Mansoor. Symposium on rainwater harvesting for water security, Feb. 28, 1998. "Rainwater harvesting in the community water supply and sanitation project".	• E. coli count was not high. Only 21% of samples showed 100 colonies/ 100 ml of TC
Srilanka	NWSDB			National Water Supply and Drainage Board, Sri Lanka. Chemical and bacteriological analysis report (15.10.98, 14.12.98 and 16.12.98).	• Bacteriological analysis (TC, EC & FS) was done and contaminantless was found. The board recommended boiling of water before consumption
Mitraniketan (Kerala)				All India Coordinated project report, sponsored by CAPART, Science and Society Division, Mitraniketan, Kerala.	• Bacterial examination was done on a few samples. The stored water had potable status.
Palestine (West Bank)	Sharekh		Level of total coliform contamination were found 27% > 0 coliform	M.S. Abu Sharekh. Rain water roof catchment systems for domestic water supply in south of West Bank. 7th International RWCS, Conference, June 21-25, 1995, Beijing, China, page 65-90.	• Rain water stored in cisterns was used for drinking & domestic purpose

A5 AUSTRALIA

(a) Biological Quality

South Australia	Fuller et al.	Vineyard & orchard areas - 7 cities Industrial areas - 4 cities Residential areas - 2 cities	• Coliform bacteria were present in 12 out of 41 tanks. Upto 500 coliform/ 100 ml were recorded • E. coli was detected in 6 tanks. 15% of 41 tanks levels upto 220 E. coli/100 ml were recorded. • Plate counts in most rain water tanks were in excess of 1,000/ml		C.O. Fuller, R.P. Walters and T.J. Martin. Domestic rainwater tanks working party, March, 81. Quality aspects of water stored in domestic rainwater tanks (a preliminary study).

(b) Chemical Quality

Australia	Ghafouri & Phillips			R.A. Ghafouri and B.C. Philips. Urban storm water re-use opportunities and constraints. Proceedings of 8th Int. Conference on RWCS, April 25-29, 1997, pp 554-565.	• Roof water is seen as one of the possible sources of collecting rain H_2O
South Australia	Fuller et al.	Water stored in domestic rain water tanks from 13 cities. Galvanised iron tanks in the range of 10,000-25,000 lit. were used.	A) Heavy metals Cadmium - one of the tanks reported relatively high cadmium concentration (0.018 mg/l) Lead - concentrations of lead in rain water from tanks were significantly higher (0.061 & 0.072 mg/l). This could be result of dust from surrounding country sides washed from roof tops with each rain fall. Zinc - zince concentrations were found to be in excess (15 mg/l) B) Pesticides were not detected in majority of the samples. C) Suspended solids - concentrations were negligible in all samples D) pH - range was 6.1-9.2 low pH values can accelerate corrosion problems in domestic appliances while high pH is an indication of under viable biological activity in the tank E) TDS - only samples taken from 2 rain water tanks had TDS concentrations in excess of 100 mg/ml (caused by sea spray)		

A6 EUROPE

(a) Biological Quality

Denmark	Per Jacobsen		Concentrations of lead (0.1 mg/l) & zinc (0.1-1.0 mg/l) exceeded the standards for drinking water in Denmak	Per Jacobsen. Metals in Rainwater in Denmark. Tokyo International Rainwater Utilization Conference, Sumida City, Summer, 94, page 9.	
Germany	Wilhelm Meemken		Parameters measured were pH, Fe, Mn, Cu, Pb, Zn, Ca, Mg, Na, K, NH_4^+, SO_4^{2-}, Cl^-, NO_3^- and electrical conductivity	Wilhelm Meemken. Quality examination of rainwater collected from roofs and stored in tanks. Tokyo International Rainwater Utilization Conference, Sumida City, Summer, 94, page 9-10.	• Rain water collected from the roofs could be used for flushing toilet washing cloths and watering plants without special treatment
Switzerland	Yakl Mason, Adrian A. Ammann, Andrea Ulrich & Laurasigg		Concentrations of Cr, Cu, Cd, Zn, Pb, Ca, Mg, Na, K, Cl, NH_4 were determined in rain water roof run off and in infiltrating water at various depths of soil.	Behaviour of heavy metals, nutrients & major components during roof run off infiltrat.	• The concentration of most parameter in roof run off were highest during the first flush at the beginning of rain events.

Milestone Report C4

DRWH DESIGN AND INSECT BREEDING

Sub-programme C: Health Implications

Project sponsored by European Commission

CONTENTS

TEXT

1 Introduction

Task C of this contract, examination of the health implication of widespread use of DRWH, addresses two aspects namely:
i) concerns regarding water quality and possible direct implications due to contaminants
ii) insect breeding related to water storage and health implication arising out of it.

With regard to water quality, two reports have already been submitted. They are Reports C1, *'DRWH-Water Quality: A literature review'*, and C3, *'Water Quality in DRWH Systems'*.

With regard to insect breeding, Report C2, *'DRWH and Insect Vectors:A literature review'* has already been submitted. In it *Anopheles*, *Aedes* and *Culex* mosquito species were identified as the major carriers of diseases and their behaviour was summarised. Dr. Mittal from Malaria Research Institute, India, collaborated in this. The characteristics of the major mosquito species were examined at the different stages of their life. Based on these, a background paper was made for an email conference on "Health Issues related to Water Quality" which was held in October, 2000.

The current report C4 brings out further findings (up to January 2001) on DRWH design parameters for controlling insect breeding. Experimentation continues.

2 Parameters which control insect breeding

The following issues were raised for discussions in the email conference coordinated by I.I.T., Delhi on Water Quality and Health. A number of people from all over the world participated in the email conference responding to the same.

a. The mosquito is the major vector to be considered in the context of DRWH water storage, although entry of lizards, rats and other small animals also need attention.
b. Breeding parameters and behavioural patterns differ for different species of mosquitoes; design for mosquito control must take these into consideration.
c. Whatever the species of mosquitoes, denying access to water is universally effective in controlling breeding. So all openings in DRWH should be closed by suitable meshes, preventing the entry of not only adult mosquitoes, but if possible also that of eggs and larvae which may be washed off from the gutter. It is important not to allow water to stagnate in the gutter. If water in storage gets heated to 50^{o}C, the viability of egg and larvae are reduced.
d. In spite of preventive measures, mosquitoes may enter storage. What would be the appropriate measures to deter ovi position (egg laying) and larval growth? The outcome of the e-conference discussions are shown in appendix 1. It was seen that the web site http://www.ent.iastate.edu/mailinglist/mosquito-1 deals specifically with mosquitoes. The site is being scanned for information useful for DRWH.

Based on the above interactions and on experiments conducted by I.I.T. Delhi, the issues related to control of mosquito breeding in DRWH will be dealt with under the following heads:

- Barriers for preventing the approach of adult mosquitoes to water in DRWH (Sect. 3)
- Quality of water and other parameters which discourage or encourage ovi-position and larval growth (Sect. 4)
- Treatment of water in storage (Sect. 5)

3 Barriers for preventing approach of adult mosquitoes to water in DRWH tanks

Three types of barriers may be envisaged to prevent entry of mosquitoes:

i. Have repellents in the surrounding areas so that mosquitoes are deterred from entering DRWH sites. Burning of leaves, wood smoke and other repellents (e.g. mint, *Vitex negundo* & other essential oils) are deterrents. Further research is needed in this regard.
ii. Have traps with suitable attractant so that the mosquito reaching the site gets attracted and enters the trap (Use of CO_2 trap and other attractants, www.mosquitoes.com/biting/menacing2.htm,www.ent.iastate.edu/department/research/vandyk/hostseek.html). Availability of reagents and cost economics would however be an issue.
iii. Have physical barriers such as screens which will physically prevent entry of mosquito and larvae into the DRWH site.

3.1 Repellants and traps

Studies on the issues (i) & (ii) pertain to general measures for mosquito breeding and control. The I.I.T., Delhi team has some experience in this regard.

A large number of aquatic fauna (e.g. *Spirogyra* sp., *Hydrilla, Ipomea, Eichhornia* and *Pistia*) may support mosquito breeding. On the other hand Covell (1941, malaria control by anti mosquito measures. edn. 2, Thacker Spink and Co., Calcutta) in his book on anti malaria measures has grouped aquatic vegetation preventing mosquito breeding into three types.

- Thick growths on the surface actually preventing breeding, e.g. *Lemna, Azolla, Wolffia, Anacharis, Trapa* etc.
- Those which act as traps, e.g. *Utricularia* i.e. bladderworts, which are well known to entrap and digest insects including mosquito larvae
- Those which are actually poisonous e.g. *Chara*.

3.2 Barriers

However, specifically for DRWH design, issue (iii) on integrating barriers for denying entry to mosquitoes was taken up for study. The following questions were addressed:

(a) Can the adult mosquito be deterred from reaching water surface by depths or torturous paths (U bends)?
(b) What is the role of gutters?
(c) How effective are the screens in preventive entry of the mosquitoes.

Depth and path-related issues Literature review and discussions with experts in Malaria Research Centre indicated that mosquitoes can descend by at least 300 ft (in air) and also go through curvaceous paths.

"There are records of mosquitoes found in deep mines, particularly *Culicine* mosquitoes. They have been found at depths of over 1,000 m in the Kolar gold mines in Karnataka.

The following reports are available on different species:

- *Anopheles annularis* and *A. vagus* have been reported at depths of 300-600 ft.
- *A. culicifacies, A. nigerrimus, A. stephensi* and *A. subpictus* at depths of 300 ft.
- *Culex fatigans* was found breeding at 600 ft."

(Source: *The Anophelines of India*, ICMR, New Delhi, 1981 by T. Ramachandra Rao)

These data indicate that in DRWH, the mosquitoes can easily travel down to water through the down pipes.

Gutters It is well known that mosquito will breed even on 1 mm layer (minimal depth) of water. So if there is stagnation of water, breeding will occur. Thus, gutters form a very important breeding site. Infact, for houses it is even advocated that gutters may be avoided or painted with larvicidal components. (http://www.env.gov.sg/cop/dd/ cop4/hb-7.html).

However, in DRWH it is imperative to have gutters, nor can it be painted as above! Hence, at least the gutter design should allow for smooth flow of water and must be accessible to inspection. Dry leaves should not remain on it and hold water. Inspite of all these precautions if eggs are hatched and water is available they can reach larval stage. Hence it is important to study the effectiveness of screens for preventing entry of not only mosquitoes but also of eggs and larvae.

Screens There is sufficient evidence that screens are useful in preventing the entry of mosquitoes and larvae. However, reports were not available relating to the effectiveness of different mesh sizes with respect to not only adult mosquitoes but also larvae and eggs. The size of adult, larvae and eggs are reported in C2. In *Culex*, where egg come in rafts, the overall size is higher although the individual eggs are small. Besides the size of eggs, the stretchability of mesh and speed with which water flows pushing the screen, are factors which can affect the entry of larvae and eggs.

Under the project, experiments were undertaken on the efficiency of screens differing in mesh size, in preventing the entry of adults. Results of laboratory level experiments with different screens with varying hole sizes are shown in table 1. The screens, made of nylon or cloth net, were bought from the local market. Actual number of holes per inch square on each of these was determined by counting. It was noted that all the mesh sizes used prevented the entry of adult mosquitoes. Since adults are of size 0.5 cm or 0.2 inches in length and the hole size on the screens are in the range of 0.01 - 0.05 in square, the screens were effective in filtering out the adults.

Experiments on passage of mosquito larvae and eggs were also conducted and the results are shown in table 1. It is seen that I to III instar larvae of all the mosquitoes passed easily through the screens. Only the late third instar as well as fourth instar larvae were filtered out. This is because, by the time they moult into fourth instar, they are comparable or even bigger than the adult in size. Only muslin cloth with very small hole size (more than 500 holes per square inch) was able to prevent entry of larvae at all its stages of growth. As for the eggs, the eggs of *Aedes* and *Anopheles* pass easily through all meshes. Even muslin cloth does not prevent passage of *Anopheline* eggs. On the other hand *Culex* lays eggs in rafts which are bigger in size. The entry of eggs of this species is prevented by all meshes.

Thus, while all the screens used were preventing entry of adult mosquitoes, there is enough chance of early instar larvae of various species being washed off into the storage tanks. Only muslin cloth is effective in this regard. However, it is to be seen whether muslin cloth when placed on the inlet, allows for the passage of water at a flow rate of 50 l per min. Designs have to be evaluated, in terms of the roof area, area of the inlet, as well as rate of rain fall at its peak. Also debris will collect with time on the screen and it has to be washed periodically. However, use of the cloth may be better than wire mesh made of iron or other metals. It may be used at the mouth of first flush device or at the junction between first flush device and storage. It could filter out mosquito, egg and larvae as well as dust particles. Further work may be done in optimisation.

4 Quality of water and other parameters which discourage or encourage ovi-position and larval growth

The effects of the following were studied:

a) Type of container
b) Quality of water in terms of oxygen availability and nutrient status

4.1 Effect of type of container

Common types of water container used in DRWH are made of ferrocement, plastic and clay. In a set of experiments, tap water (A), rainwater harvested from ferrocement tanks (B) and from syntex tanks (C) were withdrawn into clay pots and plastic tubs. To investigate the effect of both water type and cover type upon mosquito egg-laying, a set each of the containers was (i) left open, (ii) covered with clay lid, (iii) covered with iron mesh or (iv) covered by a plastic sheet. The results are presented in table 2. It was seen that in all cases when the containers were left open, mosquitoes entered and laid eggs. Wherever, there was a complete closure e.g. by a clay lid, which did not sag, there were no eggs/larvae. In the case of plastic cover held tight there was no ovi-position. However, where plastic cover was loosely held, small amounts of water accumulated where the cover sagged. This was sufficient for mosquito to lay eggs. An iron mesh under these circumstances did not encourage ovi-position. So the above experiments reiterate that water availability is the most important factor. Nature and shape of material used have no bearing on ovi position.

4.2 Effect of quality of water in terms of oxygen availability, nutrient status and temperature

Mittal et al. (Annual report, 1982, Malaria Research Centre, ICMR) have studied extensively the egg-laying of mosquitoes in water samples with different levels of salts and dissolved oxygen. The relevant data are reproduced from their report (Table 3). It is clear from this that the average dissolved oxygen requirement for *Culex* is 2.1 and for *Aedes* and *Anophele* is 6.2 and 6.6 ppm respectively. It has also been quoted by others that mosquito larvae can tolerate 4 ppm dissolved oxygen or less (www.mp.usbr.gov/geospat/olympiad/olyimage/larvae.html). Generally, rain water has sufficient dissolved oxygen at the time of harvest as well as storage. Hence oxygen levels are not likely to deter ovi-position in rain water. As for nutrients, for ovi-position high levels may not be needed initially.

However nutrient levels are a significant issue for larval growth. It is in fact known that *Anopheles* and *Aedes* prefer clean water while *Culex* can breed in water of higher BOD. To further study these issues, experiments were conducted on ovi-position and larval growth using rainwater samples as well as tap water and double distilled water for comparisons (Tables 4 & 5). Ovi-position in rain water and tap water was of a similar order whereas in freshly double-distilled water ovi-position was less. It was also seen that tap water, rainwater and double-distilled water supported larval growth up to third instar. In the case of double-distilled water and tap water there were no fourth instar larvae and in the rain water a few larvae could develop into fourth instar. However, in none of these cases there was emergence of adults, indicating that nutrient availability could be the limiting factor. When nutrient was added in the form of yeast and dog biscuits to tap water, out of 25 larvae, a good number (i.e. 14) emerged as adults whereas in the control (tap water) no larvae developed beyond third instar. In another set of experiments, rainwater and groundwater samples were compared. It was again seen that rainwater supported ovi-position (Table 6 & 7) and larval growth up to second instar, but larvae did not grow to adults.

Thus, although rain water supports ovi-position and larval growth, nutrient availability may be the limiting factor for adult emergence. Wherever a roof is under overhanging trees and gutter holds leaves and other materials which can provide nutrients, larval growth in rain water could be high enough for adult emergence. Also the growth of algae in storage may provide nutrients for mosquito breeding.

4.3 Effect of temperature on larval growth

Water tanks may get heated up by solar radiation, so we should examine the effect of temperature upon larval development. The speed of larval growth is accelerated in warm water and lessened in cold water. Warmer temperatures also stimulate growth of aquatic plankton and provide more food to the larvae than cold water. However, the larvae can not survive extremely high temperature. The upper limits of temperature at which no larvae can survive is called "thermal death point" (TDP). For example, for *Anopheles minimus,* the TDP is 41^{o}C and for *Anopheles vagus*, it is 44^{o}C. At 52^{o}C all larvae die immediately. This is the limit of biological tolerance of high temperature (*The Anophelines of India*, ICMR, New Delhi, 1981 by T. Ramachandra Rao).

5 Treatment of water in storage

WHO guidelines on use of chemicals for preventing mosquito breeding are presented in table 8 & 9. However, most of these are not suitable for use in DRWH, i.e. with respect to potable water. Only Abate (temephos) has been recommended by WHO as a larvicide for potable water also and the dose for application is given in the table. This requires further discussions.

It has been shown that kerosene, in small amounts sufficient to cover entire surface area of water kills larvae, by blocking oxygen. (www.nt.gov.au/nths/publich/entomology/programs/dissure/dengueph.html). Some experiments were done at the laboratory level at I.I.T., Delhi on the effect of kerosene oil addition. The results are presented in table 10. While kerosene is effective as larvicide, the kerosene oil locally available in developing countries may not be suitable for adding to drinking water.

6 Conclusions

- Stored water in DRWH can be a potential breeding site for *Aedes* and *Anopheles*. The amount of oxygen, light as well as nutrients in rain water are sufficient for ovi position and larval growth. However nutrient availability may be the limiting factor for adult emergence. In experiments with rainwater from roofs *no* larvae achieved adulthood and it seems that only where organic content is significant (or perhaps where light levels permit algal growth) will successful breeding occur.
- First-flush devices and the use of a screen between the first-flush system and storage could be tried as a barrier for preventing entry of adult mosquitoes. However the finest practical (peak-flow-permitting) screens are too coarse to hold back the eggs of *Aedes* and *Anopheles* or the first instar larvae of any mosquito species. To do that Nylon mesh or muslin cloth with 500 holes or more per square inch would be needed.
- There are several surface or whole-fluid agents that can be (and are) used to safely kill mosquito larvae or prevent ovi-position in water tanks. However none is simple to apply automatically nor, once applied, will last for many months.

7 Plan for further action

Some of the experiments initiated will be continued. The findings will be discussed in the dissemination workshop scheduled from April 18th-20th, 2001. Based on these discussions, additional experiments may be undertaken up to June, 2001. The literature review will also be continued. Information already presented in C1, C2, C3 and C4 will then be integrated with additional data obtained, in the final report to be submitted in July 2001.

TABLES

Table 1: Passage of mosquito eggs and larvae through different nylon/cloth screens

Mesh sample label	**Mesh size (No. of holes/inch^2**		***Culex quinfasciatus* (raft)**	***Aedes ageypti***	***Anopheles stephensi***
A	**Muslin mesh cloth (more than 500)**	Egg	x	x	√

	Kerosene oil (2 drops)	All dead	All dead

Closed lid: means control water in tightly closed BOD bottles

Note: 10 larvae were placed in 150 ml of rain water and distilled water in BOD bottles and the effect was observed

APPENDIX

Summary of email conference discussions prepared by Padma Vasudevan, I.I.T., Delhi

Mosquito Breeding

It must be noted that firstly availability of mosquito in the vicinity is an important pre-requisite for mosquito breeding. Also only mosquitoes which are carriers vectors of various diseases are a health hazard; otherwise mosquito bite would only be an irritant and not a major risk. Flight range of different species of mosquito (refer report C-2) is of the order of 50 m to 3 km.

John Gould and others have referred to reports available on the presence of mosquito, in DRWH, prevention and control of its breeding (see references). In the e-conference the Indian/ Srilankan partners reiterated that mosquito breeding is a potential threat to health issues if not already one. Arya Bandhu observed that mosquitoes enter the tank even when they are reasonably secure. He invited factual evidence of egg and larvae getting washed off and entering the tanks through filter systems. Innovative methods are needed to free the water tanks from mosquito especially for poor households who do not have proper guttering and sufficient labour to attend to first flush systems. Based on discussions with Malaria Research Centre, India (see report C-2 under the EU project), it is noted that eggs and larvae could be small enough to pass through screens. Further research is in progress in examining whether they could be retained by nets of appropriate mesh size and filters. Terry Thomas has summarised the 5 strategies to reduce the mosquito breeding and control.

1. <u>Sealing</u>

   Terry Thomas felt that it is not easy to properly seal household tanks and maintain the seal. However, Brian Skinner felt that tight cover can be produced for ferrocement tanks. Paper or polythene could be used for this. He suggested that initially casting a slight upstand on the roof around the edge of the access hole, to give a raised flat rim (say 50 mm wide), and then casting a flat overlapping cover (e.g. thin concrete or ferrocement slab) on this upstand will produce a good tight closing access cover. One could of course also use mud or very weak cement mortar under the cover to play safe. Perhaps other alternative could be a gap filler made from a continuous piece of string laid on the upstand.

According to Arya Bandhu old cycle tube seals have provided good protection against mosquito entry. It basically seals the tank to cover interface. These are individual household practices and thus are not widely practiced. In his opinion a light weight galvanised cover over the entire mouth with proper fit on the upstand part would be most appropriate.

2. Screening

Unless the inlet of a storage tank has a mosquito screen, obviously they can enter and leave via the inlet pipe.Having a proper mosquito screen which will not permit entry of mosquito seems to be a very important step. Use of suitable mosquito nets of appropriate mesh size needs to be considered.

An inclined mosquito screen, set into a small chamber (200 mm x 200 mm in plan) position on the roof of the tank directly under the discharge from the down pipe and over hole over the roof would be useful. One side of the chamber, on the low side of the mesh, should be opened so that the debris screened out of the water are washed off the mesh. There should also be a split cover over the chamber, around the pipe to prevent the light entering the pipe through the mesh covered hole into the roof.

3. Surface Barrier

Use of kerosene and plastic balls have been mentioned as surface barrier. Infact Malaria Research Centre, India (see C-2 report) have also recommended the use of expanded polystyrene beads (EPS). Brian Skinner has described an idea successfully used to control mosquitoes in septic tanks and wet pit latrines by floating a 20 mm layer of particles of polystyrene on the surface.

According to Allan D. Weatherall, in Australia, mosquito larvae are being eradicated from domestic water storage tank by using couple of drops of kerosene which forms a thin film and floats on the water surface. However these methods may not be entirely be satisfactorily for DRWH tanks meant for storing drinking water.

4. Use of chemicals

Vince Whitehead sent useful information which can be found at: http://www.ent.iastate.edu/mailinglist/mosquito-1/. The WHO website http://www.who.int/ctd/whopes/progress.htm showed under the heading of the first table 'products under evaluation by WHOPES (Sept., 2000)' that Methoprene or temephos are used as a mosquito larvicide. One comment from Argentina mentioned use of ABATE as a larvicide not toxic at the concentration used for water tanks. During a visit to household in Cambodia, Vince Whitehead came across 1 cu. m tank that having about 6 small packets laid, equally spaced out on the bottom of the tank. The house owner explained to him that these were to kill mosquito larvae. The contents of the packets presumably dissolved into the tank over a period of time. Indian participants suggested the use of herbs. <u>Indepth research on toxicity is needed before suggesting chemicals as larvicides in drinking water</u>.

5. <u>Biological Control</u>

   Dragon fly/fish and other methods of biological control including use of *Bascillus thurigenesis* Bti had been summarised by Padma Vasudevan in report C-2, page 14. Brian Skinner pointed out that if it is not feasible to totally screened the tank from mosquito then they can be controlled in the tank by using dragon fly larvae which consumes mosquito larvae. However, the consumers may not relish the idea of such creatures in the tanks and presumably they need a continual supply of dragon fly larvae for control.

   Shiela Carmen has described use of fish in ferrocement water storage tanks in the St. Vincent Grenadines. The water from these tanks had been used for drinking and cooking and users are of the opinion that this method reports no ill effects, though the quality of water has not been tested.

   A participant indicated that WHO has recommended use of BTi in the storage tanks for potable water. This is a very promising area.

Dynamically-compacted cement stabilised soil blocks for low-cost walling

Dedication

Sometimes at the beginning of a publication one finds a dedication to a certain person or member of the family who has been an influence in the author's life either in general or specifically in generating the work in question. There is one person in my life that immediately springs to mind that is worthy of such a dedication. Furthermore, my experience with this person is not unique as millions of others have found him to be a great inspiration, comfort, guide and friend. "What's his name?" you may be asking yourself and, "Why haven't I heard of this incredibly influential person?" You most probably have but you have never accepted him as such, or welcomed him into your heart and life. Well, now you have an opportunity to do just that. Please read on.

For years the name Jesus was just an everyday swearword to me. The historical individual did not mean anything to me and religion seemed hypocritical, oppressive and irrelevant to modern life. However, during my late teens I was given opportunities to live life to the full and experience many different things. Yet I still seemed unsatisfied and kept searching for something else. I was invited to a Christian gathering at university where I heard about the love of God and Jesus being God's only Son sent into the world to die for the sins of the world. I was told about an individual who had the power to forgive sins and transform lives. He also wanted to forgive my sins and change me into a child of God. That night I welcomed Jesus Christ into my heart and life and accepted Him as my saviour. Jesus suddenly became a real living person in my life and through the Bible He has helped and guided me through life. Trusting in Him was the best thing I ever did, and I cannot recommend Him more highly to anyone. Man has gone a long way away from God, but He still loves us and commands us to return to Him for forgiveness, reconciliation with Himself and rich blessings in this life and throughout eternity. The Lord Jesus Christ is still searching for people willing to trust Him in simple faith, will you be one of those people today? Please ponder the verses below and thank you for taking the time to read this.

David E. Montgomery

"*For God so loved the world, that he gave his only begotten Son, that whosoever believes in him should not perish, but have everlasting life.*" John 3:16.
"*For the Son of man is come to seek and to save that which was lost.*" Luke 19:10
"*And the times of this ignorance God winked at; but now commands all men every where to repent.*" Acts 17:30
"*For whosoever shall call upon the name of the Lord shall be saved.*" Romans 10:13
"*For by grace are ye saved through faith; and that not of yourselves: it is the gift of God: not of works, lest any man should boast.*" Ephesians 2:8,9.
"*Jesus saith unto him, I am the way, the truth, and the life: no man cometh unto the Father, but by me.*" John 14:6.

Acknowledgements

My sincerest and deepest thanks goes to my supervisor Dr. Terry Thomas, without whose unending support and guidance I would not have completed this work.

The academic and technical staff at the University of Warwick have been a great help in this research and their skills and commitment have helped to make the project forthcoming and successful.

I would also wish to thank my late mother, Elizabeth, who has been an inspiration and a challenge particularly with respect to her writing skills that were executed with a high degree of professionalism and creativity. Thanks also goes to my wife Rachel for her patience and longsuffering throughout the progress of the PhD.

Declaration

I, David E. Montgomery, hereby declare that this thesis reports previously unpublished work that I have personally done during the three-year PhD programme at the University of Warwick.

Summary

This document contains the detailed results and conclusions of work carried out during a PhD to investigate the process, production and performance of dynamically compacted cement-stabilised soil blocks suitable for sustainable low-cost building. An earlier project carried out by the author demonstrated that full-size blocks could be manufactured by dynamic compaction. It was hoped that this technique could be applied to the self-evident need for low-cost housing in the humid tropics. The apparent advantages of this process, over quasi-static compression (slow steady squeezing), have lead to further investigation into the critical factors influencing the production of such building units.

Initial tests on small cylindrical samples produced by both quasi-static compression and dynamic compaction provided a means of comparison and helped to develop relationships between dominant variables. These tests showed that the moisture content of the compact was a critical variable, influencing its consolidation and its final cured strength. Optimisation studies were undertaken to determine acceptable parameters for impactor mass, drop height and number of applied blows. These chosen parameters were then extrapolated to full-size block production with the necessary adjustments for practicality and cost. Full-size block production using the Test Rig indicated similar relationships as those discovered at the smaller scale, including the more effective consolidation offered by dynamic compaction. From this experience a production prototype was designed and disseminated to a collaborator in India for further trials and feasibility studies. These trials demonstrated that dynamic compaction could produce blocks with a 7-day wet compressive strength of between 3-5MPa with only 5% cement. Feasibility studies there indicate dynamic compaction offers potential savings of 40% compared with local high-tech CSSB manufacture.

The dynamic compaction mechanism was more closely analysed to determine the forces delivered during the impact blow. These were found to be fraction (30kN) of the forced delivered by an equivalent hydraulic press (400kN). This results in less complex and less expensive machine manufacture that is amenable to local manufacture and maintenance. Furthermore, dynamic compaction presents an economically viable and sustainable alternative to other methods of block manufacture.

Abbreviations

BS: British Standard
CEB: Compressed Earth Block
C. of V.: Coefficient of Variation (estimate of population unless otherwise stated)
CSSB: Cement Stabilised Soil Block
M.C.: Moisture Content
O.M.C.: Optimum Moisture Content
P.D.D.: Projected Dry Density
Pop'n: Population
S.T.P.: Standard Temperature and Pressure
S.D.: Standard Deviation (estimate of population unless otherwise stated)
W.C.S.: Wet Compressive Strength

Glossary of terms used

Aggregate: Pieces of crushed stone, gravel, etc. used in making concrete.
Block: A larger type of brick not necessarily made of fired clay, but stabilised in some way, sometimes with central cores removed to reduce the weight.
Brick: An object (usually of fired clay) used in construction, usually of rectangular shape, whose largest dimension does not exceed 300mm.
Bulk Density: Density calculated including any moisture present in the material.
Cement: Ordinary Portland Cement (OPC).
Clay: The finest of the particles found in soil, usually of less than 0.002mm in size and possesses significant cohesive properties.
Concrete: The finished form of a mixture of cement, sand, aggregate and water.
Dynamic Compaction: A process that densifies soil by applying a series of impact blows to it.
Fines: General category of silts and clays.
Frog: A tapered addition to a block mould to create a void in the finished block.
Gravel: A mixture of rock particles ranging from 2mm to 60 mm in diameter.
Green: Describing the state of material containing cement and water before it reaches the critical time, after which further plastic deformation hinders the final set strength.
Green Density: The density calculated immediately after ejection prior to any curing, drying or soaking.
Green Strength: The strength of a material immediately after forming and before any drying or curing has taken place.
Impactor: Solid object of known mass that is repeatedly dropped onto the surface of the soil within a mould.
Mortar: The sand/cement mix used to join block courses.
Projected Dry Density: The calculated density at ejection assuming no moisture is present in the formed sample, only solid matter.
Permeability: Describing a material that permits a liquid or gaseous substance to travel through the material.

Porosity: A measure of the void volume as a percentage of the total material volume.
Render: The sand/cement mix used to cover and protect walling.
Sand: A mixture of rock particles ranging from 0.06mm to 2 mm in diameter.
Silt: Moderately fine particles of rock from 0.002mm to 0.06mm in size.
Soil: Material found on the surface of the earth not bigger than 20mm in size, not including rocks and boulders and predominantly non-organic. If soil is to be used for building material it must not contain any organic material and it can be a natural selection of particles or a mixture of different soils to attain a more suitable particle distribution.
Stabilised soil: Soil which has been stabilised (treated to improve structural characteristics) by using one or more of the following stabilisation techniques: mechanical, chemical and physical.

1 Introduction

This is a short chapter that briefly outlines the motivation for this work, and explains why research in this area is of interest to us. This is done by broadly outlining the problem of housing shortage specifically in developing countries. The final section outlines the structure of this thesis and informs the reader of certain conventions used throughout.

1.1 Justification for this work

There is a self-evident need for adequate and durable housing, especially in the urban and peri-urban areas of developing countries. The poor are most adversely affected by this housing shortage. Assuming land availability and planning permission for further development, the need is to deliver more durable housing at lower cost.

The cost of a dwelling can be split into a number of separate areas as follows:

1. Initial land survey
2. Land preparation on paper – division into plots with access, (needs approval)
3. Physical preparation of ground – clearing vegetation, debris, boulders, etc.
4. Installation of services (optional) – water, sewerage, electricity and telephone
5. Purchase of the plot – cost direct to the homebuilder
6. House erection – foundations and walling (entailing materials and labour)
7. Roofing – spanning beams and roof material
8. Openings – windows and doors with fittings

9. Services – connection up to services if available, (optional, may require approval)

Items 6 to 8 constitute the most significant part of the total cost of the dwelling. Furthermore, the walling constitutes the most significant part of the physical structure, 60% according to (Agevi, 1999). From this it makes sense to concentrate work on low-cost walling. Research recently conducted at Warwick University has indicated that dynamic compaction may provide a method of improving the performance of stabilised soil blocks for walling and at reduced cost.

A further motivation for research into stabilised soil blocks is their environmental sustainability. Cement Stabilised Soil Blocks (CSSB) use low quantities of cement, locally available soil and have a low energy requirement. Currently popular alternatives such as clamp fired brick and concrete blocks do not have these advantages. Environmentally unsustainable practices are also sometimes used in their production such as burning firewood and dredging river sand, (Agevi, 1999), (Mbumbia et al., 2000).

Earth construction is very successful in arid areas, but significant stabilisation is required for adequate performance in humid areas. Unfortunately poor production practises of CSSB have resulted in a chequered history and a limited following (International Labour Office, 1987). Research conducted at Warwick by Kerali indicated that a six-fold increase in wet compressive strength could be achieved using improved curing regimes for CSSB, (Kerali, 2001). With good production control CSSB can perform quite adequately, but further improvements in material performance will help to outweigh sloppy production practices.

CSSB block presses have been designed and used for self-build initiatives in the past, for example, the Cinva-Ram (manual block press) and the Brepak (hydraulically assisted block press). These presses require high quantities of cement for adequate performance or are too expensive and complex for local production and maintenance. A less expensive and less complex machine would be more amenable to local production and small-scale capital investment. These are the areas where CSSB production technology needs to be taken and dynamic compaction shows promise.

1.2 Some notes on this thesis

This thesis is designed to report the academic findings from the research carried out during this Ph.D. project. Its function is also to present the information to an examining body for assessment for awarding the degree of Doctor of Philosophy to the author. The thesis has been written to reflect the chronological order of events with a minimum of forward and backward referencing of the different chapters.

The thesis is divided up into 9 chapters and each chapter contains a number of sections and further subsections. These three hierarchical levels are identified by numbers and break down the majority of the text into manageable portions. A further fourth level identified by bold italics is not numbered. Most chapters finish with a chapter summary.

After this introduction comes the literature review in chapter 2. Experimentation on quasi-static and dynamic compaction is described in chapters 3 and 4. The analysis of dynamic compaction is then reported in chapter 5. Chapter 6 was a difficult chapter to fit in chronologically, as it includes design analysis used in the production of the Test Rig. This was used to gain the data presented in chapters 4 and 5. However, this also includes the design suggestions and modifications for the Production Prototype. Chapter 7 details the overseas collaboration and technological dissemination of the Production Prototype, comparing the new machine with existing machines. An economic analysis and feasibility study for the Production Prototype is presented in Chapter 8. Finally chapter 9 summarises the conclusions made throughout the thesis and makes recommendations for further research to be conducted.

Data is presented in three different formats in this thesis. Graphs are used to show trends and to highlight possible relationships. Tables are used to present statistical analysis of the data collected. These two formats appear in the body of the text as close to their point of reference as possible, but not necessarily on the same page. Raw numerical data is recorded in the appendix for cross-referencing if necessary.

2 Literature review

Our having stated the need for low-cost housing in the previous chapter, this chapter of the thesis provides the background to the subject of interest. It will outline some of the existing practices and methodology for brick and block manufacture and analyse them for sustainability. Having established the potential contenders, a summary of raw material selection and characteristics will be given. Existing techniques of stabilisation will be reviewed and suggestions made for areas of possible improvement. Finally the previous research conducted on dynamic compaction will be outlined identifying the gaps in understanding and scope for further research.

2.1 An introduction to brick and block manufacture

Many different materials are used around the world for walling. Where quarried stone and timber are not readily available, earth is the most common material used. Earthen architecture has been used for centuries in many different parts of the world. (Houben & Guillaud, 1994) states: “Thirty percent of the world’s population, or nearly 1,500,000,000 human beings, live in a home of unbaked earth.” Accounts from the Bible (Exodus 1:11-14, 5:6,7) indicate that around 1500BC earth mixed with straw was a typical building material. Earlier accounts from the Bible (Genesis 11:3) also speak of burning bricks and using slime as mortar. Archaeological evidence in very dry areas have also shown that earth building was a highly popular material for dwelling construction. Earth is still used today in many parts of the world where access to other forms of building material is restricted by location or by cost.

Each building material has its own advantages and disadvantages. Some of the problems with existing materials are their poor use of environmental resources, poor quality control of the finished product and consequently a significant variation in durability. The long-term sustainability of some methods is being questioned in many places. Other alternatives are being sought after that are environmentally sustainable whilst also being of a suitable strength and durability for use in humid areas.

2.1.1 Existing processes described

Within this thesis it is not necessary to provide an exhaustive list of building materials as previous authors have already done this, (Houben & Guillaud, 1994), (Stulz & Mukerji, 1993). Instead the focus will be on some of the more popular methods of providing walling at tolerable cost. Hollow and aerated concrete blocks, clamp and kiln fired brick and compressed and stabilised soil blocks (hereafter CSSB) are the five main building materials chosen for consideration. These have been selected because they are well known, have been adequately assessed for performance and have appropriate standards for evaluation. Aerated concrete is considered an advanced material and is included here for comparative purposes as its performance and characteristics are highly desirable for low-cost building.

***Aerated concrete blocks* –** Aerated concrete is a light form of concrete (density around 500kg/m^3) that uses coal ash from power stations and omits the use of coarse aggregate. A cement rich mixture has a foaming agent applied to it before the material is pumped or can be cast into suitable moulds (Craig, 1997). It has been developed into a high performance building material and is currently marketed as aerated concrete blocks or “Aircrete” (Thermalite, 2001). Although these blocks are not considered suitable for heavy load-bearing conditions, (over 7MPa), they are wholly adequate for low-rise structures such as typical homes. Other features such as high wall area per block, low thermal conductivity, easily shaped by hand tools and low moisture penetration make this a highly attractive material.

<u>Figure 2.1 – Aerated concrete blocks</u>

Aircrete　　Thermalite Block　　Thin mortar joints

The above photographs show the structure of aircrete, it’s ease of handling and the high dimensional accuracy required for thin mortar joints. The textured surface of the blocks help to bond the render to the block, (if render is desired as it is not necessary on external walling).

Hollow concrete blocks **–** These are relatively expensive due to their need for graded sand and large amounts of cement (12-17% by weight). If manufactured properly they can have very high strength and good durability. Significant cost and weight reduction is achieved by removing material from the central region of the block. Machinery for production requires a vibrating table to settle the cement mix into the mould. Sometimes, instead, a heavy hinged lid slammed a couple of times or low pressures are applied to compress the material.

Good dimensional accuracy means that these blocks can be laid on a 10mm mortar joint. However, due to the voids in the block, mortar falls down these holes and is wasted. (In calculating the required mortar it has been assumed that the mortar actually used is closer to that needed for the surface area of the entire top surface of the block rather than just the edges where a joint is made with the neighbouring block.) These blocks are sometimes rendered for aesthetic reasons, which we will omit from any calculations for the time being.

Kiln-fired brick **–** Over the centuries the process of burning clay to make brick has become more and more automated, sophisticated and complex, but not necessarily more cost effective, particularly in developing countries. (Parry, 1979) very eloquently and persuasively describes two methods of brick production in terms of cost and shows quite clearly that where labour costs are low, kiln-fired brick production would be economically unsuitable. Kiln-fired brick production requires a high capital investment and a significant amount of infrastructure to support production. Brick production must be located near to high quality clay deposits (often unavailable locally), staff needs to be more highly skilled, spares and servicing is highly specialised and energy requirements are considerable. Production output is very high, typically 10,000 - 30,000 bricks per day and needs to be continuous if to achieve high efficiency and to achieve the greatest return on investment. Modern kilns efficiently recycle heat, giving a modest energy consumption per brick (3MJ) (International Labour Office, 1990).

The characteristics of such kiln-fired bricks are highly desirable as the material has a high wet-compressive strength and does not deteriorate rapidly over time even in the harshest of climates (Hanson, 2001). The material is pleasing to the eye and is sought after as an attractive material for home building.

Clamp-fired brick **–** Can be inexpensive in monetary terms because the raw materials can usually be dug from the ground fairly locally and the energy required firing the brick could come from collected firewood. Clamp fired bricks are of a lower quality than kiln-fired bricks and can tolerate the use of smaller and poorer sources of clay deposits. Forming the blocks requires a wooden or metal mould and after forming they are laid out to dry. After drying they are stacked into a clamp where fires are burnt inside (Parry, 1979), (International Labour Office, 1990). These fires raise the temperature of the blocks to the point where the particles bond together (Stulz & Mukerji, 1993). Thorough burning is necessary to fire all the blocks properly and this takes several days to achieve and uses approximately 16MJ of energy per brick.

The finished blocks can be quite badly misshapen and this requires a thick layer of mortar between the blocks, sometimes as thick as 20mm. Furthermore, if the blocks are poorly fired then in order to achieve adequate durability they may need to be rendered as well. Fired blocks are usually considered attractive and so they are not generally rendered unless necessary.

Figure 2.2 – Clamp fired bricks

This is a poor example of clamp-fired bricks in Uganda, demonstrating thick poorly used mortar. The result is unattractive and wasteful of cement.

However, due to the high cement content of the wall and the fired brick used it will probably achieve adequate durability.

The poor dimensional accuracy of the bricks can be clearly seen in this photograph.

Compressed and Stabilised Soil Blocks – These blocks use the same parent material as plain earth blocks but offer the significant advantage of wet compressive strength. Improved strength and stability in wet climates is generally achieved by a combination of two methods of stabilisation. One method is to compact the soil by applying some mechanical effort to reduce the voids in the material. Increasing the density of the material gives it a higher compressive strength and also reduces the potential for ingress of moisture into the block (Houben & Guillaud, 1989), (Norton, 1997). CSSB are further stabilised with the addition of a chemical stabiliser that helps to bind the particles together. Cement or lime are expensive additives but are generally available and although the practice of adding them to soil is reasonably popular the results can be disappointing unless it is done carefully (International Labour Office, 1987).

CSSB can be compacted using low or high-pressures or dynamically compacted via impact (Houben & Guillaud, 1994). The greater the level of compaction the greater the compressive strength of the block and the more effective any added stabiliser becomes, (Gooding, 1993). CSSB compacted to higher densities are also usually more dimensionally consistent and therefore can be laid using a thinner mortar layer of around 10 – 15mm. Some CSSB need to be rendered or waterproofed in order to enhance their protection from the elements (Yogananda, 1999), but this can usually be avoided with higher levels of compaction and or higher quantities of stabiliser. Making a hollow CSSB can be done by straight-through perforations or deep and shallow frogs (Houben & Guillaud, 1989), (Centre for the Development of Industry, 1998). Each of these reduces the material volume present and therefore reduces the stabiliser quantity necessary for each block.

Figure 2.3 – Compressed and stabilised soil blocks (CSSB)

Here is a good example of a wall made of stabilised soil blocks in Uganda.

The blocks are approx. 0.4 × 0.2 × 0.125m and may have some voids through the centre. No render has been applied to the wall and no significant roof eaves have been used.

A solid cement rich foundation had been used to build the blocks onto. This is a high quality construction and would have been quite costly but not as much as hollow cement blocks.

Figure 2.4 – Interlocking CSSB

The development of interlocking blocks, as shown here in Tanzania, provides a very low cost alternative for walling. These are advertised as “no mortar” and “no render” blocks, reducing the cement requirement to soil stabilisation alone. Very high dimensional accuracy is required for these blocks to be successful.

2.1.2 Processes analysed for sustainability

Some of the materials listed in the previous subsection require different methods of construction in order to produce satisfactory walling. These differences will be assessed and compared for the production of one square meter of wall. Some for example require more mortar between block courses to compensate for the irregularities of the block shape. The issue of durability is only qualitatively explored in the texts and no quantitative results for the durability of these materials has been found. Durability is typically defined in the range of “poor” to “excellent” (Houben & Guillaud, 1994), (International Labour Office, 1987). This could have something to do with the absence of suitable accelerated or short-term tests to indicate potential durability or as a relative measure between different materials.

Throughout the assessment of these materials it is assumed that they are able to perform the basic function of a finished wall, (i.e. support its own weight and the weight of any structures above it for a long period of time withstanding environmental attack). Whilst aesthetics play a part in material selection, it will be considered small by comparison to the material performance and cost and will therefore be ignored.

Possibly one of the most striking differences between these different types of walling units is their width. Some hollow concrete blocks are 250mm (10”) wide whist the clay fired brick is usually only 103mm (4”) wide. A wider block is more stable and can be used to build taller walls with a high slenderness ratio, (width/height). A single-skin brick (103mm thick) wall is not considered to be stable enough except for in-fill walling between columns and beams or for relatively small structures. In our analysis of single-skin brick construction we have included a buttress pillar of two bricks at 1-metre centres, which increases the brick and material requirement by almost 25%. It is more common to make a single-skin block wall of closer to 150mm (6”) thick and this practice has been extended to two storey construction successfully.

We have chosen to assess the walling materials described in the previous section according to the four following measures:

- Primary energy consumption for production and delivery in MJ per m^2 walling
- Cement usage in kg per m^2 walling
- Ranking for suitability for small-scale (‘local’) production
- Ranking for suitability for on-site production using mainly on-site materials

The table and associated notes below is a summary of a spreadsheet used to make the calculations for comparison of the selected materials. The raw data for this comparison can be found in Appendix E.

It is important to notice that the different materials each has a wide variety of different characteristics and the table below does not attempt to normalise these characteristics in any way. For example the wet compressive strength of the hollow cement block will be several times larger than the low-density CSSB and this is not really indicated from the energy and cement cost. The table does however generally give the real costs of each type of walling.

Table 2.1 – Comparison of different walling materials

Material	Dimensions ($l \times b \times h$)	Note	Energy	Cement	Suitability for production 'Locally'	On-site
	Mm		MJ/m^2	kg/m^2	Ranking	(1 = best)
High-density CSSB	290 × 140 × 90	1	290	18.7	2	1
Low-density CSSB	290 × 140 × 90	2	420	34.1	1	1
Brick (kiln-fired)	215 × 105 × 65	3	430	8.1	2	3
Brick (clamp-fired)	215 × 105 × 65	4	1340	11.4	1	2
Hollow Cement block (N)	300 × 150 × 200	5	430	27.0	1	2
Hollow Cement block (F)	300 × 150 × 200	6	590	27.0	1	2
Aerated-cement block	440 × 140 × 215	7	230	12.4	2	3

Notes

0. All cement is assumed to have been transported 100km.
1. High-density (2000kg/m^3) solid blocks manufactured on-site from local soil/cement mix (5% cement), laid with 10 mm of soil/cement mortar (20% cement) and no render.
2. Low-density (1700kg/m^3) solid blocks manufactured on-site from local soil/cement mix (10% cement), laid with 15 mm of soil/cement mortar (20% cement) and 15mm render.
3. Kiln-fired brick (3000MJ/1000 bricks) laid with 10 mm of sand/cement mortar (20% cement) and no render, double brick buttress column at 1m centres.
4. Clamp-fired brick (16000MJ/1000 bricks) laid with 15 mm of soil/cement mortar (20% cement) and no render, wall has double brick buttress column at 1m centres.
5. Hollow (50% voids) cement blocks made from 10% cement mixed with gravel and sand from nearby source, with a 10mm mortar joint, (sand/cement, 4:1 ratio).
6. Hollow (50% voids) cement blocks made from 15% cement mixed with gravel and sand transported from 50km away, with a 10mm mortar joint, (sand/cement, 4:1 ratio).
7. High-tech aeration process using coal ash mixed with cement (15%) to make a very light (480kg/m^3) material. Laid with a 3mm mortar joint using cement rich paste (50% cement). Blocks transported 50km.

There is increasing evidence that local production of hollow concrete blocks and clamp-fired bricks use unsustainable resources. The practices of using river sand for the former (Shan & Meegoda, 1998) and firewood as fuel for the latter (Mbumbia et al., 2000) are environmentally unacceptable, and in any case likely to face rising prices driven by increasing scarcity. Consequently the only small-scale method of block manufacture left deals entirely with the stabilisation of locally available un-graded soil.

Of the materials listed above, only three use less than our assumed target of 15kg of cement per m^2 of walling; two of them are unsuitable for local production and the third has an extravagant energy requirement. High-density CSSB is the only material that uses but a modest amount of cement ($\approx$ 18kg/m^2), has a low energy requirement and is suitable for local and on-site production. The question that now needs to be answered is whether or not methods exist that may further reduce the cement requirement of high-density CSSB to less than 15kg per m^2 of walling.

If we want to concentrate on the field of CSSB block production for its environmental and sustainability advantages, we still need to make significant improvements on performance whilst reducing the cost. It has generally been noted that CSSB walling that is un-rendered and unprotected does not perform satisfactorily over time in the humid tropics. Consequently improved levels of stabilisation are required without a significant increase in cost. This could be done via a combination of improved material compaction and improved stabiliser effectiveness. As the chemical stabiliser is the most expensive ingredient in the block then its quantity should be reduced to the lowest level possible for achieving the necessary strength and durability.

There are a number of options for the chemical stabilisation used. Additives such as cement can be used to make a high-cement but thin-walled block, or a very low-cement mix throughout a very dense solid soil block or as a surface render over compressed soil without any cement present. Mortarless construction is a very attractive proposition and would be quite compatible with in-wall curing of very-low-cement homogenous blocks. Also the production technique employed for producing very-low-cement blocks is quite straightforward and permits immediate stacking after moulding making it more attractive than thin walled blocks that require more careful handling and curing.

Applying render over raw soil doesn’t yield satisfactory results in the long term, as the render permits moisture migration to the soil behind and swelling and shrinking can cause render cracking and failure. This may be improved with higher levels of compaction that resist moisture migration better. The costs of a high-cement render over a soil wall are still higher than a very-low-cement block and would be a costly maintenance requirement if the wall had to be re-rendered. Consequently the very low-cement solid block has been selected as a prime candidate for further research and improvement.

2.2 Raw material selection and characteristics

Soil is readily available over the vast proportion of the landmass on the planet and hence it is not surprising that it has been widely used for dwelling construction. This section of the thesis will briefly summarise the existing knowledge of soil selection for making CSSB. Wide ranges of soil are suitable for this building material and their defining characteristics will be outlined below. The use of cement as a chemical additive is also very common in CSSB manufacture. The use and understanding of cement is widespread and it’s application to soil had received much attention in recent years. Adding cement to soil is very different to adding it to aggregates and the requirements and characteristics of such a union will be described in the following subsections.

2.2.1 Properties and analysis of soil

Soil is found deposited on the surface of the earth and can consist of many different types. The variation in the soils present at the surface can be attributed to a series of natural effects working on the area over time (Craig, 1997) (Houben & Guillaud, 1994). On the very surface of the soil one typically finds material with a large amount of organic compounds present. This is unsuitable for block manufacture and can usually be distinguished by a musty smell especially on heating (Norton, 1997) (Wolfs-kill et al., 1965). Material underneath this organic layer is much better as it usually contains a cross section of particle sizes and includes a proportion of small soil particles called “fines”. These are usually defined as particles passing a 63μm mesh and consist of silt and clay. Clay is necessary in block production because it aids the workability of the mixture, increasing levels of consolidation and improving green strength, (International Labour Office, 1987). Larger particles “sands” found in soil can generally be assessed as minerals that are silicas, silicates or limestones. As well as the solid rock particles and fragments, soil will have a proportion of water and air that fill the gaps between adjoining particles in the soil. This gives natural soil a non-homogenous and porous nature.

Systems for identifying some major characteristics have been developed to define different ranges of soil characteristics. The most common of these is the size distribution of the soil particles. (Houben & Guillaud, 1989) lists the physical characteristics than can define a sample of soil, including: colour, shape, apparent bulk density, specific bulk density, size or texture, moisture content, porosity or voids ratio, permeability, effective surface area, adhesion, specific heat capacity, dry strength and linear contraction. Chemical properties are also sometimes of interest particularly when a chemical additive is used. These chemical properties include the composition, mineral content, metallic oxides, pH levels and sulphates in the soil (Craig, 1997).

With so many different characteristics that one could discover about a sample of soil, it would be foolhardy to try and discover them all in every situation that soil is to be used for making CSSB. Only a small number of characteristics are of real relevance to the scientist testing the soil. The chemical composition of the soil is of little importance once the absence of unstable compounds and organic matter has been established. The physical properties are of greater interest for making CSSB as these will help to determine its ease of mixing, forming, de-moulding, porosity, permeability, shrinkage, dry strength and apparent bulk density.

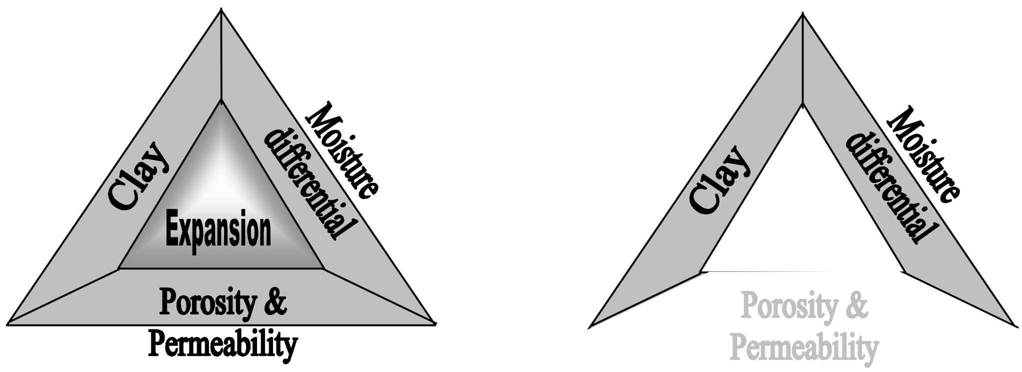
Controlling or monitoring the clay fraction is important in making CSSBs. Too much clay results in unacceptably high expansion upon wetting, requiring excessive amounts of cement to combat this. Too little clay causes low adhesion between particles and hence causes high breakage rates on de-moulding of the CSSB. An optimum fines content for making CSSB was suggested by the United Nations to be about 25% of which more than 10% is clay, (Gooding, 1993). A more useful range of particle sizes suitable for building with earth is given in (Norton, 1997) as follows:

Sand/fine gravel	40 - 75%
Silt	10 - 30%
Clay	15 - 30%

From the literature it is unclear how much a change of say ±5% to the clay content will have on the overall performance of the CSSB. Controlling the moisture content in the mixture is also important, but generally the texts use a simple drop test to determine an acceptable range. The accuracy of this test is fairly low and what effect the possible variation in the moisture has on the finished product is not clear.

The detrimental characteristic of expansion and contraction of a CSSB can only occur if three characteristics are present: "Clays" and "Porosity & Permeability" and "Moisture differential". If any one of those is absent then expansion and contraction will not occur, (ignoring thermal expansion and contraction). See diagram below.

Figure 2.5 – Characteristics of CSSB expansion



We need clay to be present in CSSB and it is impossible in humid climates to avoid moisture differentials so the only characteristics that we can seek to remove or reduce are the porosity and permeability.

2.2.2 Basics of cement usage

As a stabilising material cement is well researched, well understood and its properties clearly defined, (Akroyd, 1962), (Popovics, 1998), (United Nations, 1972). Portland cement is readily available in most urban areas, and usually available in semi-urban areas, as it is one of the major components for any building construction. Earlier studies have shown that cement is a suitable stabiliser for use with soil in the production of CSSB, (International Labour Office, 1987).

Cement is mainly composed of Lime (CaO) and Silica (SiO_2) which react with each other and the other components in the mix when water is added. This reaction forms combinations of Tri-calcium silicate and Di-calcium silicate referred to as C_3S and C_2S in the cement literature, (Akroyd, 1962), (Lea, 1970), (Neville, 1995). The chemical reaction eventually generates a matrix of interlocking crystals that cover any inert filler (i.e. aggregates) and provide a high compressive strength and stability.

The diagram on the following page attempts to illustrate how these crystals actually give the material strength. The basic mechanism is friction of point contacts between the particles taking place at a microscopic level. The duration of time for this reaction to take place is not precisely defined. There is however the definition of the "critical time" after which further working of the mix causes breaking of the crystals that have formed but before the total matrix has gained strength. The flow chart that follows shows the reaction and their effect with respect to time.

Figure 2.6 – Sketch of crystalline cement growth in sandcrete

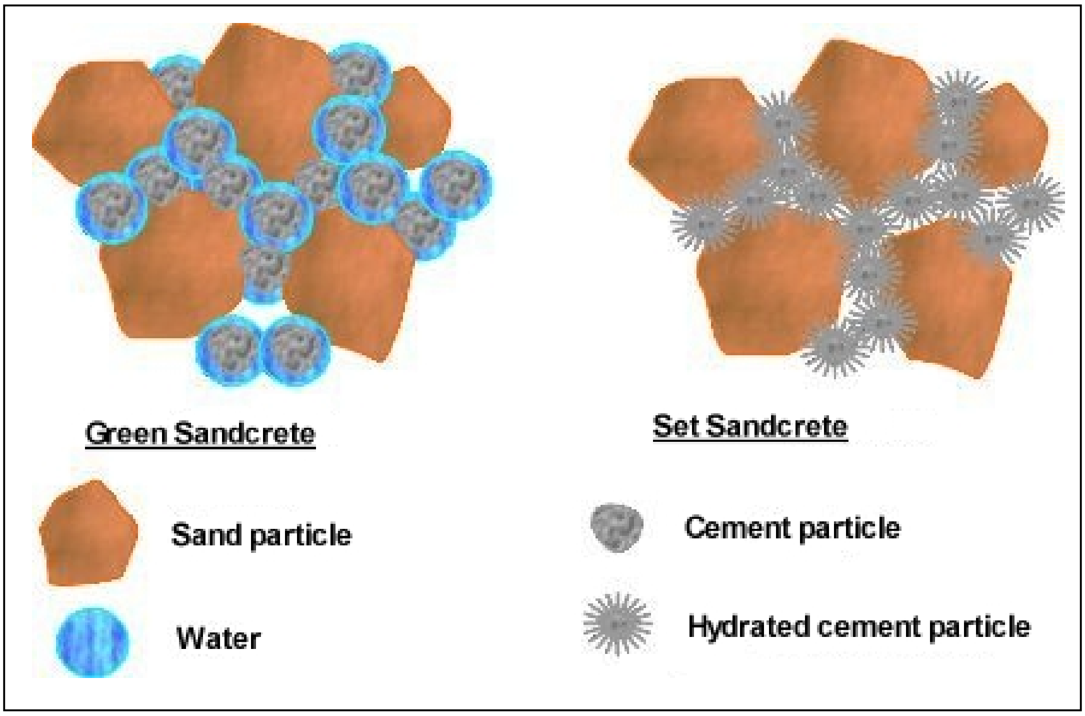


Figure 2.7 – Flow chart of the cement hardening process

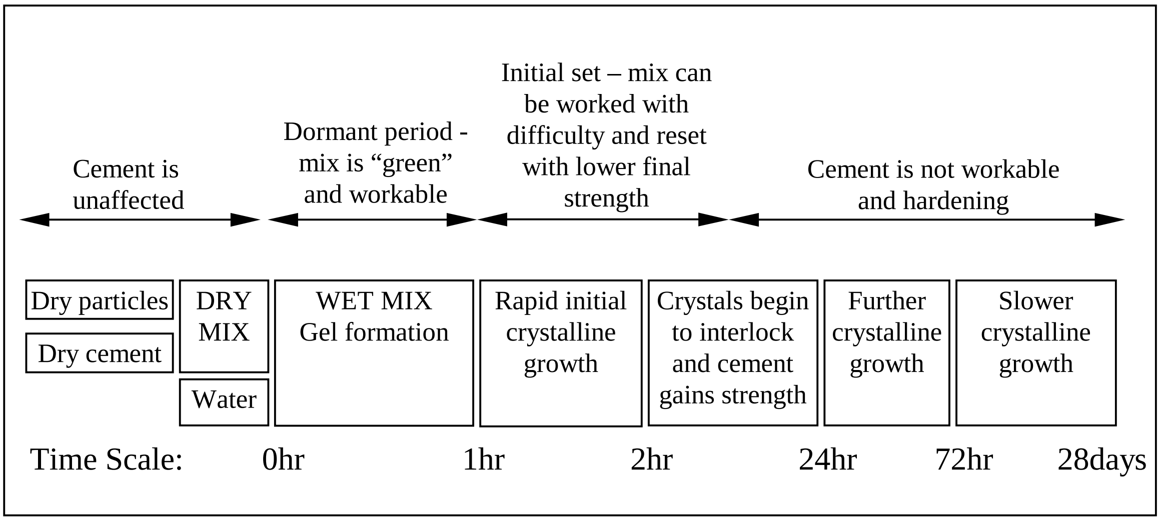
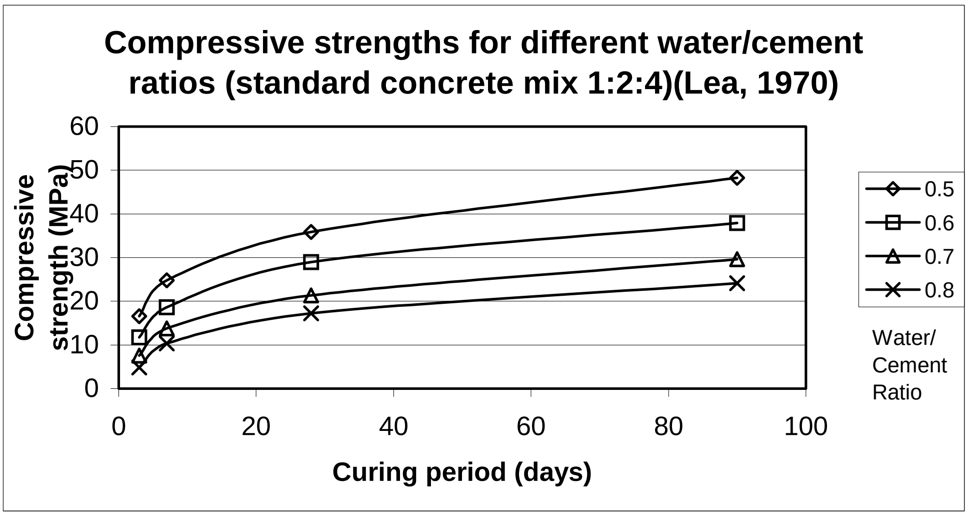


Cement is usually mixed with an aggregate to form concrete. The aggregate is usually inert filler that makes up the bulk of the material and the cement coats the aggregate in the gaps (Teychenne et al., 1988). The concrete industry has recognised that the achieved strength of concrete is highly dependent on the quantity of voids present in the mixture before curing. (Akroyd, 1962) suggests that the presence of 5% air voids will reduce the strength of a concrete mix by 33% and 8% voids by 50% compared to a sample with 0% voids present. To aid the particle intimacy, different aggregate grades are mixed together giving a spectrum of particle sizes that reduces the quantity of air voids in the material.

The water used to mix the concrete plays an important role both in placing the material and in achieving strength. The quantity of water used is typically calculated using an appropriate “water-cement ratio”. The minimum water/cement volume ratio is between 0.22 and 0.25 (Akroyd, 1962), for adequate cement hydration, but this is generally increased to the order of between 0.5 and 0.8 for normal mixes, (Lea, 1970).

Figure 2.8 – Compressive strength of concrete with different water-cement ratios



Very low water-cement ratios yield a highly unworkable mixture and more water has to be added to form the mixture into the desired shape. Additional water is called the “free-water” content and is calculated from the slump or Vebe time test. This water does not form part of the chemical reaction and will eventually evaporate from the concrete leaving voids of air throughout the material (Neville, 1995). In order to keep the free-water as low as possible concrete can be compacted or vibrated to aid workability and consolidation.

2.3 Soil stabilisation

The methods of making earthen structures more durable fit into primary and secondary categories. Primary methods stabilise the raw material making it more durable, and subsequently any structure made from it, whilst secondary methods provide protection from the elements rather than enhancing the material properties. Soil stabilisation improves the characteristics of the soil so that it can tolerate greater loading and perform better when it is exposed to the elements. Stabilisation usually involves work of some kind to be done to the soil, and this section will briefly describe some of the methods of soil stabilisation that have been used.

Raw earth can be stabilised in a number of different ways. (Houben & Guillaud, 1994) suggests that there are six different mechanisms for soil stabilisation, namely: raising density, reinforcement, linking, binding, waterproofing and water repellent treatment. The two most common techniques used in block manufacture are binding (with chemical additives such as cement or lime) and raising density (by some method of compaction). In this section the guidelines of cement addition to soil will be summarised, the methods of soil compaction will be explored and the current role of stabilisation will be outlined with a view to further possible enhancements.

2.3.1 Cement addition

By now we have a better understanding of the way cement bonds with itself and other particles in making concrete. We also know some of the important guidelines that need to be followed when making successful mixes of concrete. Furthermore, many of these guidelines and principles should be followed when mixing cement with soil.

The quantity of cement that is required for adequate stabilisation depends on several criteria, namely; the required compressive strength, soil type, environmental conditions and levels of quality control. Cement can very easily be wasted if it is not utilised in the correct manner and significant cement reduction can be attained through good production management and quality control. Controlling the moisture content, level of compaction and the curing regime will play a big part in getting the most from the added cement.

For relatively quick analysis of soil characteristics for cement stabilisation the CSSB literature suggest the use of a linear shrinkage mould, (Houben & Guillaud, 1994), (Norton, 1997), (International Labour Office, 1987), (Rigassi, 1995). Soil is mixed with water to its liquid limit and then left to dry out in a mould with dimensions 40 × 40 × 600mm. The linear shrinkage is measured and the quantity of cement required to adequately stabilise the soil is calculated. The following table is taken from (International Labour Office, 1987), recommending the cement to soil ratio for different soils of known linear shrinkage.

Table 2.2 – Cement to soil ratio for different soils of known linear shrinkage

Measured Shrinkage (mm)	Cement to soil ratio
Under 15	1:18 parts (5.56%)
15 – 30	1:16 parts (6.25%)
30 – 45	1:14 parts (7.14%)
45 – 60	1:12 parts (8.33%)

The volumetric shrinkage of a CSSB will depend on the fraction of clay present and the moisture content of the mix. If the moisture content is low then the shrinkage will also be low when it dries out. This is harmonious with the recommended low water-cement ratio for maximising the cement strength. However, on subsequent wetting the forces exerted by the expansive clay particles must be restrained by the cement matrix in the CSSB. So the cement requirement will also depend on the degree of wetting that the CSSB will experience, hence the environmental conditions.

As mentioned earlier the degree of wetting depends on the ability for moisture to migrate in and out of the material, dependent on the porosity and permeability. Methods of reducing the migration of water to the clay fraction can therefore also provide a method of reducing the cement required for adequate stabilisation. This technique is more commonly referred to as compaction or consolidation and will be main focus of the next sub-section.

2.3.2 Compaction of material

Within the civil engineering industry there are several methods of compaction that are used in ground stabilisation that use methods of static, vibration and dynamic blows to compact soil (Parsons, 1992). Block compaction uses similar methods and similar technology only on a smaller scale and typically compaction takes place in a confined space rather than in unconfined open areas (Houben & Guillaud, 1989), (Norton, 1997). Block compaction has predominantly used vibration or slow steady squeezing (quasi-static) compaction to achieve the desired levels of soil consolidation. Until very recently the dynamic element used in block manufacture has been limited to the compression piston coming into contact with the surface of the soil at some speed followed by static pressure being applied to the material (Houben et al., 1994).

The following three figures demonstrate the different types of compaction, the particle intimacy around the O.M.C. (as found in (Head, 1980)), and the relationship between moisture content and achieved density for different compaction energies.

Figure 2.9 – Unconfined, semi-confined and confined compaction

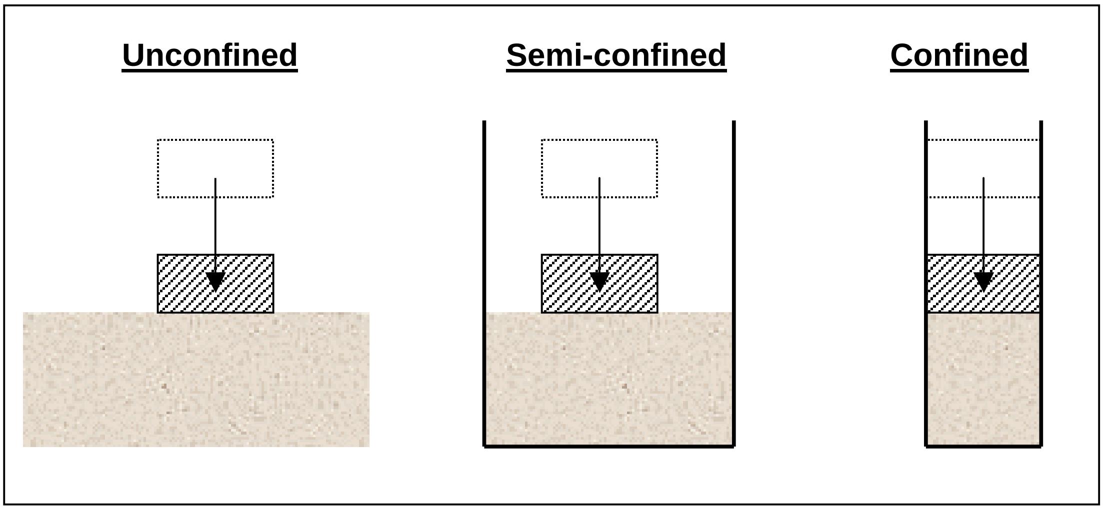


Figure 2.10 – Diagram of particle intimacy around the O.M.C.

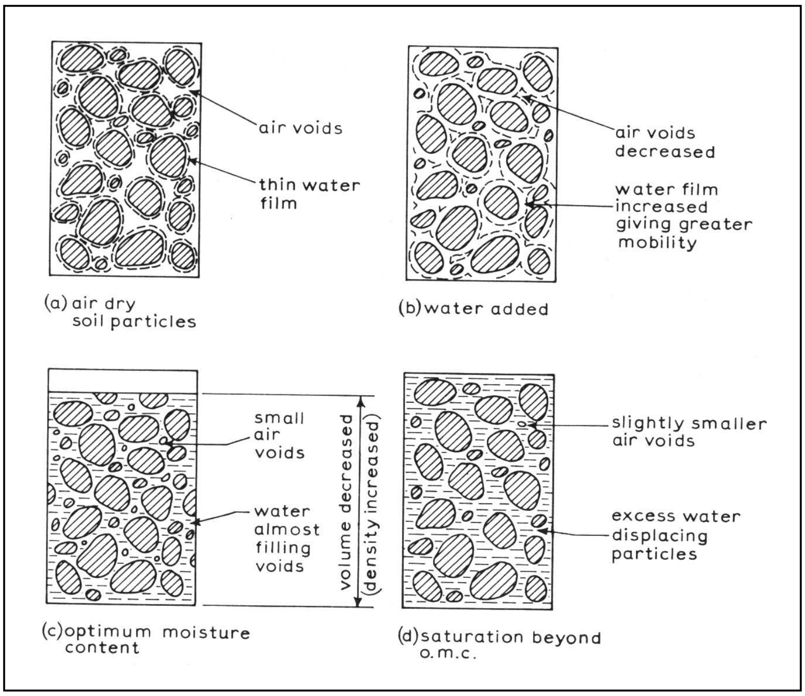

Figure 2.11 – O.M.C. for soil at different compaction energies

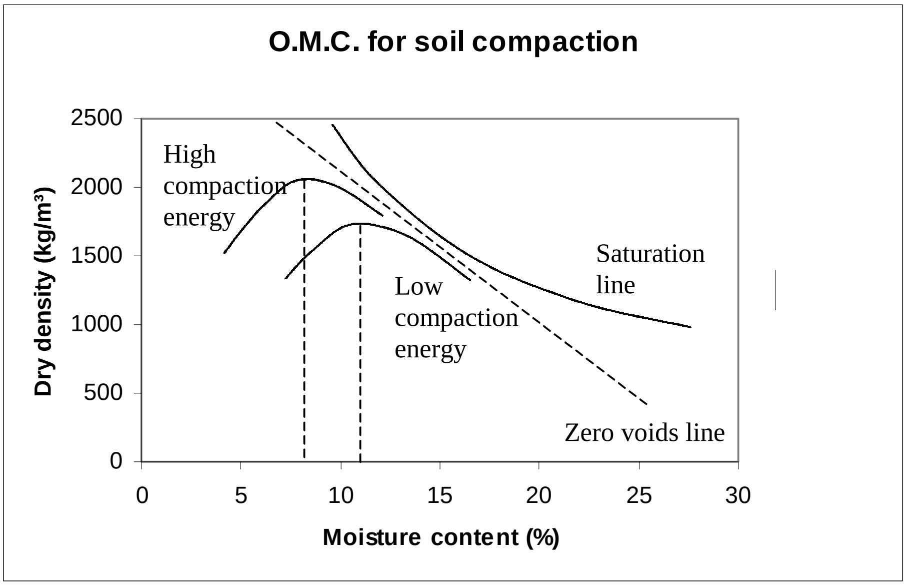

Improved levels of compaction have a significant effect on the compressive strength of the sample and on the effectiveness of the cement stabiliser added. The following two graphs are presenting data collected by (Gooding, 1993) to indicate the relationships between cement content, compaction energy (defined in MPa pressure) and the resulting bulk density and subsequent 7-day wet compressive strength.

Figure 2.12 – Relationship between cement content, compression pressure and 7-day wet compressive strength

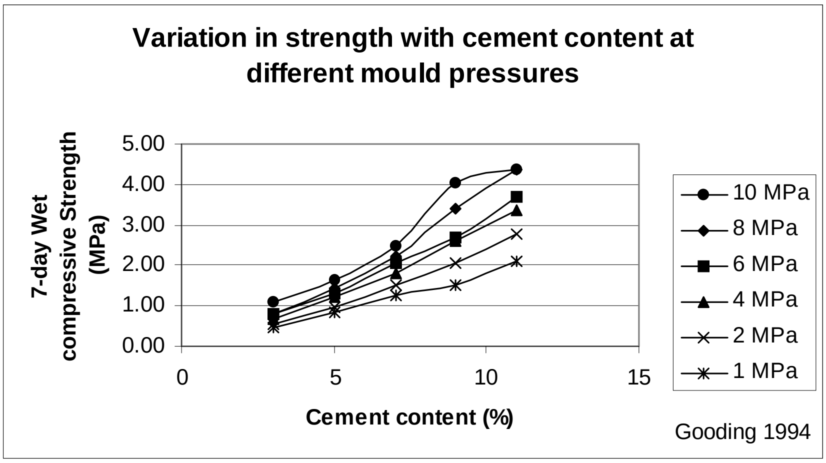

Figure 2.13 – Relationship between bulk density and 7-day wet compressive strength for different cement contents

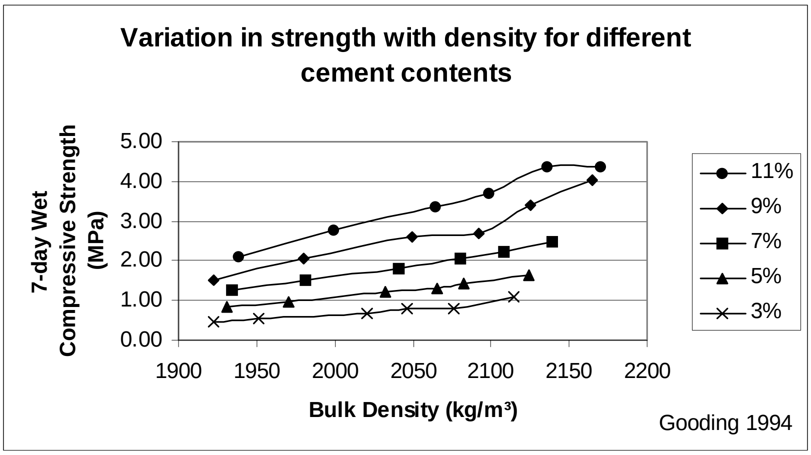


The above data clearly shows the significant advantages that increased compaction offers. If a CSSB could be compacted to a higher density, then for the same ultimate strength the cement content could be reduced. The trade off is an increased energy cost for a reduction in chemical additives. Another thing that is apparent is the possible miss match of moisture contents desired for optimum compaction for a given energy and optimum moisture content for cement curing. This issue of what is the most appropriate moisture content to be used for a given compaction energy needs to be resolved.

2.3.3 Current role of stabilisation and its possible extension

It is usually the poor or underprivileged that need and build low-cost housing and this has an effect on the processes used to make the building material. Minimising material cost and machine requirements are typically more important than reducing labour costs. Consequently it is not uncommon to find block manufacturers using cheap machinery and minimising the stabiliser content. The photograph below shows some of the poor applications of cement to stabilise soil blocks in what seems to be a well-organised production yard. This illustrates the need for better understanding of the processes at work in soil stabilisation and improved quality control throughout the process of production. Significant savings in cement or much higher quality blocks could be attained if these were put in place. Furthermore, there is little way of knowing the performance of a finished CSSB without conducting crushing tests so the purchaser has to trust the seller as to the quality of the blocks being sold.

Figure 2.14 – CSSB production yard showing poor curing practice

CSSB production yard showing the poor block manufacturing technique of taking cement stabilised blocks and leaving them out to dry in the open rather than curing them in humid conditions. Uneven drying from the edges results in very weak cement bonds where they are needed most. Edge defects can also be seen where blocks have been damaged through poor handling and low strength. Dried blocks in the background look very grey indicating high cement content probably necessary for adequate strength.

Apart from improving the understanding of cement use and implementing better quality control in production there are advancements that can be made in the production technology as well. A study conducted by (Gooding & Thomas, 1995), as part of an Overseas Development Agency report, calculated that using more expensive high-pressure compression machinery to make blocks was not as economically attractive as adding more cement and using a low-pressure machine for the estimated life of each machine.

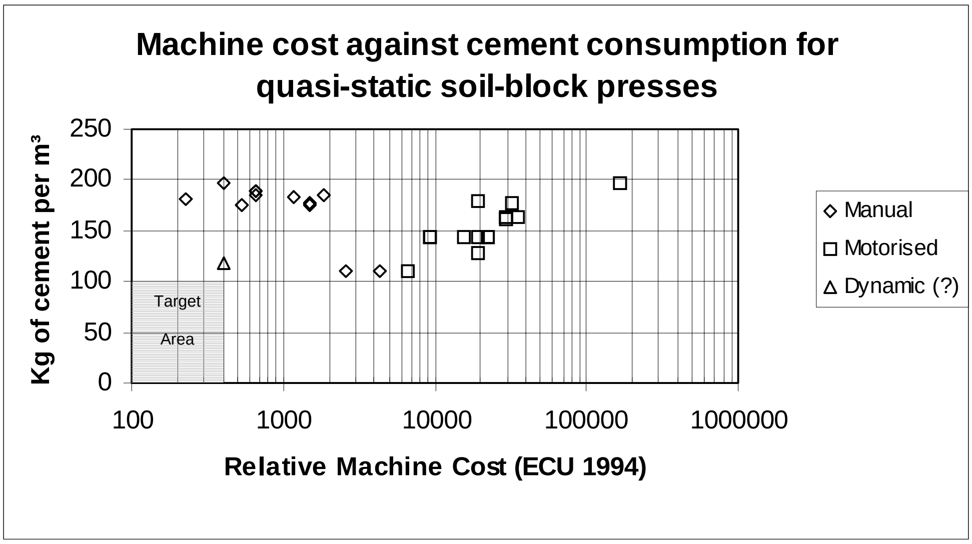
Terms used for different moulding pressures as described in (Houben & Guillaud, 1994):

Very low pressure	1 – 2	MPa
Low pressure	2 – 4	MPa
Average pressure	4 – 6	MPa
High pressure	6 – 10	MPa
Hyperpressure	10 – 20	MPa
Megapressure	20 – 40	MPa

Improvements in methods of compaction would greatly improve the characteristics of the finished CSSB, both immediate green strength and long term strength as well as reducing the porosity and permeability of the material. It could also facilitate in the further cost reduction of the material making the CSSB building material available to a wider group of people and more attractive and desirable for dwelling construction. From the graph shown in Figure 2.12 an increase in moulding pressure from 2 MPa to 10 MPa can double the wet compressive strength. Alternatively such an increase in pressure could successfully reduce the cement content from 11% to 7% without a significant loss in wet compressive strength. However, the argument that increasing the applied pressure can enable one to reduce the cement content without any loss in overall performance is not as attractive as it sounds. The high-pressure compaction ensures that more material is required for a block of given size and whilst some savings can be made in expensive additives such as cement the increased density offsets this advantage slightly.

The graph below is a combination of interpreted data from (Gooding, 1993) and (Houben et al., 1994), (who complied a CSSB machine catalogue with specifications and approximate prices). The graph shows the relative machine cost compared with the approximate cement usage per cubic metre of walling material. Gooding calculated the relationship between cement content, applied pressure and wet compressive strength. From this data it was possible to suggest the required amount of cement to achieve a certain block performance. This block performance has been taken as a 7-day W.C.S. of 2MPa and using the projected *density* that the CSSB press could achieve a cement requirement was calculated. It clearly shows the area of where a machine is necessary to fill the low-machine cost and low-cement usage area. Data points in the upper region of the graph represent machines that use low-pressure lever systems whilst points in the lower region include machines with a hydraulic compression mechanism delivering high-pressure. Motorisation does not necessarily procure greater applied pressure but usually results in higher machine cost and faster rates of production.

Figure 2.15 – Comparison of machine cost and cement requirement



From this graph it can also be shown where dynamic compaction could feature and that it may be able to provide the low-cost and low-cement block machine that is currently unavailable. Research into dynamic compaction is in its infancy, but significant discoveries have already been made. The next section of this chapter will describe the research conducted to date and to identify gaps where further investigation is required.

From the above it is now possible to summarise some of the different aspects of compaction that we would like to see improved or included in stabilised soil block manufacture.

- Higher density blocks exhibit greater strength and increase the effectiveness of any chemical stabiliser added to the block.

- Reduced porosity and permeability of the material hindering the ingress of water and slowing the rate of deterioration in humid conditions.
- Increased green strength to reduce breakages during early handling and to enable stacking immediately after forming.
- Compaction achieved via a mechanism that is easy to manufacture and to maintain using tolerable levels of materials, equipment and skills.

It is hoped that dynamic compaction may be able to deliver on some of these criteria and the following section will give details of experiments carried out to determine the potential of full-size dynamically compacted blocks for use in the humid tropics.

2.4 Dynamic compaction research

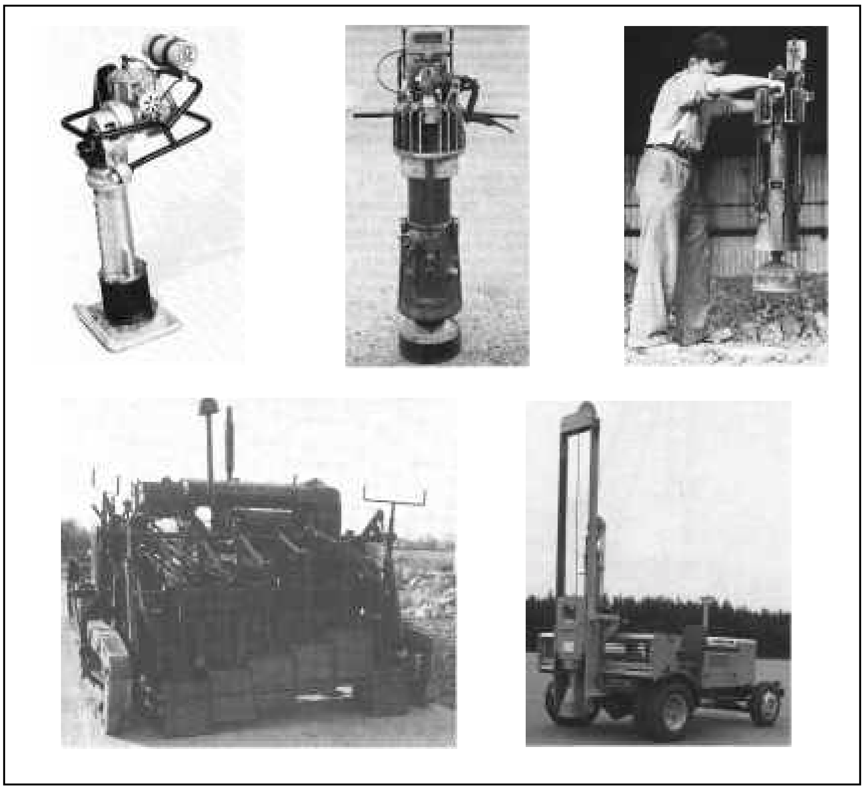
It has been found that the information on dynamic compaction of stabilised soil blocks is very scarce. Up till now the author is only aware of two pieces of work that cover this topic, and only one of which he has been able to access. There are however, other publications that deal with the subject of soil compaction using impact, both from a theoretical and practical viewpoint. This section will review the conceptual research on impact compaction carried out by the Transport Research Laboratory identifying both theoretical models proposed and experimental results of significance. Following this an overview of the optimisation experiments conducted by Gooding will be presented identifying areas of further research required. Finally the application of impact compaction to soil blocks as carried out by Montgomery (the author) will be reviewed.

2.4.1 Conceptual Research

The majority of the research into dynamic compaction of soils has been conducted by the civil engineering industry with a view to improving soil consolidation, (both efficiency and depth) for subsequent placement of a structure. Road compaction is one of the areas that has particularly focused on this technique with the application of vibrating rollers and vibrating sheep's foot rollers, (Parsons, 1992), (Ingles & Metcalf, 1972), (Hausmann, 1990). These techniques do not really apply to the confined soil compaction that would be experienced with CSSB manufacture by impact. However, research has also been conducted on dropping weight compactors, vibro-tampers, power rammers and single and multi-weight dropping machines, (Parsons, 1992). Such research is of greater interest despite the compaction taking place in the unconfined rather than confined state.

The figure below contains photographs of some of the "impact" compacting equipment available in the civil engineering industry. Each deliver a known quantity of energy over a known surface area and would be given an "energy transfer per unit area" rating of between 4.3 – 120kJ/m² depending on the model and settings of compactor.

Figure 2.16 – Civil engineering compaction equipment using impact



Theoretical and experimental analysis of the impact method was also conducted to try and determine the most effective machine for ground compaction and to improve the understanding of impact compaction. A test rig was developed and tests were conducted on a variety of soils by dropping a known mass through a known height and comparing the compaction with the 2.5 kg standard compaction test for the same soil. Measurement of the impact pressures experienced by the soil was also carried out using piezoelectric gauges buried at 150mm and 300mm beneath the surface.

Parsons discovered that for an approximately constant energy transfer per blow a smaller mass lifter to a higher height delivered a higher pressure than a larger mass lifted from a smaller height. Furthermore the pressure experienced at 300mm below the surface was approximately half the pressure experienced at 150mm below the surface. This suggests a linear decay in pressure from the surface to some point beneath the surface dependent on the energy transferred in the blow and soil characteristics. The application of more than one blow demonstrated that higher degrees of compaction could be attained for the same optimum moisture content as used in the 2.5kg standard compaction test.

Theoretical analysis of the compaction of the soil by impact included mechanical characteristics of the soil (plastic deformation on impact), the impactor velocity, mass and impactor surface area. From these a theoretical pressure applied to the soil could be calculated. The main variable of interest in this analysis is the dynamic modulus of deformation, which can only be found by measuring the deformation of the soil after an impact has been delivered. The analysis suggests that this variable will be constant for the type and moisture content of the soil. Whist this may be true for soil in the unconfined state it almost certainly is not the case with soil confined in a mould.

Another text (Scott & Pearce, 1975) suggested that impact compaction can be modelled as a highly damped spring with characteristics that depend on the Young's Modulus, Dilation Velocity, Poisson's Ratio, and Elastic Limit of the soil. They give an equation that links these characteristics to the rate of deceleration of a moving mass in order to model the stress and movement at the impact surface for an unconfined mass of soil. They investigate the effect of unsaturated and saturated soils monitoring the elastic properties, surface deflection and stress concentrations. They also suggest a model for a one-dimensional situation that may be analogous to dynamic compaction within a constrained mould. However the assumptions made for the development of the model are not clear so application to the specific case of dynamic compaction of soil blocks has not been possible.

Throughout the texts that deal with soil consolidation there seems to be a lack of explanation or understanding of what is actually happening during compaction. Each text can describe the characteristics before and after the consolidation has taken place but they don't attempt to explain the process. Soil is a complex material and consolidation takes place at the microscopic level of particle placement and interface with other particles. This is a very difficult area to model, but it would be beneficial to discover some of the prevalent mechanisms that occur during compaction whether by impact or otherwise.

2.4.2 Compaction optimisation of confined soil samples

Research in the previous sub-section concentrated on the compaction of un-confined soils. This sub-section covers in some depth the research conducted by (Gooding, 1993). It is the sole text that has put forward a systematic approach to determining the most effective method of compacting soil confined in a mould. It has also been helpful in experimental design for this Ph.D. and it's summary helps to explain some of the parameters selected for dynamic compaction of CSSB. Although Gooding thoroughly investigated the dynamic compacting process, he did not stabilise any of the dynamically compacted samples with cement. The characteristics and effectiveness of the combined processes was not looked into.

Before dynamic compaction was investigated, he looked into the process of quasi-static compaction (i.e. slow-squeezing). His research included varying the cement content, the applied pressure, mould taper, double and single sided compaction, pressure cycling and mould wall roughness, (some of these results have already been shown in earlier sections). Throughout his tests he used a fabricated soil called '*soil-A*' with a constant moisture content of 8%. His analysis of *soil-A* is included in Appendix A.

A relationship between compression pressure, 7-day wet compressive strength and cement content was developed and a model suggested estimating the wet compressive strength of a sample with known cement content and applied pressure. This model was based on actual experimental results taken from tests carried out using a range of pressures and cement contents. A small cylindrical mould specified in BS1924 was used for all of these tests. All the cylinders had their wet compressive strength tested after seven-day curing and subsequent soaking for 16 hours.

Gooding investigated the efficiency of impact compaction using *soil-A* without any cement present. The compressive strength had to be estimated from the achieved density compared with compressed samples. The wet compressive strength of dynamically compacted soil samples could not be measured, as the compacted samples would break apart when immersed in water. Each sample received the same energy but by different impact arrangements and the achieved density was recorded. Density was calculated by measuring the final cylinder height (±0.05mm) and mass (±0.1g) on ejection from the mould. Each cylinder received a constant 279 J/kg and the mass of each cylinder was kept at around 1.66 kg. Other factors such as the number of blows and impactor momentum were varied to find any optimum parameters for this technique.

Each sample received one of 1, 2, 4, 8, 16, 32 or 64 blows. The optimum number of blows (number that yielded the greatest density) was found to be at 16 blows, but it was also noted that only a 3-4% reduction in compaction efficiency occurred when this was varied from 8 to 32 blows for each of the different masses.

Different momentum transfer was also explored for the same energy transfer. Smaller impactor masses were lifted higher and larger impactor masses were dropped from a lower height. Three different masses were used in the experiments on the samples (23.35kg, 35.00kg and 46.80kg) and it was noted that the bigger masses dropping at slower speeds were more effective. Yet, the 23.35kg mass and the 35.00kg mass were only 0.4% and 0.2% less efficient respectively at the 16 blow configuration than the 46.80kg mass.

It was discovered that the method of dynamic compaction was more effective in consolidation than quasi-static compression for the same total energy transfer into the material. The selection of 279J/kg was taken from the energy required to quasi-statically compress *soil-A* to 9.7MPa. It was possible to achieve the same density through impact compaction with the application of only 25-50% of the energy necessary with quasi-static compression.

The experiments conducted by Gooding to optimise dynamic compaction for the same energy transfer is very interesting and helpful for machine design, but it does not indicate the levels of compaction that could be possible with additional energy. Nor does it indicate the best method of applying a certain amount of energy if a limited number of blows are to be applied. Are earlier blows more effective than latter ones? Does the impact energy need to increase as material becomes more compacted? The research also does not include the very necessary ingredient of compaction with cement present. Impact compaction of cement is not practised in the concrete industry, so the combination of these two elements needs to be experimentally assessed.

The only example of buildings made from dynamically compacted material was surveyed by Gooding as part of a survey of CSSB structures in several countries (Gooding & Thomas, 1995). He compares them with other structures in the area, constructed using similar appropriate techniques, with some interesting observations. The building made from dynamically compacted low-cement (6%) material, using a manual impact machine, had been standing for 10 years and was still in excellent condition. Other buildings in the same area made from CSSB that had been made using expensive motorised compression machinery and 9% cement were already deteriorating after only two years. Block production costs using the dynamic machine were 25% and 40% less than “sandcrete” and cement blocks respectively and were almost half the cost of CSSB made using the motorised compression machines. Such significant savings in cost and improvements in performance certainly warrant further investigation.

2.4.3 Application of impact to block compaction

As part of an undergraduate degree programme the author undertook a project labelled "Design and realisation of a test rig to research the production of full size dynamically compacted soil-cement blocks"(Montgomery, 1997). This project was completed in 1997 and achieved the following results. A full-size dynamic compaction test rig was designed and manufactured. The design chosen was suited to the level of technology available in developing countries. Several blocks were produced and their densities and surface penetration resistance was measured. Two blocks were stabilised using cement, but these were not used in the experimentation as they were only intended to be demonstrator blocks.

The theoretical formulae suggested in (Parsons, 1992) were applied to the results attained during the dynamic compaction of full-sized blocks in 1997. The table below shows the increase in energy that was delivered by the impactor as the soil block was compacted. It also indicates the total transfer of energy into the block after a certain number of blows.

<u>Table 2.3 – Summary of results of dynamic compaction conducted in 1997</u>

Impactor stroke (m)	0.1364	0.1571	0.1661	0.1748	0.1814	0.1866	0.1913
Energy(J) / blow		55.5	58.7	61.7	64.0	65.9	67.5
Energy increase		7.3	3.2	3.1	2.3	1.9	1.6
Energy transferred	0 blows	1 blow	2 blows	4 blows	8 blows	16 blows	32 blows
after blows (J)	0	55.5	104	221	468	980	2035

Between the initial resting-place of the impactor and the resting-place after one blow there is a distance of (0.1571 – 0.1364) = 0.0207m. This is the deformation of the soil during impact. The velocity of the impactor prior to impact can be assumed to be $V = \sqrt{2gh} = \sqrt{2 \times 9.81 \times 0.1364}$ = 1.64 m/s …etc.

Below is a table with the rest of the calculations for multiple blows during a compaction cycle using the above formulae.

Table 2.4 – Analysis of forces from dynamic compaction conducted in 1997

	1 blow	**2 blows**	**(3 blows)**	**(4 blows)**	**(8 blows)**	**(16 blows)**	**(32 blows)**
Velocity prior to final impact (m/s)	1.64	1.76	1.81	1.83	1.88	1.91	1.94
Stopping distance (m)	0.0207	0.0090	0.0043	0.0044	0.0016	0.0006	0.0003
Mean deceleration (m/s²)	64.6	171	375	384	1070	2800	6380
Calculated stopping time (s)	0.025	0.010	0.005	0.005	0.0018	0.0007	0.0003
Pressure generated (MPa)	0.057	0.152	0.332	0.341	0.948	2.488	5.656
Dynamic modulus of deformation	2.8E+6	1.7E+7	7.6E+7	7.8E+7	5.7E+8	3.8E+09	1.9E+10
Mean force in tonnes (final impact)	0.233	0.616	1.35	1.38	3.85	10.1	23.0

Note: The velocities and stopping distances for the blow numbers in brackets have been linearly estimated from compaction data for multiple blows. These figures are probably accurate to ±10% and can only show the continued trend.

Two things are immediately obvious from the table of results above. Firstly, the dramatic increase in force that is applied during impact between the first blow and much later ones. Secondly, the dynamic modulus of deformation for a soil compacted in a confined manner increases as it becomes compacted. Therefore the characteristics and behaviour of the soil will change during the compaction process. This will make accurate modelling the compaction significantly more difficult than an unconfined soil with a constant dynamic modulus of deformation.

Gooding quasi-statically compressed a block to 9.7MPa and noted that it achieved a bulk density of 2038kg/m^3. This compaction pressure equated to a transfer of 279J/kg. By comparison, Montgomery dynamically compacted a full size block to a bulk density of 2040kg/m^3 by applying 32 blows to it from a 36kg impactor. This block received a total of 2035J from the falling impactor. For a 10kg block this equates to approximately 204J/kg, some 26% less energy required than the quasi-statically compressed block, which is a significant saving. This research indicated that the savings in energy that Gooding had found could be extrapolated onto full size blocks and therefore warranted further research.

Montgomery also did not stabilise any of the full size dynamically compacted blocks as these were trials to test the feasibility of full size compaction. Consequently there are not any known characteristics of the produced blocks apart from a handful of penetrometer tests done on the freshly de-moulded blocks. These give little indication of the core strength and only sought to establish the level of uniformity of density throughout the block.

2.5 Chapter summary

The assessment of different building materials at the beginning of the chapter helps to focus on the more appropriate materials that can be employed in developing countries. For environmental reasons clamp-fired brick and ‘sandcrete’ blocks not sustainable in the long term. Aerated cement blocks and kiln-fired blocks are large-scale industrial processes that require high levels of technology and are unsuitable for local block manufacturing techniques. The only remaining material with any immediate promise is the compressed and stabilised soil block, which has a reasonable following in areas where the soil is suitable and fired-brick is scarce. However, this material is still inferior in performance to more advanced materials and needs to be improved to gain greater acceptance.

The potential for appropriate technology to help in this area has been seen already with the development of manual block presses in the 1950's (Cinva-Ram block press). It is hoped that technology may have a further role to play in improving the block manufacturing techniques still further. The project will be directed to provide a sustainable solution that is technologically appropriate and provides a significant improvement over existing processes.

An attractive option for cost reduction is the evidence that the cement content can be reduced if the material density is increased. However, current technologies that deliver increased material density are prohibitively expensive and are not economically attractive. There is evidence that an alternative method of compaction through the application of a dynamic blow may provide high levels of densification without the prohibitive machine complexity and cost. Earlier research into this area has indicated that not only is dynamic compaction a possibility for soil block production but also potentially is more energy efficient in compaction than quasi-static compression.

To date there has been very little experimentation into the application of a dynamic blow to compact a soil block. If the method does indeed have significant advantages over the more expensive hydraulically assisted high-pressure quasi-static compression then this warrants further research into this area. Research will require the designing and development of a suitable experimental rig with a view to low levels of complexity and cost if it is to be transferred for use in developing countries. The academic understanding of dynamic compaction also seems to be highly limited and any research into this area should seek to explain some of the dominant mechanisms at work during the impact blow. This will require the close analysis of the impact blow and possible model generation to describe the actions taking place within the material throughout the compaction process.

3 Preliminary experiments with stabilised soil

The previous two chapters identified the growing need for low-cost housing and the potential for dynamic compaction of CSSB to provide a low-cost environmentally sustainable alternative to existing walling materials. This chapter now focuses on the findings of early experiments conducted to improve the understanding of quasi-statically compressed stabilised soil and the processes involved in its production. Throughout these experiments several independent variables have been selectively altered and the effect on one or several dependent variables has been noted. These findings have aided the process of parameter selection for later tests to be conducted on *dynamic* compaction of stabilised soil, dealt with in the following chapter.

These preliminary experiments were conducted for several reasons. Firstly to reduce the large number of independent variables to a manageable number. Secondly to identify main relationships not covered in the literature. Thirdly to select (for those independent variables not held constant) what experimental values to use. And fourthly to assess experimental variability and hence select suitable sample sizes.

3.1 Summary of input variables and output measures

Many parameters can be varied in the production of stabilised soil. Careful experimental design will therefore be needed to minimise the number of experiments to assess key characteristics and relationships. For the moment we will omit mentioning the variables associated with dynamic compaction as they feature in the next chapter. The ranges of input variables, as shown below, were largely determined by practical constraints.

- Moisture content – taken as a percentage of solid material (range 2-10%)
- Compression pressure – usually recorded in MPa (range 4-20MPa)
- Mould wall thickness (range 0.5-32mm)
- Size and shape of sample (tall and short cylinders and blocks)

Other input variables kept constant except where explicitly stated otherwise are:

- Soil type – including particle size distribution (soil-B)
- Cement content (5% by weight)
- Mould wall surface finish (machined to approximately IT10)
- Delay before compaction (5-10min)
- Curing period and conditions (100% humidity for 7 days)
- Ambient temperature and humidity (20°C and 35% relative humidity)

The output measures used to monitor the process are as follows:

- De-moulding force
- Projected Dry Density (P.D.D.)
- Wet Compressive Strength (W.C.S.)
- Non-destructive tests

These output measures give the basis for determining any trends from the results and will be used to identify the relationships between variables of interest.

3.1.1 Input variables

From the literature review there seems to be a number of relationships that need clarifying. For example, what is really happening with the water in the compacted sample? How does the quantity of water present at compaction affect the consolidation combined with the cement curing to achieve strength? Varying the water content during the tests may help us to determine what are the dominant mechanisms in action.

Moisture Content (M.C.) **–** The previous chapter mentioned the problem of selecting the moisture content. The soil literature suggests one thing and the concrete literature another. The only solution is to explore different moisture contents to see what effects they have on both the achieved density and the final strength. Previous experiments using *Soil-A* investigated a range of moisture contents up to 10% (at which the samples became unmanageable). Consequently the moisture content used during the experiments ranged from 2 to 10%. 6% was deemed a good compromise between the different factors in achieving density and necessary strength, and was used as a normal value. Selected values for moisture content 2, 3, 4, 5, 6, 7, 8, 9 and 10%.

Compression pressure **–** This can vary from very-low-pressure 1MPa to hyperpressure 20MPa. The majority of experiments employed 10MPa, but other pressures were looked at to discover trends within the material. Selected values for pressure 4, 6, 8, 10, 12 and 20MPa.

Mould-wall thickness **–** The relative stiffness of the mould wall to restrain the pressures applied might have some effect on the degree of possible consolidation for a given energy transfer or pressure applied. The effect that this has on the compaction characteristics has not been explored previously. The mould wall thickness is of greater importance with dynamic compaction. It is believed that the forces applied to the mould walls during compaction are smaller and of much shorter duration than those occurring during quasi-static compression. Moulds from 0.5mm up to 32mm thick were used. Clearly the extra cost for much thicker moulds is a significant consideration and using the thinner moulds is much more attractive. Selected values for mould wall thickness 0.5, 2, 8 and 32mm.

Size and shape **–** For research purposes it is inconvenient and expensive to manufacture full-size blocks to check each variable and characteristic. Indeed, previous dynamic compaction research had been carried out on 100mm diameter cylinders as opposed to blocks for this very reason. Similarly, after a few initial experiments on full-size blocks (290 × 140 × 90 mm), most experiments were conducted on small short cylinders (∅54.4mm, approximately 45mm high). These cylinders were easier to manufacture, cure and test, than the full-size blocks that would also be produced later in the research. Extrapolation of findings from small cylinders to full-size blocks is not straightforward, however the *ranking* of properties at one scale is likely to be the same as the ranking at a different scale.

Unless specifically stated the input variables below have been kept constant throughout the experiments. The selection of those constant values is discussed each in turn:

***Soil type* –** In the field this can vary considerably and it is known that some soils are more suitable than others for the production of CSSB. In the previous research conducted by Gooding a suitable soil was mixed from builders sand and kaolin clay. Some of this original soil (*Soil-A*) was still available in small quantities and consequently was used for a few initial experiments. Later on in the research a different soil using similar ingredients had to be mixed and this was called soil-B and was used for the remainder of the experiments. The analysis of Soil-A and B can be found in Appendix A.

Cement content – Cement is usually the dominant cost in CSSB production, so the reduction of its quantity is very desirable. The relationship between cement content and compressive strength has been well researched in the past so it is not necessary to investigate it further here. How much cement is necessary depends on three factors, the clay content of the soil used, the degree of compaction during moulding and the required wet compressive strength of the finished block. Previous stabilised soil research (Rigassi, 1995) has indicated that cement contents below 2 or 3% will not actually enhance the wet compressive strength or improve stabilisation. Consequently 5% by weight has been selected as the smallest amount of cement practical to employ for CSSB and has been used in the vast majority of the experiments.

***Mould surface finish* –** Throughout the tests the moulds had a machined surface finish to an approximate tolerance grade of IT10.

Delay before compaction **–** As soon as moisture is added to the dry soil/cement mixture the cement reacts chemically with the water. Any delay between adding the water and the material compaction should therefore be kept as short as possible. For research purposes any variation in the delay period between mixing and compaction should be minimised as this might have an effect on final properties. Typically the compaction occurs between 5-10 minutes after mixing of water into the mix. The order of production within a batch may also have an effect on the final sample characteristics and while this is not large it is a factor that requires addressing. Indeed it would be useful to know whether a significant loss-of-strength penalty is incurred when a period as long as say 20 minutes elapses between mixing a batch and making the final sample.

Curing period **–** The vast majority of the tests conducted on stabilised soil had the soil curing for 6 days in a 100% humidity environment (samples placed in sealed bags containing water-saturated air). This was then followed by soaking for a further 24hours giving a total curing time of 7 days. This was a suitable period as many texts gave data for cement properties at 7 days and enabled reasonably quick feedback of results from tests.

Ambient temperature and humidity **–** The experiments have been carried out under laboratory conditions, typically at 20°C and with a low relative humidity.

3.1.2 Output measures

The list below describes the set of different measures used for assessing the finished material after stabilisation and consolidation. Each measure was not carried out on every experiment, as this was often either impractical or impossible. For example the wet compressive strength of a compacted sample cannot be found if the sample has no cement. These measures have been the key method of identifying any relationships between input variables.

- De-moulding force – measured using the compression rig
- Projected Dry Density – calculated from measured bulk density
- Wet Compressive Strength – measured using the compression rig
- Non-destructive tests – penetration resistance and indentation size

De-moulding force – After compacting a CSSB in a mould it must be successfully removed from the mould without damage. The majority of small tests done using a compression machine involved a straight-sided mould and the compacted sample was pushed up from the bottom. Where possible, this ejection force was measured.

Projected Dry Density (P.D.D.) – The *dry density* is calculated from the dry mass of the solids divided by the volume of the material. Since we know the dry mass of the material prior to mixing and compaction we can calculate the P.D.D. of the material upon ejection. The P.D.D. gives an indication of the level of consolidation that has occurred irrespective of the water present in the sample. The bulk density measure includes the mass of the water in the density calculation and therefore yields a higher value for density that can be misleading, especially where different moisture contents have been investigated. (Dry densities between 1900 and 2000 kg/m³ are considered to be excellent for CSSB manufacture (Houben & Guillaud, 1989), (International Labour Office, 1987).).

Wet Compressive Strength **–** Existing low-cement CSSB manufactured by low-pressure compaction have compressive strengths adequate for the majority of low-rise structures *provided that* water penetration is kept to a low level. However, when saturation of such CSSB has occurred it has often proved to be too harsh for the material to withstand whilst maintaining a load: surface flaking (spalling) or even collapse has followed. Wet compressive strength is measured by placing a cured and water-saturated sample between the jaws of a compression machine. Then slowly applying a force to the sample recording the maximum force sustained. Wet compressive strengths of over 2MPa are considered to be excellent for CSSB (Houben & Guillaud, 1989).

Non-destructive tests **–** Some of the samples produced had tests performed on them to indicate characteristics such as the 'green' strength of the material. These tests were also conducted to try and develop surrogates for determining characteristics that could only be found otherwise by destroying the sample. A penetration test was used to determine the green strength of a formed block. This involves pushing a rod a specified distance into the surface of the block and recording the force required (usually done using a penetrometer). The green strength of the block will not depend on its cement content, as the cement particles will not have had time to hydrate and add any strength to the material. Another test, the indentation test, was also developed specifically for the stabilised soil material as the penetrometer test proved unsuccessful in many circumstances. This test was developed towards the end of the research so unfortunately the number of tests conducted is relatively small.

3.2 Experiments employing full-size blocks of Soil-A

A number of full-size blocks were produced early on in the project using *Soil-A* (the predecessor to *soil-B*) to learn about the interaction of variables using the quasi-static compression technique. A Brepak earth block press was available for block production that could deliver pressures of up to 10MPa and this was used to compress blocks with different moisture contents to 10MPa.

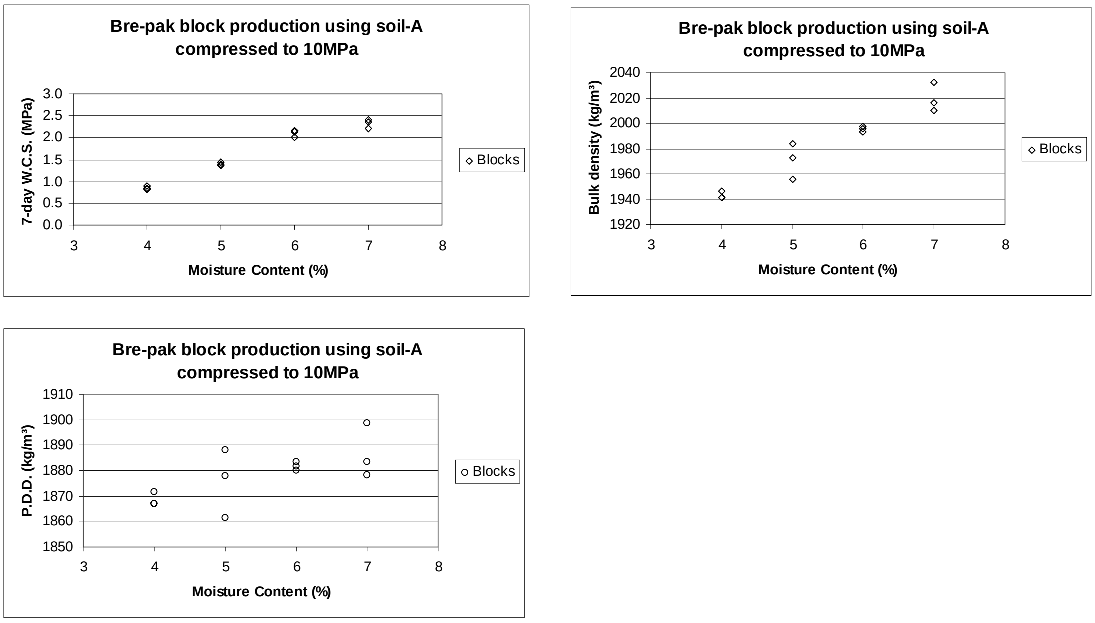
3.2.1 The effects of moisture on strength

The data included in Appendix G shows the measured results from 12 stabilised blocks that were produced using the Bre-pak machine using *soil-A* at four different moisture contents (4, 5, 6, 7% by weight) and a constant compression pressure of 10MPa. Due to an error in the mix calculation the cement content was 5.2% instead of the intended 5% which is a small error considering the variability of the material as a whole. The processing time for the production of each block was approximately 15 minutes to include dry and wet mixing of the material, compression and ejection.

Figure 3.1 below shows the variation in the 7-day W.C.S., the bulk density and the P.D.D. with moisture content. Increasing the moisture content from 4% to 7% delivers over 100% increase in strength yet only a 4% increase in bulk density and less than

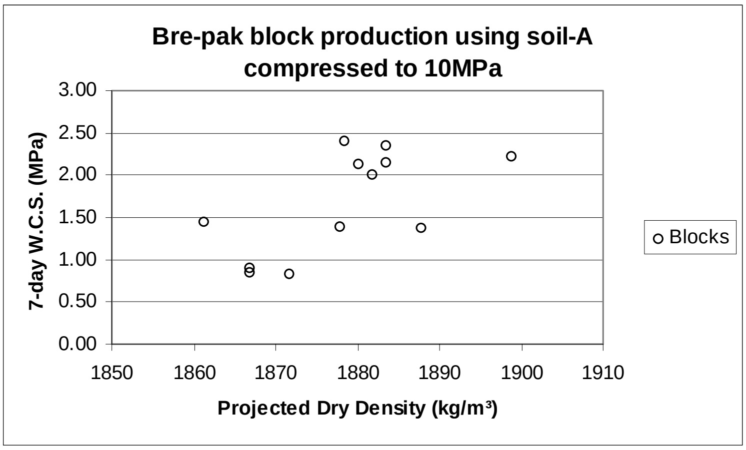
1% increase in P.D.D. These results would seem to suggest that a higher water/cement ratio is in fact not as deleterious as originally anticipated. In fact the contrary seems to be the case.

Figure 3.1 – Strength, bulk density and P.D.D. variation with moisture content



The graph indicates that there may be optimum moisture content for *strength*, as it would appear that the graph is levelling off above 7%. This could correspond to the optimum moisture content for *density* as described in the soil literature, but the shape of the graphs showing density do not confirm that this is the case. However, we can see that the increase in strength is in some way connected to in the increase in density. Comparing strength and density on the same graph (shown in Figure 3.2) demonstrates the possible relationship that exists between the two output measures. Unfortunately, there is quite a bit of spread in the data presented and this makes it difficult to see any relationship clearly.

Figure 3.2 – Strength against P.D.D. for full-size blocks

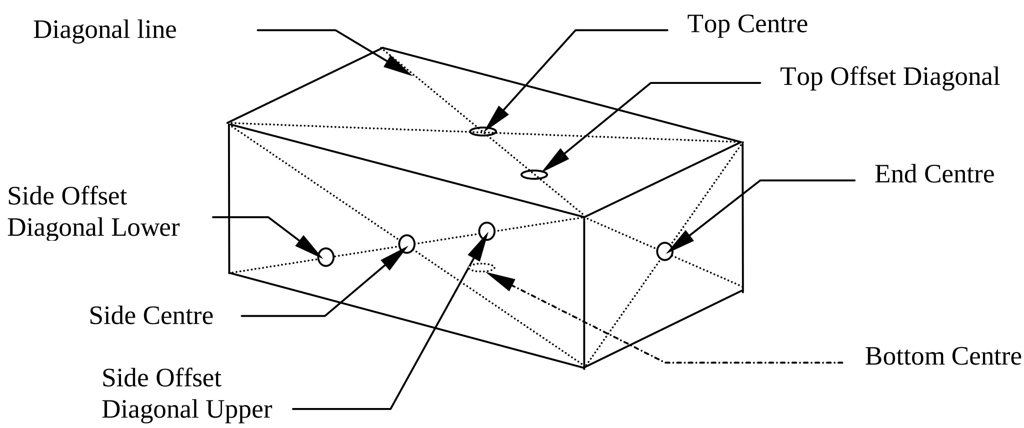


We believe that a denser material has a greater compressive strength, but we cannot conclude that 1% increase in P.D.D. alone can result in 100% increase in W.C.S. The extra water seems to be enhancing the strength of the material, a phenomenon that contradicts the cement literature. It is possible that additional water is permitting a better curing of the cement. However, when considering that the water/cement ratios for 4% and 7% moisture are about 0.8 and 1.4 respectively, these values are much higher than the recommended guidelines for concrete manufacture. Clearly the water content of the mix has a major effect on subsequent block properties.

3.2.2 Moisture content effects on penetration resistance

The results discussed in the previous subsection suggest that pushing the water content even higher than 7% would be advantageous to final strength. However blocks with a very high water content have so little green strength that they become unmanageable. The excessive quantity of water does not permit sufficient cohesion between particles and the blocks regularly break during ejection and subsequent handling. Consequently a compromise has to be made. CSSB texts mention the problem of handling but fail to give any guidelines for production except by using trial and error. To address this question of green strength another set of seven blocks made from *soil-A* were produced in the Brepak machine. *soil-A* was used without cement, compressed to 10MPa and with a range of moisture contents from 2% to 8.7%. Immediately upon demoulding, a soil penetrometer was used to measure the penetration resistance up to a maximum pressure of 0.45MPa. Penetration sites were chosen on the surfaces of the block to determine if there was significant variation in surface strength in different portions of the block. Figure 3.3 below illustrates the penetrometer sites used.

Figure 3.3 – Penetrometer sites on a finished block



Some of the blocks with very low moisture content were impossible to penetrate successfully, whilst blocks with higher moisture permitted easy penetration. The data for these blocks is presented in Appendix G and a summary of the data is shown below in Table 3.1.

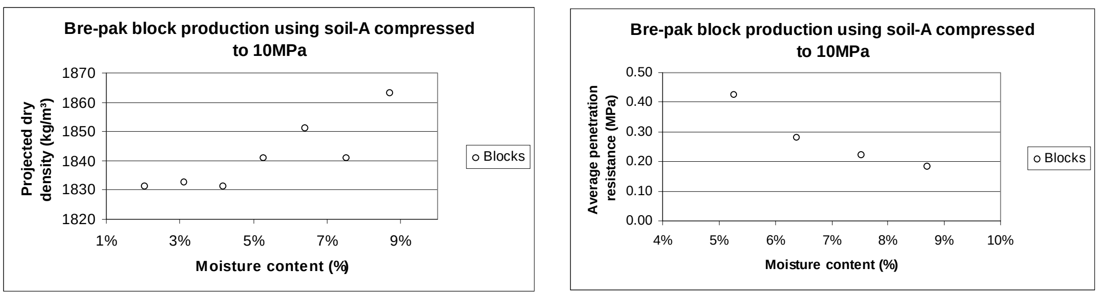
Table 3.1 – Penetrometer results from Brepak blocks

Moisture Content	%	2.0	3.1	4.2	5.3	6.4	7.5	8.7
Projected Dry Density	kg/m³	1831	1833	1831	1841	1851	1841	1863
Bulk Density	kg/m³	1857	1878	1896	1926	1958	1968	2013
Penetrometer Pressure (P_p) Average	MPa	N/A	N/A	N/A	0.43	0.28	0.22	0.18
(P_p) Standard Deviation	MPa	N/A	N/A	N/A	0.02	0.04	0.03	0.03
(P_p) Coefficient of variation	%	N/A	N/A	N/A	4.8	14.2	12.1	15.3

Note: N/A represents a reading that was off the scale of the penetrometer, (i.e. > 0.45MPa).

This data has been represented graphically in Figure 3.4 below concentrating on the effect of moisture on P.D.D. and penetration resistance. The relationship of increasing P.D.D. with moisture content that eluded us in the earlier experiment can be more clearly seen here, probably because the experiments covers a wider range of moisture contents. It is interesting to see that the penetrometer average plotted against the moisture content demonstrates that higher moisture levels yield lower penetration resistance and hence lower green strength. The fall in green strength, despite rise in P.D.D., suggests that the dominant mechanism controlling the green strength is the cohesion between particles and the amount of water that surrounds them rather than particle intimacy.

Figure 3.4 – P.D.D. and penetration resistance variation with moisture content.



Both of the sets of results investigated so far have demonstrated that there is some relationship between density and strength. As the density is an easily measurable quantity and can be calculated immediately after block manufacture it is an attractive measure both for research purposes and for quality control in block production. As the production thus far has concentrated on the production of blocks at a single compaction pressure and therefore constant energy transfer there is little variation in the achieved density. In order to suggest a strength density relationship it is necessary to explore a wider range of densities and corresponding strengths. Exploration of this is not very practical using either the Brepak machine or full-size blocks due to the problems with the machine and the high material cost of making lots of blocks. Consequently a smaller scale test needs to be applied for further analysis of this phenomenon.

3.3 Experiments employing small cylinders of soil-B

Further tests were conducted at a different scale and with a slightly different material, but greater consistency could be assured with the new material and the smaller scale permitted much faster sample production. This scale of production also offered greater control and reliability than with the Brepak block press. Small cylinder production commenced with the development of a set of cylindrical moulds with different wall thickness including 0.5, 2, 8, and 32mm. All of the moulds had an internal diameter of 54.4mm and produced samples around 45mm high with a dry soil mass of 200g (±0.5g). This was selected as a suitably small quantity that could be dumped into the mould without the need for tamping. Also, 200g was a round number for easier calculation of water mass to achieve desired M.C. Furthermore a sample of this size could also be easily manufactured by dynamic compaction using a similar rig and the same moulds, as the next chapter will explain more fully.

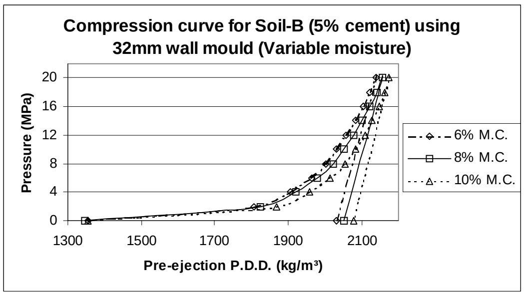
A new soil had to be developed at this stage to accommodate the future tests that were to take place on small scale as well as full-size blocks. This material consisted of builder's sand and kaolin clay and was supposed to be similar to the original soil-A. The sand material was oven dried to 105°C and sieved down to 5mm prior to mixing with the kaolin in the ratio of four parts sand to one part kaolin. As the majority of the tests conducted required stabilisation, cement (5% by weight of the total mix) was also added to the dry mix.

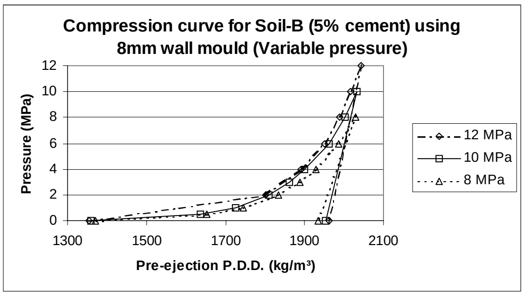
3.3.1 Pressure density relationship

Three separate investigations were carried out to determine the relationship between applied pressure and achieved density. The development of this relationship specific to soil-B was necessary in order to assess the effectiveness of dynamic compaction against a suitable standard. As dynamic tests were also going to be conducted at small scale this relationship would provide a good means of comparison between the two different compaction techniques. The first investigation involved the compression of three samples at three different moisture contents, 6, 8, 10%, and monitoring the density within the mould during the compression cycle up to 20MPa. The second investigation produced compression curves for three sets of three samples at 6% M.C. soil-B compressed to 8, 10 and 12MPa. The third investigation produced five sets of three samples at each of the following pressures 4, 6, 8, 10 and 12MPa and subsequently cured and crushed them to discover their compressive strengths. The data for all three investigations can be found in Appendix F.

The figure below shows a summary of the results of the first and second investigation measuring the P.D.D of the samples during the compression cycle. The left hand graph clearly shows that the further increase in moisture content to 10% increases the level of compaction achieved above 8% and 6% levels, which is consistent with the relationship suggested by the soil literature. It also indicates the elasticity of the material when the compression pressure is reduced to zero. Each curve represents the average of three sets of samples taken for each moisture content. On the right side is the graph showing the data from the second investigation displaying the compression curves for 8, 10, 12MPa and their respective elastic restitution for the single moisture content of 6%.

Figure 3.5 – Pressure density relationship for soil-B

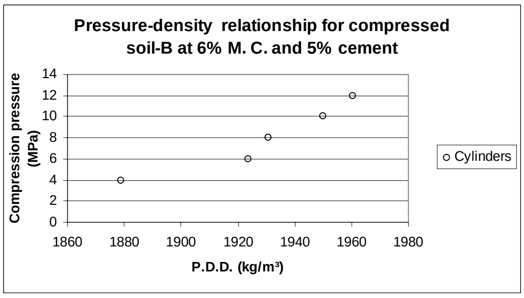


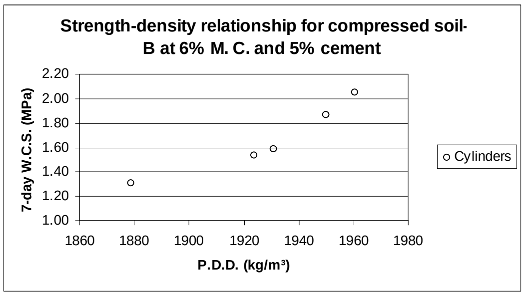


From these graphs we see that the P.D.D. that can be achieved by 10MPa pressure will be around 1950kg/m³ for the 6% M.C. condition. This will be taken as the target for the dynamic compaction tests to confirm the potential of dynamic compaction providing the necessary degree of consolidation. The moisture content of 6% was selected for these tests, as it seemed to be a good compromise between final strength and green strength that could be used on the full-size tests later.

Figure 3.6 below displays the data for the third set of samples produced under different compression pressures. Each point represents the average of three points of data and this most easily demonstrates the general trend of increasing pressure leading to increased P.D.D. and subsequent 7-day W.C.S. It was noticed that the variation within the batches was quite high and this led to questions regarding moisture loss or decreased workability over time in each batch.

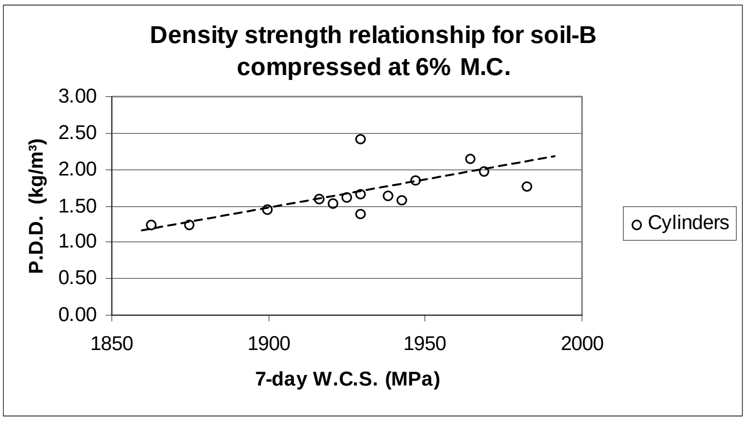
Figure 3.6 – Results of compression tests on soil-B at 6% M.C.





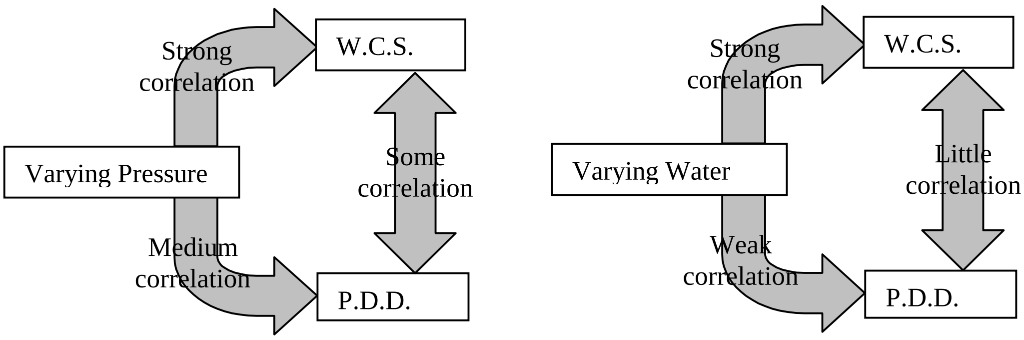
It has been hinted at already that there may be some connection between the achieved density and the 7-day wet compressive strength. The data collected from the third investigation can be presented to demonstrate this phenomenon. Unfortunately the variation in the strength is quite high for each P.D.D., which indicates that if a relationship is developed between strength and P.D.D. it might not be very accurate. Statistical analysis of the variation is required to provide a relationship with any degree of certainty. The figure below shows the general trend that increasing the density has a significant increase in the strength. It indicates that a 5% increase in density yields an increase in strength of approximately 50%. Such a relationship would suggest any small increase in density would be greatly advantageous.

Figure 3.7 – Strength density relationship for soil-B at 6% M.C.



The figure below diagrammatically represents some of the inter-relationships that can now be suggested from the experiments conducted.

Figure 3.8 – Inter-relationships of pressure and water content with outputs



3.3.2 Assessment of de-moulding forces

The third investigation above also provided the opportunity to investigate the forces required ejecting different density samples from a mould. Analysis of de-moulding forces has been omitted from all of the CSSB texts and is investigated here to help with machine design. The forces necessary to eject a full-size block from a mould are often of significant magnitude to warrant a separate ejection mechanism and these tests will indicate possible forces necessary. The small size of these cylinders will have a significant effect on the magnitude of the ejection force compared to a full-size block, but it is hoped that the relative size of the forces for different levels of compression will be representative. This study may also indicate whether or not any difference in the de-moulding force exists between quasi-statically compressed samples and dynamically compacted samples. Data from these squeezed cylinders will be used later with data from impacted cylinders.

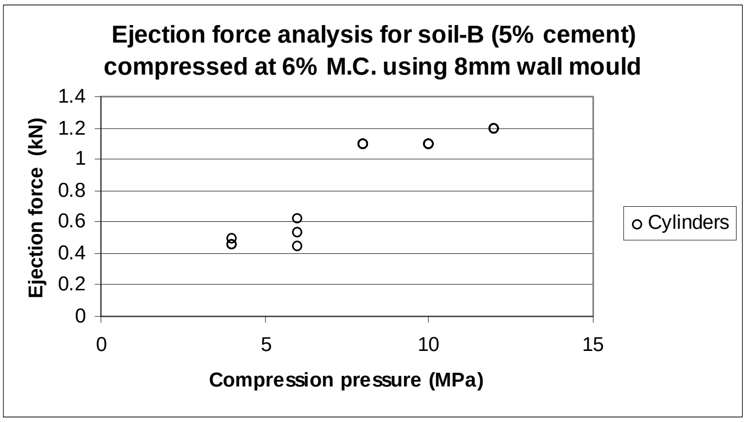
The table below is a summary of the data from the third investigation described in the previous subsection. Three samples were produced at each pressure and the averages of the vales are shown. Full results can be found in Appendix F.

Table 3.2 – Summary of data for compressed small cylinders at different pressures

Pressure	MPa	4	6	8	10	12
Energy Transfer	J	54	70	83	97	111
Ejection force	kN	0.5	0.5	1.1	1.1	1.2
Ejected height	mm	45.8	44.7	44.6	44.1	43.9
Bulk Density	kg/m³	1992	2039	2047	2067	2078
P.D.D.	kg/m³	1879	1924	1931	1950	1960
7-day W.C.S.	MPa	1.31	1.53	1.59	1.87	2.05

The graphical view of the variation in ejection force with compression pressure can be seen in the figure below. It demonstrates that ejection force is roughly proportional to moulding pressures. It should be noted that many of the data points are overlapping each other in the graph, hence less than 15 points are visible. If we assume that the ejection force is a function of both the compression pressure and the mould wall area in contact with the sample, then we may be able to suggest a formula to determine the ejection force required for full-size blocks.

Figure 3.9 – Ejection force analysis for different compression forces



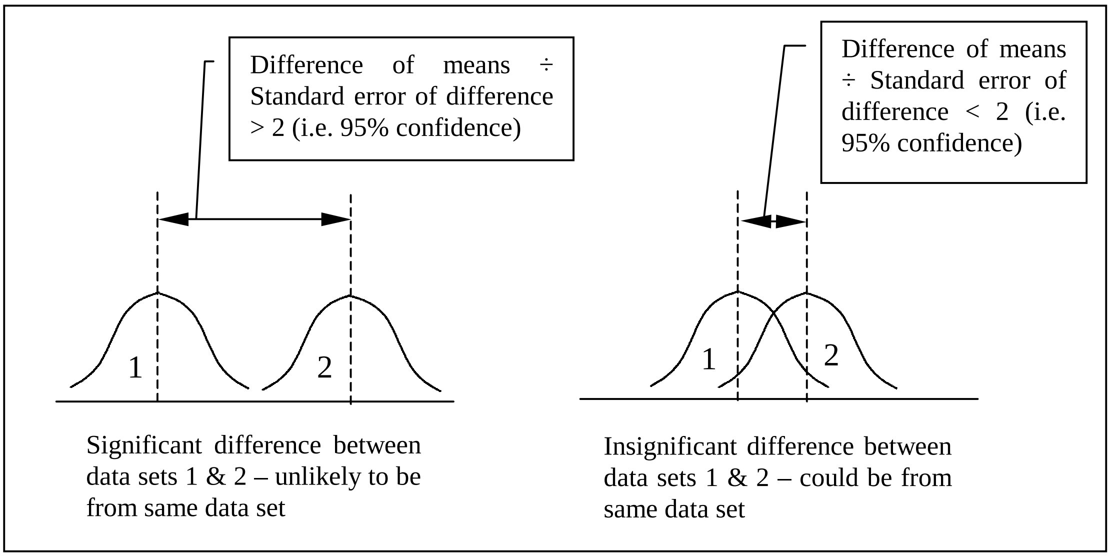
The mould wall area for a small cylinder is 0.0076m². This equates to an ejection shear stress (force per unit area of mould wall area) of approximately 145kPa. A standard block is 0.29 × 0.14 × 0.09m and hence has a mould wall area of 0.0774m². This yields a *projected* ejection force of 12.5kN for a full size block with 6% M.C. compressed to 10MPa. The actual (measured) ejection force for a block compacted to 9.7MPa using soil-B at 6% M.C. was between 15-20kN. These results are of the same order of magnitude and will be useful for machine design.

3.3.3 Strength variation in cylindrical samples

In order to accurately assess interrelationships between variables we need to know the inherent variability of the material in use. Earlier experiments indicated significant variation in the ejected densities of the cylinders produced using quasi-static compression. This density variation has an effect on the wet compressive strength of the material. We do not know what the variation in the strength within the material is for different samples all compressed to similar densities. To discover the actual variation in the material strength and to discover if there is a statistically significant difference between the first of the batch and the third in the batch a further set of small cylinders were produced.

A total of 18 samples were all produced by compressing soil-B with 6% M.C. to 10MPa. The batch size was three, and each of the first, second and third within each batch were averaged together investigating the Projected Dry Density, 7-day Wet Compressive Strength and Ejection Force. If a large difference exists between the first and the third in the batch, a statistical test can be applied to these results to determine whether or not the results could have come from the same data set. If the test shows that they do not come from the same data set then it can be assumed that there is a significant difference in the two sets of data. The diagram below illustrates the statistical theory of this test.

Figure 3.10 – Statistical test for difference between two data sets



The data presented in Appendix F has been analysed below in Table 3.3a, b and c using the standard error of difference test. The test used deems that a significant difference between sets of data exists if the difference between the two sample means is greater than 2 times the standard error of difference (giving a 95% level of confidence for a normal distribution).

Knowing that strength is highly sensitive to changes in density it is not surprising to find that the coefficient of variation of strength is an order of magnitude larger than the coefficient of variation for density. The data also highlights the large variation that is experienced in the ejection force required to eject compressed samples from the mould. This will partly explain the difference between the extrapolated ejection force from small cylinders and the measured ejection force for full-size blocks.

Table 3.3a – P.D.D. variation in cylindrical samples compressed to 10MPa

Order in batch	Units	First	Second	Third
Average of P.D.D. of samples (a)	kg/m³	1950	1938	1934
Estimate of population S.D. from samples	kg/m³	9	13	8
Coefficient of variation	%	0.4	0.7	0.4
Standard error of (a)	kg/m³	3.5	5.2	3.4

Difference of means (1st & 3rd)	kg/m³	15.3	
Standard error of difference (1st & 3rd)	kg/m³	4.9	Sample
DoM/ SED	kg/m³	3.1	size
Significance (Normal distribution)	%	99.8	n = 6 (×3)

Table 3.3b – 7-day W.C.S. variation in cylindrical samples compressed to 10MPa

Order in batch	Units	First	Second	Third
Average of 7-day W.C.S. of samples (a)	MPa	1.76	1.61	1.63
Estimate of population S.D. from samples	MPa	0.09	0.13	0.11
Coefficient of variation	%	5.3	7.8	7.0
Standard error of (a)	MPa	0.04	0.05	0.05

Difference of means (1st & 3rd)	MPa	0.14	
Standard error of difference (1st & 3rd)	MPa	0.06	Sample
DoM/ SED	MPa	2.27	size
Significance (Normal distribution)	%	97.7	n = 6 (×3)

Table 3.3c – Ejection Force variation in cylindrical samples compressed to 10MPa

Order in batch	Units	First	Second	Third
Average of Ejection force of samples (a)	kN	0.95	1.07	1.13
Estimate of population S.D. from samples	kN	0.18	0.14	0.09
Coefficient of variation	%	18.9	13.4	8.0
Standard error of (a)	kN	0.07	0.06	0.04

Difference of means (1st & 3rd)	kN	0.18	
Standard error of difference (1st & 3rd)	kN	0.08	Sample
DoM/ SED	kN	2.17	size
Significance (Normal distribution)	%	97.0	n = 6 (×3)

These results give us the needed information about the inherent variability of the material. Density variation is of the order of 1% throughout a batch, whilst strength variation is around 10%. This demonstrates adequate control of the production process and gives us confidence in making assertions with data sets that differ significantly more than experienced here. A more worrying trend in the above data is every characteristic of interest has a significant difference between the First and Third members of each batch. This clearly suggests that something out of our control is happening to the sample during the 5-10 minutes between the first and the third sample in the batch. Despite the small variation in these characteristics of interest, a larger variation would be more typical during a normal production regime. Whilst a variation of 1% on density during these strict laboratory tests is tolerable if this were to increase to say 5% in the field, a then a much more significant variation of around 50% of strength would result. For further laboratory tests a sample set of three should be sufficient for determining the characteristics of a sample with selected parameters.

3.4 Block characteristics that help to reduce construction costs

In the interests of reducing walling costs, a number of techniques have been assessed particularly with a view to incorporation into block manufacture using dynamic compaction. These subsections detail several methods of cost reduction available to the block manufacturer, some of which can also save costs in wall construction. Our desire is to find a method, or combination of methods, that significantly reduce the total cost of the building unit, which we hope to apply to the production of blocks made via dynamic compaction.

3.4.1 Material reduction

The raw material used in producing a block has a cost associated with it, both in terms of the actual material used and any associated transportation costs. Reducing the raw material will reduce the cost of the block, and placing indentations or perforations in a block can be an effective way of achieving this. In order to remove significant amounts of material from the centre regions of a block there must be sufficient block width to accommodate the voids left behind. Also the minimum material thickness needs to be carefully chosen so that the material does not become too weak to support the necessary loads. The drawback to including any perforations or voids in a block is that it increases the mould complexity and reduces the ease of block manufacture, particularly block ejection.

According the graph in Figure 2.12, a sample with 10% cement and compressed to 4MPa has a wet compressive strength of 3MPa. A standard block with dimensions $0.29 \times 0.14 \times 0.09$m and an approximate bulk density of 2060kg/m^3 would have a cement mass of around 0.7kg. If the compaction pressure was increased to 10MPa, then cement content could drop to 8% and still achieve the same 3MPa compressive strength. The block now has a bulk density of 2160kg/m^3 and would have cement mass of around 0.58kg present in it. A 150% increase in pressure results in only an 18% drop in cement content. This has already been shown to be a false economy in quasi-static compression because this extra moulding pressure seriously increases the machine cost and complexity.

If half of the material present in the block is removed then the cement mass would naturally drop to 0.28kg per block which is less than half the amount required for the block compressed to 4MPa. This material removal could be achieved by the inclusion of voids in the material, an already popular technique. The higher density of the material would yield sufficient strength for forming and handling and whilst the absolute load that the block could sustain would be less, the compressive strength would still be within the required limits. This option would not be possible with blocks of lower densities, as they would not be strong enough to have such large voids placed in them and still be strong enough for forming and handling.

3.4.2 Tall thin blocks

The ratio of a block’s height to width is its’ slenderness ratio (height/width), (Norton, 1997), (Keable, 1996). For most blocks this slenderness ratio is not more than 1 but with some more advanced materials at can be as high as 2. If the height of the block is large then this will reduce the number of blocks necessary to fill the same area of walling. In order to maximise the use of the material therefore we want to have a high slenderness ratio and a large surface area of the external face of the block. Requiring fewer blocks per square meter of walling also reduces the amount of mortar required between block courses. Increasing the slenderness ratio reduces the volume of material required per square meter of walling, whilst only increasing the block height makes reductions in the quantity of mortar that is required. Increased slenderness may be more difficult to achieve with CSSB than increasing the block height, so for the moment we will concentrate on this alone.

Throughout this project we wish to reduce the cement consumption of the walling as much as possible. It is possible to calculate the projected cement requirements of different walling strategies using blocks of different characteristics. One of the characteristics that can be adjusted in this study is the block height. This increases the amount of cement required in the material, mortar and render per block, but actually decreases the overall cement requirement per square metre. Although the decrease was quite small, if also applied to blocks with less cement in the material, laid with thinner mortar and without any render then significant combined savings can be made.

The application of tall thin blocks presents an issue of stability that needs to be considered. We can compare different walling materials and their structural modes of failure to consider the implications of tall thin blocks for walling. If house walls ‘fail’, it is usually by surface erosion, by overturning or by internal material changes like swelling. To prevent erosion we require adequate surface properties such as hardness or wet compressive strength that are unaffected by whether or not the building blocks are hollow. To prevent overturning we look first to architectural measures such as providing adequate foundations, connecting perpendicular walls or constraining the outward thrusts from the roof. However the block properties also affect a wall’s ability to resist horizontal forces applied to its top. Increasing both block mean density (ρ) and wall thickness (Block width b) are beneficial.

Although there are various overturning failure modes, almost all have a force threshold determined by ρb^2. For example the formation of a hinge at the wall bottom (assuming the mortar has no tensile strength) occurs when $F = \rho g b^2/2$ where F is the outward force per unit length of a wall. The table shown below compares different materials by this criteria. Note: employing hollow blocks instead of solid ones lowers F because it lowers the mean block density ρ.

Table 3.4 – Assessing the failure force for different blocks

Material	Wall Thickness (b)	Mean Density (ρ)	Failure Force (F)
	m	kg/m³	N/m
Single skin brick	0.105	1350	74
Double skin brick	0.220	1350	327
Solid cement block	0.150	2200	248
Hollow (50%) cement block	0.150	1100	124
Foamed cement block	0.140	480	47
Low-density solid CSSB	0.140	1700	167
High-density solid CSSB	0.140	2000	196
High-density hollow (30%) CSSB	0.140	1400	137

The above table illustrates why double skin brick and solid cement blocks are most favourable for taller structures as they have the highest failure force. For the purposes of low-rise dwellings this is not necessary and consequently a lower failure force can be accommodated. High-density solid CSSB is a good contender in terms of failure force, but if the walling material were made even thinner then it may not be quite so appropriate.

3.4.3 Cement rich skin

As an alternative to reducing the cement content of the block to low quantities, it may be possible to concentrate the cement in the area where it is needed most, i.e. the exterior surface. This cement rich layer would effectively be acting as a built in layer of render protecting the less stable material behind it from the elements. For example instead of having 5% cement throughout the block one could put 10% cement in the first 20mm and have the rest of the block stabilised with only 3% cement. Providing that the cement rich layer did not suffer from de-lamination from the rest of the block, this could reduce the cement demand for each block. Catastrophic de-lamination is reduced because the block contains cement and the courses of blocks are joined with a cement based mortar.

The production of such blocks with this cement rich layer greatly increases the complexity of the block production and construction process. A clear means of identification would be necessary to indicate which face of the block was cement rich, and furthermore the staff erecting the structure would need to be trained to lay the blocks in the correct manner. Homogenous blocks would also be necessary for the corners and any exposed edges, adding another type of building material to the construction. The calculations carried out on this type of construction shows that the saving in cement is only a modest 13%.

3.4.4 Summary of cost reduction methods

The table below summarises the different possible variants that can be accomplished with the CSSB and how each one performs with reference to the unmodified CSSB. By combining several of these variants into a single block the material can theoretically achieve a tolerable cement requirement, (less than 15kg/m^2), without excessive energy consumption. The tall, hollow, interlocking block as described below even uses less cement then the clamp fired bricks assessed in Table 2.1. As this is one of the more common and more wasteful methods of making satisfactory building materials, this confirms that this variant of CSSB is a real contender. The raw data for this comparison can be found in Appendix E.

Table 3.5 – Theoretical comparison of different CSSB variants

Material	**Dimensions** ($l \times b \times h$)	**Note**	**Energy**	**Cement**	**Suitability for production**	
					'Locally'	**On-site**
High-density CSSB	Mm		MJ/m^2	kg/m^2	Ranking	(1 = best)
Normal	290 × 140 × 90	1	290	18.7	2	1
Hollow	290 × 140 × 90	2	220	15.1	2	1
Cement-rich skin	290 × 140 × 90	3	270	16.3	1	2
Interlocking	297 × 140 × 97	4	270	15.4	2	1
Tall	290 × 140 × 90	5	280	17.6	2	1
Rendered	290 × 140 × 140	6	300	19.3	2	1
Tall, Hollow, Interlocking	297 × 140 × 147	7	190	11.0	2	1

Notes

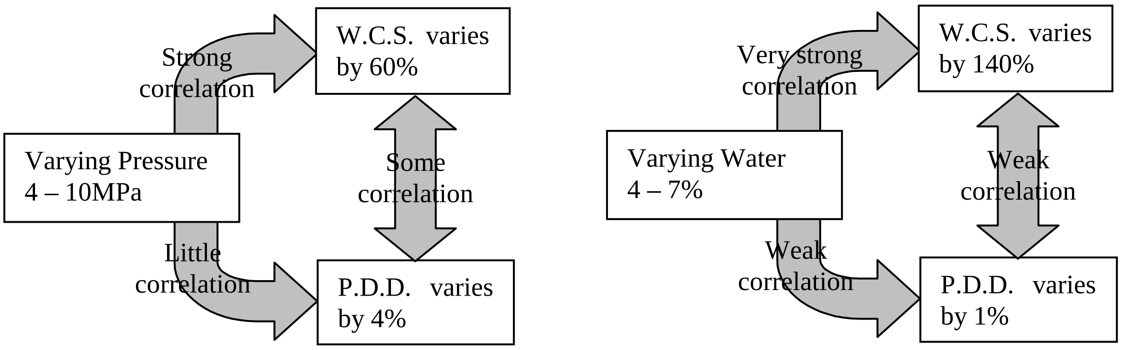
1. High-density (2000kg/m^3) solid blocks manufactured on-site from local soil/cement mix (5% cement), laid with 10 mm of soil/cement mortar (20% cement) and no render, (Cement transported 100km).
2. As 1. but with 30% material remove from the block core.
3. As 1. but with 10% cement in first 20mm of exterior block surface and 3% in the body of the block.
4. As 1. but constructed with thin mortar only 3mm thick.
5. As 1. but with increased block height to 140mm to reduce mortar per square metre.
6. As 1. but with 15mm render on a block with only 3% cement in the body of the block.
7. As 1. but with a combination of tall, hollow and interlocking arrangements.

Apart from the improvements that can be offered by increased material compaction, there are modifications that can be made to the shape and size of the CSSB to minimise material costs. The addition of perforations in the block could reduce the material cost by as much as 30%. Furthermore the improvement of dimensional tolerances of the block could promote the use of thinner mortar between block courses. The application of taller blocks would also reduce the number of courses that need mortaring. A combination of these block features has indicated significant saving in cement and shows the most promise for providing lower-cost walling.

3.5 Chapter summary

Throughout this chapter experiments on stabilised soil have been conducted to assist the understanding of CSSB characteristics and production. The variables that exist in the process have been identified and possible relationships that may exist between variables and output measures of interest have been suggested. Experimentation had indicated that the moisture content of the sample has a large effect on the achieved density but also on the achieved strength. The strength seems to be directly related to the density achieved for given moisture content. The general trend that an increase in density of 10% yields a 100% increase in strength has been suggested.

Figure 3.11 – Revised inter-relationships between pressure and water with outputs



Investigations on small cylinders have given an improved understanding of the pressure-density relationship, which will be very useful for comparative tests on dynamic compaction. The aim during future tests will be to achieve a projected dry density of at least 1950kg/m³ as this is representative of compression to 10MPa. These tests have also indicated the ejection forces required to de-mould a sample and that it is roughly related to the compaction pressure and mould wall area. It will be interesting to see if the process of dynamic compaction yields significantly different values for the ejection force at similar achieved sample densities.

A more concerning discovery has been the significant variation in the achieved density and strength of samples produced in the same batch a short time apart. The variation in density is only around 1% but this in turn results in a 10% variation in strength. It would be excellent if variation during regular block manufacture could be kept as low as this; however, this is highly unlikely because of the more strict production methods using during research. It does indicate that for the sample size selected, the variation achieved is on the lower limit of practical significance and therefore the sample size of three is acceptable for future tests. The reason for this variation has yet to be determined; it may be linked again to moisture, as it seems unlikely that the cement would be providing any resistance to the consolidation process after such a short period of time. For research purposes full-size block production typically has a batch size of 1 block per batch so this problem should not plague later tests, but it will need to be considered during future batch tests and for block production generally.

After conducing the experiments described in this chapter we feel more confident about working with the soil in question. We have gained a better understanding of its performance under compression and its characteristics at different achieved densities. Armed with this knowledge we can now proceed to investigate the application of *dynamic* compaction and assess its performance against quasi-static.

4 Dynamic compaction of stabilised soil

The experiments described in the previous chapter concentrated on tests using stabilised soil. These tests have enhanced our understanding of how soil (specifically soil-B) behaves during constrained consolidation. This chapter extends the investigation to include dynamic compaction of this soil, initially as small cylinders and then as full-size blocks. This will be a lengthy chapter, as the majority of the experimental results from the Ph.D. will be presented here. After briefly discussing the reasons for selected methods of experimental practice and outlining some new variables of specific interest to dynamic compaction, the relationships that exist within dynamic compaction will be presented and explored. This will then be followed by results taken from full-size tests and finally a comparison of the dynamic compaction process with the quasi-static compression process will be made.

4.1 Experimental design

4.1.1 Sample size selection

The experiment conducted earlier on small cylinders, quasi-statically compressing them to 10MPa (described in subsection 3.3.3), indicates that for a sample set of six (the first member of a batch of three taken from six separate batches) the coefficient of variation is around 0.5% of the density. This variation in turn results in a variation of 5% in strength, which is a tolerable variability for experimental purposes. It demonstrates quite a high degree of repeatability within the material and the process of production used. The variability test will need to be repeated for the new production method of dynamic compaction of both small cylinders and full-size blocks to confirm a similar variation. As discussed below, the variation was similar and a sample size of three was selected for small cylinder production. The sample size necessary for full-size block production will be examined experimentally as well.

The variability of the dynamic compaction process for small cylinders was investigated by making 18 cylinders of soil-B stabilised with 5% cement. Each cylinder received 16 blows from a 5kg impactor being dropped from 0.2m. The cylinders were produced with a batch size of three and the respective first, second and third members of each batch formed 3 samples each of six members. The ejection force was measured, the P.D.D. of each cylinder was calculated upon ejection and the 7-day wet compressive strength was measured for each cylinder. The results in the tables 4.1a, b and c below show the variation experienced with this method of production for three output measures.

Table 4.1a – P.D.D. variation in dynamically compacted cylindrical samples

Order in batch	Units	First	Second	Third
Average of P.D.D. of samples (a)	kg/m^3	2022	2010	1998
Estimate of population S.D. from samples	kg/m^3	9	5	5
Coefficient of variation	%	0.5	0.3	0.2
Standard error of (a)	kg/m^3	3.80	2.10	1.95

Difference of means (1st & 3rd)	kg/m^3	23.50	
Standard error of difference (1st & 3rd)	kg/m^3	4.28	Sample
DoM/ SED	kg/m^3	5.49	size
Significance (Normal distribution)	%	>99.9%	n = 6 (×3)

Conclusion: There is a statistically significant drop in density of 1.1% between the First and Third members of each batch.

Table 4.1b – 7-day W.C.S. variation in dynamically compacted cylindrical samples

Order in batch	Units	First	Second	Third
Average of 7-day W.C.S. of samples (a)	MPa	2.38	2.23	2.12
Estimate of population S.D. from samples	MPa	0.14	0.15	0.18
Coefficient of variation	%	6.1	6.5	8.3
Standard error of (a)	MPa	0.06	0.06	0.07

Difference of means (1st & 3rd)	MPa	0.25	
Standard error of difference (1st & 3rd)	MPa	0.09	Sample
DoM/ SED	MPa	2.72	size
Significance (Normal distribution)	%	99.3	n = 6 (×3)

Conclusion: There is a statistically significant drop in W.C.S. of 11% between the First and Third members of each batch.

Table 4.1c – Ejection force variation in dynamically compacted cylindrical samples

Order in batch	Units	First	Second	Third
Average of Ejection force of samples (a)	kN	1.33	1.35	1.36
Estimate of population S.D. from samples	kN	0.15	0.10	0.12
Coefficient of variation	%	11.6	7.4	9.0
Standard error of (a)	kN	0.06	0.04	0.05

Difference of means (1st & 3rd)	kN	0.03	
Standard error of difference (1st & 3rd)	kN	0.08	Sample
DoM/ SED	kN	0.34	size
Significance (Normal distribution)	%	26.6	n = 6 (×3)

Conclusion: There is no statistically significant difference in ejection force between the First and Third members of each batch.

From the results above it is now possible to suggest that the process of dynamic compaction does not add any further variation to the P.D.D. or the 7-day W.C.S. of small cylinders than did the quasi-static compression process. A variation of about 1% in density across the batch still exists and approximately 10% variation in 7-day

W.C.S. still applies. Greater comparison between the dynamic compaction method and the quasi-static method will be done later in this chapter.

For practical reasons we wished to make several (*n*) specimens from each batch. Increasing *n* will reduce the variance of the sample mean about the population mean, which is good. Unfortunately it will also introduce a bias. If we choose a sample size of *n*, we reduce the Coefficient of variation of our estimate of the population mean by a factor of $\sqrt{n}$, which is good. Unfortunately to get *n* samples from a single batch entails the passage of time, so that the last member of the batch has a longer time delay before compaction than the first member. This variation in production time will therefore introduce a new source of variation in P.D.D. We hoped that 3 would be a sufficient sample size n. From the table above we see that:

(a) with $n = 3$, the Coefficient of variation is $< 0.5 \div \sqrt{3} = 0.3\%$.

(b) with $n = 3$, due to increased production time, the average will be biased downwards by typically 0.5%, (varying with the speed of production)

Such a small variation is at the lower limit of practical significance and consequently we can continue to use a sample size of three, $n = 3$.

This analysis confirms that using a sample size of three would be acceptable experimental design for investigation of small cylindrical samples, but no assumptions can be made with full-size blocks as yet. In order to check the variability of producing full-size blocks, a set of five blocks was produced by dropping a 36.8kg impactor approximately 300mm onto the surface of soil-B (0% cement). Only eight blows were applied during the production of each block, resulting in a relatively low P.D.D. The results in the table below show the average of the measured block height and the calculated P.D.D. for five blocks. It clearly indicates that the variation of the process of dynamic compaction is still of the order of 0.5%. As these blocks were not made with cement it is not possible to determine the variation of the 7-day W.C.S., but this is assumed to have the same relationship with density as seen before.

Table 4.2 – Variation in P.D.D. for full-size blocks

Block Number	No. of blows	Block Height mm	Block P.D.D. kg/m³
1	8	113.4	1738
2	8	112.7	1748
3	8	113.6	1735
4	8	112.6	1750
5	8	112.2	1756
Standard Deviation			9
Coefficient of variation			0.5%
Coefficient of variation of mean of 3			0.3%

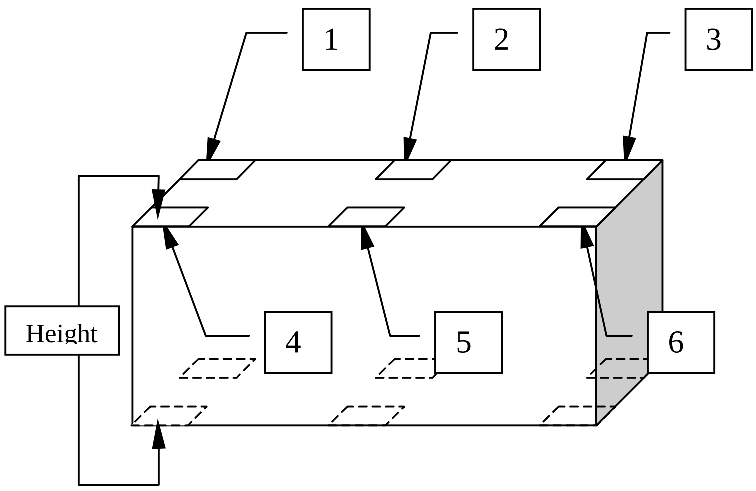
From these tests it is now possible to say with greater assurance that the inherent variation of the consolidation of soil-B results in a variation of less than 1% of P.D.D. and less than 10% of 7-day wet compressive strength. Consequently experimentation can now begin to look for characteristics within dynamic compaction that yield changes in results greater than normal variation. These changes will give indications to relationships between input variables and help to improve our understanding of the process.

4.1.2 Primary measure of performance is P.D.D.

In the majority of the tests presented in the following sections, the Projected Dry Density (P.D.D.) has been used as a primary measure of performance to monitor sample and block production. This measure has already been indicated as a suitable measure for compaction and possible strength prediction. The P.D.D. of the compacted material is used to monitor the relative levels of compaction between samples or blocks produced using different production variables. This immediate measure has been very useful in determining the dominant variables without having to wait for feedback data from the wet compressive strength test.

It should be noted at this time that the method of measuring the samples needs to take into account the possible variation in the shape of the sample. Dynamically compacted small cylinders typically exhibited a small slope on their top surface. The cylinder diameter remained constant throughout the tests but the height had to be averaged from the highest and lowest point on the cylinder circumference. The variation in height was usually only between ±0.3 - ±0.6mm, but this is significant in a such a small sample. Full-size blocks exhibited this same phenomenon and consequently the block height had to be measured at six points on the surface of the block.

Figure 4.1 – Six block height measuring points



4.2 Variables of dynamic compaction

The process of dynamic compaction presents not only new challenges in the method of application but also new variables that will need to be assessed for significance and subsequently optimised. The impactor mass, drop height and number of blows have all been investigated before but these parameters need to be extended to cover both small cylinder and full-size block production.

Impactor mass **–** Previous research conducted on dynamic compaction of soil indicated that a larger impactor mass was generally better than a smaller one. The limitations therefore imposed on the impactor design are ones of practicality, safety and cost. For the small cylinder production the following range of impactor masses were used: 2.5kg, 5kg and 10kg. However for full-size block production a range of larger impactor masses was used during the tests including 36.8kg, 46.8kg and 60.0kg.

Drop height **–** Apart from the practical limitations and safety issues of lifting a large heavy mass through a large height, there is evidence to suggest that a large drop height is undesirable for confined soil compaction (see subsection 2.4.2.) This was seen with samples produced by the application of one or two blows with high momentum. The effect of this high momentum transfer apparently resulted in a shock wave rebounding off the foundation and shattering the sample. It was suggested (Montgomery, 1997) that impactor velocities of over 2m/s should be avoided for this reason. Consequently the drop height was initially set to 200mm, but this was later increased up to 400mm (equivalent to 2.8m/s) without any adverse effects being noted.

Number of blows – After the imposed limitations of impactor mass and drop height, the number of necessary blows comes down to a trade-off between energy transfer and production time. Energy transfer is necessary to achieve the required consolidation, but the application of a large number of blows is time consuming. Previous research indicated that an optimum was between 8 and 32 blows. It was hoped that after initial trials at large numbers of blows a bit of balancing between drop height and the impactor mass this number could be reduced to less than 16.

From the variables listed above it is possible to state one further variable that is of interest to us, energy transfer. Calculation of the energy transfer using dynamic compaction is a trivial exercise involving the impactor mass, drop height and the number of blows. The total energy transferred into a sample takes the form of the following: $E_T = mg\sum_{i=1}^{n} h_i$ (1)

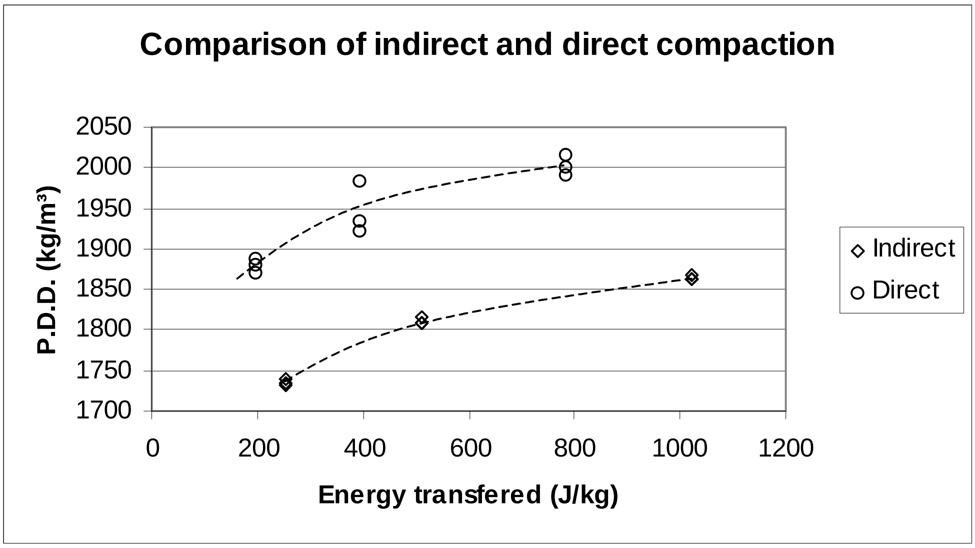
Where m is the impactor mass, g is the universal gravitational constant (9.81), h_i is the drop height for the i^{th} blow and n is the number of blows applied. If the point from which the mass is dropped is fixed relative to the foundations then the actual distance the impactor falls will be dependent on the blow number. Later blows will have a larger drop height than earlier blows, because of the significant consolidation that is achieved. This variation in the drop height will be considered and included in calculations where appropriate and experimentally possible.

The following subsections deal with some more interesting and significant aspects of dynamic compaction that would be of great interest to the machine designer. Aspects such as direct and indirect impact, mould wall thickness and soundness of the machine foundation have been explored and reported here. These are other variables to the production process that are kept constant once their significance has been determined and a suitable parameter selected.

4.2.1 Indirect and direct impact

It would simplify machine design if a billet could be placed between a falling impactor and the block it is compacting (‘indirect’ blows). However, early on in the Ph.D. it was noted that there is a noticable difference between samples compacted through direct and indirect blows. Experiments conducted on small cylinders indicated that the use of an intermediary billet of steel (mass of 2.5kg) between the sample surface and the falling impactor yielded significantly lower levels of compaction. Data from two sets of experiments is presented below in Figure 4.2. It clearly shows that indirect compaction produces much less compaction for the same energy transfer. All the samples were compacted using a 2.5kg impactor falling through either 0.2m (direct) or 0.26m (indirect) onto 200g samples with 6% moisture. Either 8, 16 or 32 blows were applied and the total energy transfer was calculated and converted to energy per unit mass. The graph indicates that the two methods of compaction differ by almost 10% on density, constituting a practically significant difference between the two methods. These results suggest that up to 50% of the strength could be lost if indirect compaction was chosen.

Figure 4.2 – Analysis of direct and indirect compaction



The numerical results for the above experiments can be found in Appendix F. From these results it was concluded that the additional complexities of direct impact compaction were justifiable given the significant improvement in achieved consolidation. Consequently all future experiments were conducted using the direct impact method.

4.2.2 Foundational effects

The process of dynamic compaction relies on the availability of a firm surface onto which compaction can occur. The firmness of the foundation affects the effectiveness of the dynamic blow applied simply by virtue of energy dissipation. A firmer foundation will not yield as much under a dynamic blow and will therefore permit greater compaction energy to be transferred into the sample. A single experiment was conducted to determine the penalty of soft foundations on the block density. Softer foundations were produced by having the full-size block mould placed on top of a 20mm steel plate separated from the 100 tonne strong floor by washers in each corner.

The firmer foundation was achieved by applying a layer of dental paste between the mould and the strong floor to ensure maximum surface area for contact and therefore greatest strength.

It was no surprise that the block compacted on the soft foundation performed worse than the block compacted on the firm foundation. The significance of the stiffness of the foundation was high, but not as high as expected. Two samples compacted with a 46.8kg impactor falling through approximately 200mm for 24 blows yielded densities of 1739 and 1811kg/m^3 for the soft and firm foundation respectively. This represents a variation of about 4% suggesting that the different foundations have a significant effect on the level of consolidation. It was assumed that larger drop heights would further reduce the potential density and consequently the firm foundation was selected as the best option for experimental research.

4.2.3 Delay between impacts

Another variable that dynamic compaction offers is the duration between consecutive blows applied to the sample. As yet it is not fully known what exactly is happening during material consolidation and even less is known about impact compaction mechanisms. This gap in our understanding led us to conduct a test to determine whether or not a time delay between consecutive blows has a significant effect on the level of consolidation achieved. The experiment would also help to explain some of the dominant mechanisms acting during impact compaction.

The variability within such an experiment was deemed to be higher than normal and consequently to have a greater confidence in the achieved data five blocks were made for each arrangement as opposed to one or three. The first arrangement involved dropping a 36.8kg impactor through 300mm directly onto the surface of the material at the rate of one blow per minute to give a total of eight blows. The second arrangement applied the same type of blow only with the blow rate set to one blow every two seconds. It was hoped that the thirty-fold reduction in compaction time would indicate if any difference existed between the two samples above and beyond the inherent variation of the samples themselves. In order to ensure than any cementitous action did not interfere with the experiment soil-B was used without any cement.

Although the densities of the blocks are quite low it is interesting to see that this time delay has an effect on the level of compaction achieved. Blocks produced fast yielded densities between 1735 and 1756kg/m^3, whilst blocks with the 1 minute delay produced blocks with densities between 1764 and 1769kg/m^3. Not only are the densities higher but they are also in a smaller range, indicating a higher degree of repeatability.

In order to prove the significance of these results a series of statistical tests were performed on the data. A summary of these tests and their results are shown in the table below.

Table 4.3 – Statistical variation in full-size block production

Blow Type	Number of samples	Average of dry density	S.D. of dry Density	Coeff of Variation of density	Standard Error
2sec/blow	5	1745	9	0.52%	4.05
1min/blow	5	1766	2	0.12%	0.92

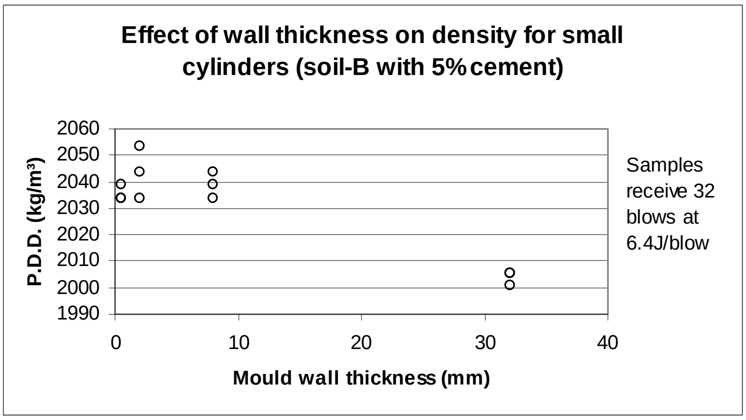
Applying the Standard error difference test to this data yields a Difference of Means ÷ Standard error difference = 5.00 which equates to a statistical significance of near unity. Whether or not the process of delaying the time between blows has a practically significant effect on the density achieved is a different matter. The improvement yielded from delaying compaction only equates to an increase of 1.2% in the density achieved. A variation of ±0.5% can be considered to be unimportant which suggests that this finding would only just be considered important and therefore incorporated into production. However, the requirement of a delay between impacts would increase production time to unacceptable levels and consequently fast compaction has been used throughout the experiments. This data suggests a further mechanism is at work during dynamic compaction and indicates what might be happening during the impact blow. This area will be discussed in more depth in chapter 5.

4.2.4 Mould wall thickness

The thickness of the walls of the mould needed for dynamic compaction is of greater concern to the machine designer than to the block producer. Clearly the use of thinner moulds is financially attractive, as they require less material for production and easier methods for mould fabrication. In order to determine if there exists any difference between different mould wall thickness a set of different moulds was created for some tests.

A set of twelve samples was produced by indirect dynamic compaction. The intermediary billet was the same mass as the impactor to try and maximise the momentum transfer. This was done mainly for practical reasons, as it would have been very difficult to ensure an accurate enough free fall for an impactor to go into a mould with 0.5mm wall thickness. The sacrifice made in achievable density is a tolerable quantity for this type of test. The samples were produced with a 2.5kg impactor falling though 0.26m delivering approximately 6.4J per blow. A total of 32 blows were applied to each sample and the projected dry density achieved during compaction was in the region of 2000-2055kg/m³. The graph in the figure below shows the density achieved by the samples relative to the thickness of the mould wall. It is encouraging to see that the very thick walls of 32mm do not provide the highest levels of compaction. It is also good that the other three moulds used are clustered together at the higher density indicating a low sensitivity over the range of smaller mould walls.

Figure 4.3 – Mould wall thickness experiment results



During the experiment the strain on the walls of the 0.5mm and 2mm wall thickness mould was measured. It was hoped that the level of compaction achieved using the

0.5mm wall mould would cause yield in the steel and therefore test the mould to failure. Interestingly the maximum strain experienced by either mould was only 40 micro-strain, a small fraction of the typical 1200 micro-strain that it takes for steel to reach its yield point. This is very encouraging, as it means that the forces sustained on the mould during dynamic compaction are only a small faction of the forces applied during quasi-static compression. The ramifications of this finding will be discussed in greater depth later in the thesis.

4.3 Small cylinder production via dynamic compaction

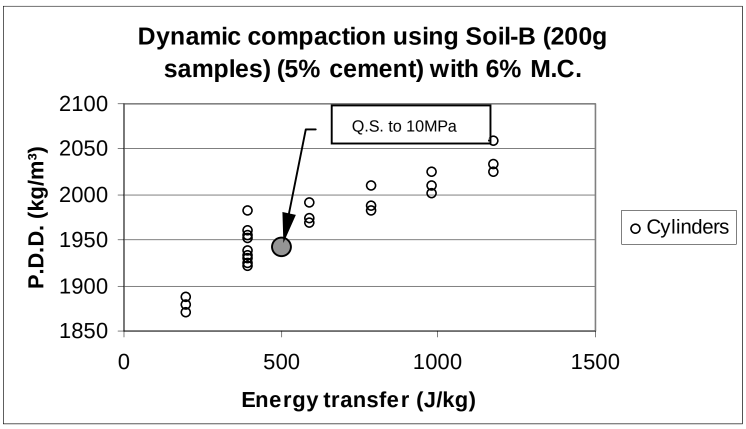
Further production of small cylinders is necessary to clarify the effect of new variables on the output measures. These tests have already been done via quasi-static compression, so for completeness they should be repeated at the same scale and with the same parameters using dynamic compaction. We are also aiming to achieve particular material characteristics (i.e. adequate material consolidation and compressive strength) and further tests applying different energy and momentum should indicate the relative performance of dynamic compaction more persuasively. The general aim is to achieve the same equivalent density as 10MPa would achieve (around 1950kg/m^3) and also to maximise the 7-day wet compressive strength (ideally over 2MPa). The results that these tests give us will also dictate some of the tests carried out on the full size blocks in the next section.

4.3.1 Energy and momentum transfer

In order to get the desired density several different combinations of energy and momentum transfer were explored. A variety of impactor masses, drop heights and numbers of blows were used to manufacture samples in batches of three. All of these samples had a constant material (soil-B) and moisture content (6%).

The graph below shows the results of a series of different tests using a 2.5 or 5kg impactor falling through 0.2m a number of times. The number of blows applied included 8, 12, 16, 20 and 24 and the P.D.D. was calculated from the ejected sample height. It can be seen from this data that the energy transferred into the sample has a direct effect on the P.D.D. However, it is also apparent that a larger amount of energy per kg is being applied at this scale compared to quasi-statically compressed full-size blocks. (Gooding estimated that 280J/kg was equal to the energy consumed during quasi-static compression of a soil block to 10MPa.) This data shows that 400J/kg is necessary to *dynamically* compact the material to 1950kg/m³ at this scale. However this is less than the 500J/kg required for *quasi-static* compression at the same scale.

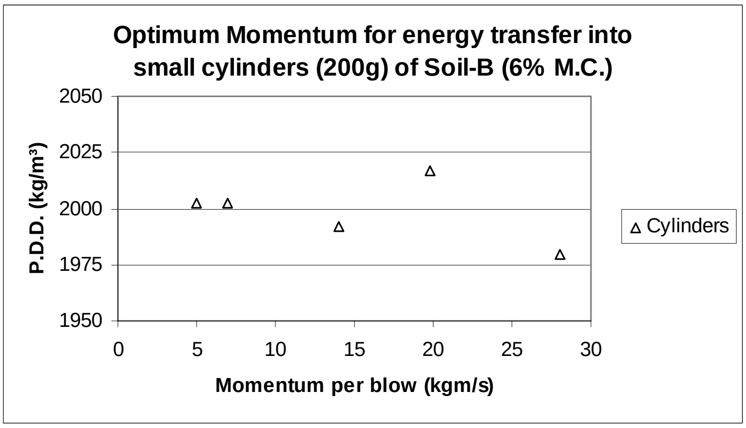
Figure 4.4 – Energy density relationship for small cylinders of soil-B



The data around the 400J/kg area indicates that for the same energy transfer a significant range of densities can result. This is because the relationship between energy transfer and density is not directly proportional. The same amount of energy can be applied to a sample in different ways, many of which will be far from the optimum configuration. The optimum momentum transfer was investigated by Gooding and determined that a low-velocity high-momentum blow is more effective. We can clarify this assertion at this scale by investigating a range of different momentum arrangements.

Another set of samples was produced using the combination of 2.5, 5 and 10kg impactors, 100, 200 and 400mm drop heights and 4, 8, 16 and 32 blows. Five combinations of these variables yield different momentum transfers for each blow applied, yet the same total energy. These results can be seen in the figure below. The data is presented more clearly by observing the averages of the P.D.D. from each sample set. The graph does not indicate a definite optimum as expected, but it does indicate that the graph is relatively flat (variation ±1%) over the region of interest.

Figure 4.5 – Optimisation of momentum transfer for small cylinders

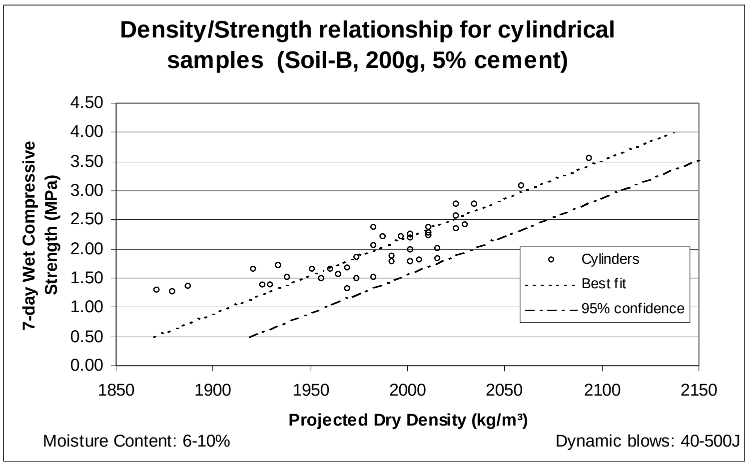


We want to be able to use this information to suggest a suitable momentum transfer for full-size blocks. But these results do not present any clear guidance and extrapolation of the data without subsequent confirmation is unacceptable. Therefore the impactor mass, drop height and number of blows used for full-size blocks will have to be determined by other factors such as practicality, cost and speed.

4.3.2 Strength vs. density

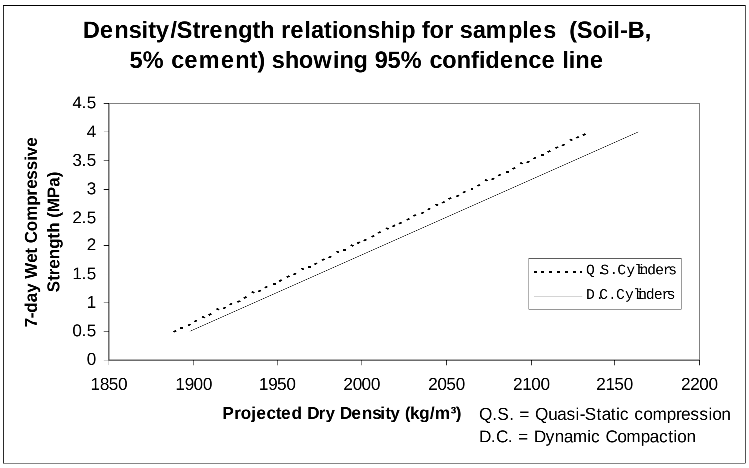
Previous experiments indicated that there is an empirical relationship between the achieved density of the sample and the strength that the sample achieves. For the limited condition of using soil-B mixed with 5% cement it is possible to define a relationship between strength and density. The graph below is a summary of cylindrical samples produced by dynamic compaction for different moisture contents and energy transfers. It indicates a linear relationship over the range of interest. We can propose the following relationship between density and strength with a 95% confidence: $\sigma_{7-day-wet} = \frac{\rho_{P.D.D.} - 1880}{77 \times 10^{-6}}$. Therefore we can say with 95% confidence that a sample with a projected dry density of 2000kg/m³ will have 7-day wet compressive strength of more than 1.6MPa. (The accuracy of this relationship is probably only limited to the range of data used to create it.) For the purposes of this investigation it shows the region of greatest interest, samples that exhibit wet compressive strengths between 1.5 and 3MPa, considered “Good” to “Excellent” by the CSSB literature.

Figure 4.6 – Density strength relationship for dynamically compacted cylinders



If the data from these small cylinders is added to the data received from the quasi-statically compressed samples then we have a bigger data set for analysis. Rather than present all the raw data together, we will only display the calculated 95% confidence lines from the cylindrical samples produced by dynamic compaction and quasi-static compression. These two lines are plotted on the graph in the figure below and it is clear that they are very similar. This gives more weight to the proposal that the strength can be calculated from the known density, a very attractive finding.

Figure 4.7 – 95% Confidence lines for density/strength relationship for cylinders



This data gives us a benchmark for the production of full-size blocks. We would aim to produce blocks with similar densities and see if their 7-day strengths lie in the same region. If they do, then assessment of the material characteristics of small cylinders can be assumed to be transferable to full-size blocks with a degree of confidence. The next section commences the extension of experimental investigation to include the production of full-size dynamically compacted stabilised soil blocks.

4.4 Full-size block production via dynamic compaction

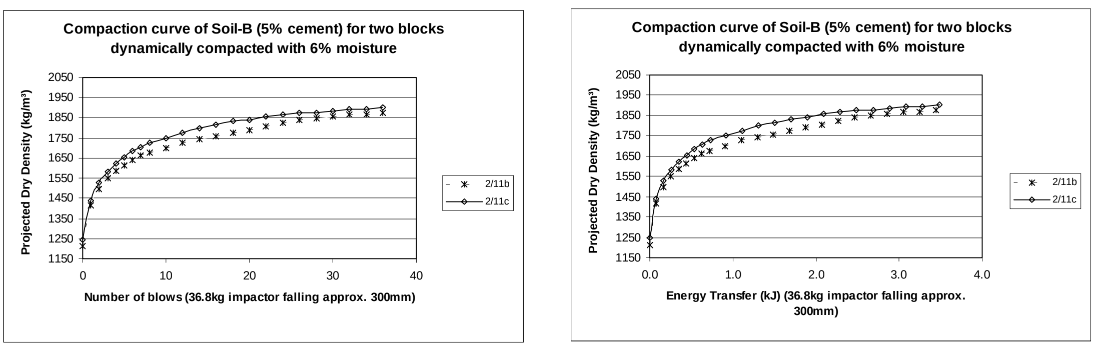
A total of 22 full-size blocks were produced using soil-B by dynamic compaction, four of them were compacted without cement. Different moisture contents were investigated, the compaction curve for the dynamic process was also recorded, and the finished blocks were cut into 100mm cubes for compression testing after 7-day curing. There are two main motivations for the development of a dynamic compaction rig capable of producing full-size blocks. The first is to continue research into the production of full-size blocks, as confirmed possible by (Montgomery, 1997), and the second is to advance the development of a suitable machine for block making. Chapter 6 will discuss the Test Rig design in more depth, but the results of the block production generated from the Test Rig will be presented in this section.

4.4.1 Compaction curve for dynamic compaction

In order to maximise the data collected from the production of each block, the block height was measured remotely after every, or every other, blow. These results enable us to plot a compaction curve for each block, monitoring the P.D.D. as well as the energy necessary to achieve it. The advantage of this system is that it offers a large number of data points for analysis that permits density estimations from known energy transfers. This information will be useful in comparing the results both between full-size and cylindrical samples and between dynamically compacted and quasi-statically compressed samples.

The remote measurement method uses a ruler guide on the impactor, so that after each blow the relative position of the impactor can be measured to ±0.5mm. Once the block is compacted, ejected and measured then this relative measurement can be used to calculate the in-situ block height during the compaction sequence. Such a compaction curve can be see in the figure below. Two blocks labelled “2/11b” and “2/11c” have received 36 blows from a 36.8kg impactor falling through approximately 300mm. The graph clearly shows the similarity between two blocks compacted by the same method. They do not follow exactly the same compaction curve, but that is expected, as there is a small degree of variation in the process. The graph on the left shows the density against the number of blows applied, whilst the graph on the right shows the density against the energy transferred.

Figure 4.8 – Compaction curves for blocks at 6% moisture

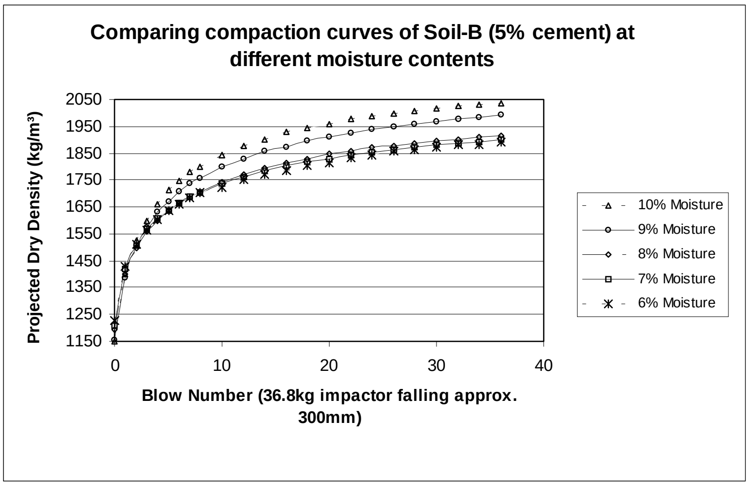


A disappointing outcome of these results is that the final P.D.D. of the blocks did not quite get to 1950kg/m^3 as was hoped. Furthermore, the quantity of energy transferred into the block (3.5kJ) was much higher than the equivalent energy to compress a similar block to 10MPa, (280J/kg × 8kg = 2.2kJ). This seems to contradict Gooding's findings of dynamic being more effective than quasi-static compression. Before we jump to any conclusions it would be good to investigate other moisture contents and other impactor arrangements to see if a comparable block can be made by this method using similar amounts of energy.

4.4.2 Different moisture contents

Experiments at small scale indicated that the moisture content has a significant effect on the P.D.D. for the same energy transfer, therefore the investigation of other moisture contents may yield more effective compaction. A total of thirteen blocks were produced each receiving 36 blows from a 36.8kg impactor falling approximately 300mm. Five different moisture contents, 6, 7, 8, 9 and 10% were explored and two or three blocks were made at each moisture content. These tests also provide significantly more data to help determine the inherent variation of the process. The graph below presents the average compaction curve for each moisture used. It is clear that the moisture content has a significant effect on the effectiveness of the compaction, as an increase in moisture content from 6 to 10% increases the density by about 8%.

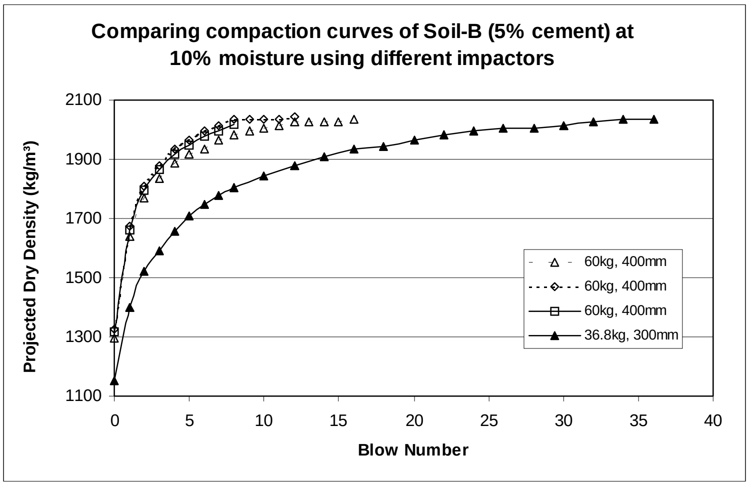
Figure 4.9 – Compaction curves of blocks at different moisture contents

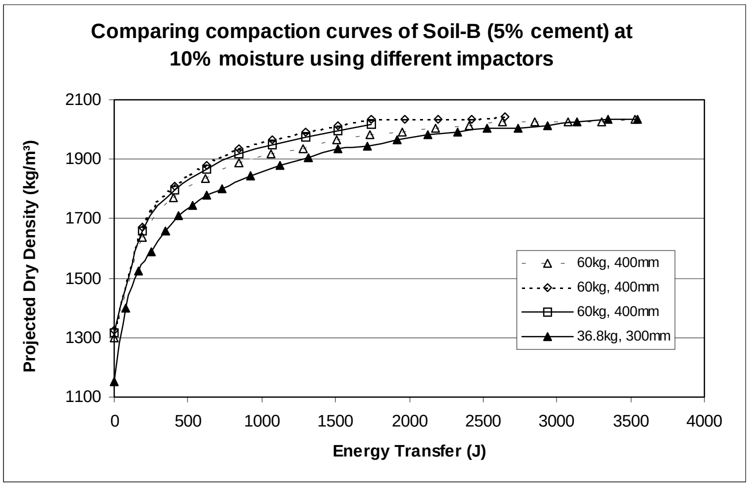


The differences between the curves on the graph are quite distinct confirming our expectations that increasing the water content would yield higher levels of consolidation. However, our motivation for selecting 6% was to achieve good handling characteristics of the finished block. Pushing the moisture content up to 10% reduces this handling strength, but fortunately this was offset due to the increased achieved density and did not present a problem.

It can be seen that the 10% moisture content line crosses the 1950kg/m³ line after about 18 blows. This lower number of blows is much more attractive as it takes less time to apply. What now needs to be determined is whether or not a block can be produced using perhaps a heavier impactor lifted through a slightly larger distance to achieve 1950kg/m³ with a more tolerable 16 blows or less. The graph in the figure below shows the compaction curve for a set of blocks compacted with a 60kg impactor falling from 400mm. Only a single block for each is used to display the compaction curve against the blow number or the total energy transferred. The top graph shows the different rates of compaction as each blow is applied, illustrating the significant difference between different impactors and drop heights. Whilst the lower graph shows the total energy transfer by either impactor arrangement and shows that the higher mass and greater lift height only slightly improves the compaction effectiveness (i.e. consolidation per unit energy transferred).

Figure 4.10 – Compaction curves for different impactors





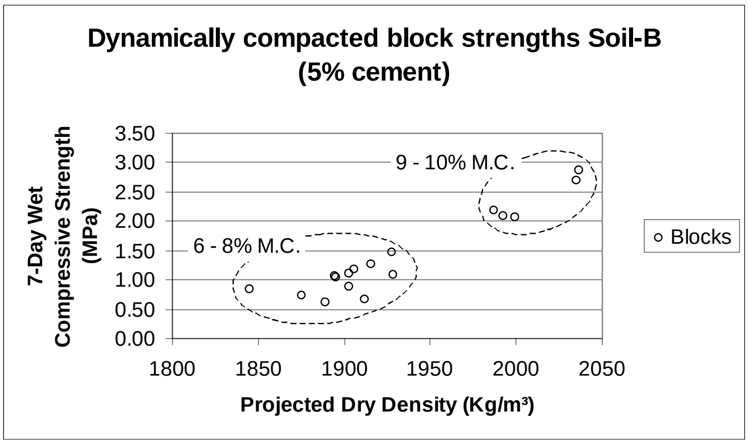
It is pleasing to see that the level of density achieved by these methods is well above the desired 1950kg/m³. It is even more encouraging that a small improvement in effectiveness is achieved if a larger impactor is dropped from a greater height. Our original concern about raising the impactor height was not found to be justified, as the ejected blocks showed no signs of shattering or de-lamination from the increased velocity impacts.

4.4.3 Block characteristics

Being able to achieve a block density of over 1950kg/m³ is only part of the necessary requirements for adequate block production. We already believe that such a density will give a material compressive strength that is enviable among CSSB, but we need to establish the actual strength of these blocks. Other characteristics of the material and the production effects will also be explored in this subsection.

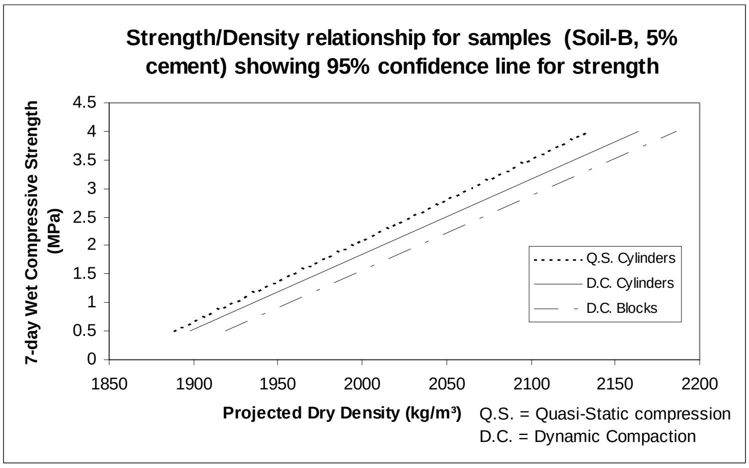
The graph in the figure below summarises two important and related output measures, namely density and strength. Most of the full-size blocks that were made with cement were cured for 6 days and then cut into 100mm cubes before spending 24 hours in water prior to getting crushed. The results of these tests can be seen below. In many cases a block was cut to form two 100mm cubes thus doubling the compressive strength data for that particular block. The graph clearly shows a significant difference between the two ranges of moisture content used. Just as blocks made with 9-10% water had much higher densities, their strengths are also much higher than blocks made with less water. This again demonstrates the need for careful control of the water present in the soil mix to maximise the achieved density and subsequent strength.

Figure 4.11 – Strength results for dynamically compacted blocks



It is not clear from this graph whether or not the relationship between density and strength is similar for these blocks as the small cylinders. But we now have the data to plot the lines of 95% confidence for small cylinders compacted quasi-statically and dynamically as well as full-size dynamically compacted blocks, (see below).

Figure 4.12 – 95% Confidence lines for density/strength relationship for soil-B



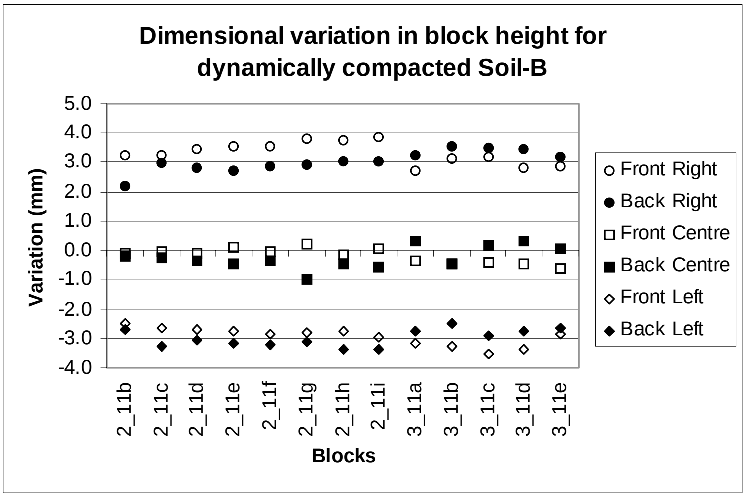
The figure above shows the three density/strength lines and it is encouraging to see that their gradients are very similar. It is disappointing that to achieve the same compressive strength dynamically compacted blocks need to be about 30kg/m³ denser than the quasi-statically compressed cylinders. This is an increase of slightly more than 1%, which cannot be considered normal variation in the material or processes but could be considered as an effect of changing scale. Indeed larger samples typically have lower strengths than smaller ones.

Another measure that has been considered with these results is the dimensional variation of the compacted blocks. The small cylinders exhibited a small variation in their length due to the impactor falling at a slight angle. The same was true for the full-size blocks. We need to be able to confirm that any dimensional variation (other than consistent and in-built variation from the dynamic compaction process, which could be eradicated later in the design) is less than ±2mm to comply with block standards found in (Centre for the Development of Industry, 1998).

We already have a set of blocks that have had their height measured accurately at six points that we can use to determine the height variation of the compacted blocks. The figure below shows a graph that has height data taken from 13 blocks made in the same production cycle over two consecutive days. The method of height measurement was the same for each block and the relative location of the front, back, left, right etc. was the same for each block.

The data is plotted not as absolute values of block height but as a variance from the average height for each block. The pattern displayed within the data clearly indicates that the impactor was not falling parallel with the base of the machine. The left-hand side of the impactor was falling lower than the right-hand side.

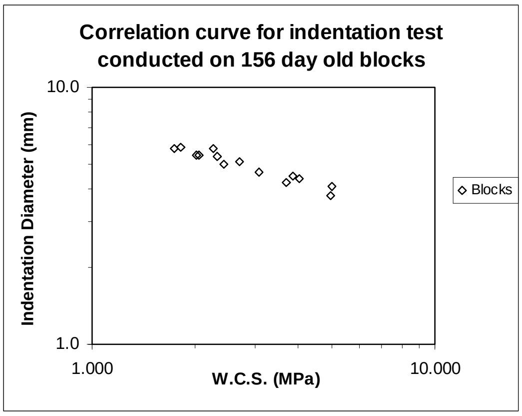
Figure 4.13 – Height variation of dynamically compacted blocks



The above data also confirms that the actual variation across the surface of the block is less than ±2mm once the variation from the incorrectly aligned impactor has been removed. This is an acceptable variation and complies with the block standards. Unfortunately such a large variation would not be tolerable in interlocking blocks unless a different method of block orientation was used.

Measuring the green strength of the finished blocks was not possible using the standard soil penetrometer. The device is not designed to work on such a compact material and the majority of blocks made by dynamic compaction were too dense to get a reading. Consequently another test was developed to monitor the green strength of the block specifically for stabilised soil material. It involves dropping a 1kg mass onto an indentation pin and measuring the resulting diameter of the indentation. It was hoped that this measure would be a non-destructive test that could indicate future block strength as well as level of achieved densification. The results shown here are taken from air dried samples cut from the above 13 blocks after 156 days. The data indicates a definite connection between the diameter of the indentation and the wet compressive strength of the block. The relationship is most easily seen when the values are plotted on log-log axis as shown below. This is a very exciting finding and one that would be well worth exploring further during field trials.

Figure 4.14 – Indentation results from tests on cured blocks



4.4.4 Block variants

The CSSB variants summarised in subsection 3.4.4. indicated that hollow blocks, cement-rich skin blocks and interlocking blocks provided the most significant savings in cement. We could not investigate interlocking blocks, as this would have necessitated mould redesign and further rig development. However, we were able to produce some hollow blocks and some cement-rich skin blocks for testing and analysis.

We produced hollow blocks by reducing the total dry material in the block from 8kg to 6.5kg and adding a pair of wooden frogs (0.0011m^3 volume) to the mould. The soil was mixed with 5% cement and 10% water and carefully placed into the mould in three separate charges to ensure better material placement around the frogs. This was further enhanced by manual prodding of the soil mixture around the frogs prior to compaction. Blocks were made using a 60kg impactor dropped twice from 0.2m and a further 6 times from 0.4m, delivering approximately 1.65kJ.

The finished blocks were ejected with great care, but they still suffered from minor crack defects. The blocks were measured and put to cure for 6 days before having their 7-day W.C.S. measured. The results of the four blocks in question are listed in the table below.

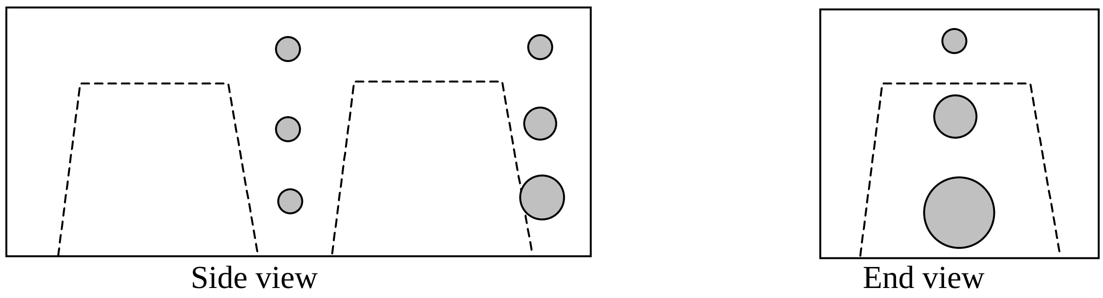
Table 4.4 – Characteristics of hollow blocks

Block Label		4/4a	4/4b	4/4c	4/4d
Average block height	mm	103.0	103.4	103.3	103.0
Standard deviation of heights	mm	0.3	0.4	0.4	0.4
Coefficient of variation of heights	%	0.29	0.38	0.36	0.36
Average P.D.D. of block (including voids)	kg/m³	1554	1548	1551	1555
Average P.D.D. of material	kg/m³	2108	2098	2102	2111
7-day block compressive strength	kN	12.69	12.17	14.18	13.41
7-day W.C.S. of block	MPa	0.31	0.30	0.35	0.33
Minimum 7-day W.C.S. of material	MPa	0.59	0.57	0.66	0.63

In order to draw meaningful conclusions from these results we will need to assess hollow blocks slightly differently than homogenous blocks. The average P.D.D. of the material takes into account the density variation that exists between the top surface and the bottom of the flanges around the central voids. The minimum 7-day W.C.S. of material indicates the compressive strength calculated using the reduced surface area for loading, making it comparable to the W.C.S. of homogenous blocks.

The hollow blocks had a very high average P.D.D. yet exhibited a very low W.C.S. We can suggest that this was because of the very high slenderness ratio of the flange (2.5-3) and the low density of the material at the bottom of the flanges where high strength is needed most. An indentation test on the flanges confirmed that the density at the bottom of the flange was smaller than at the top surface. The diagram below illustrates the results of the indentation test on the different regions of the hollow block. They clearly indicate a rapid change in density and strength in the thinnest part of the flanges.

Figure 4.15 – Sketch of indentation results on flanges of hollow blocks



The indentation tests illustrate the problem with poor material placement and non-uniform consolidation. Whilst we can demonstrate that it is possible to produce hollow blocks using dynamic compaction, these results show a massive (70%) loss in block strength for only a 20% saving in cement. Reducing the cement content from 5% to 4% would have only reduced the strength by around 20-30% and the same savings would have been realised with lower mould complexity and faster production time. The hollow block technique would require further improvement to become an acceptable alternative.

Two cement-rich skin blocks were also produced by dynamic compaction. The production technique for these blocks required the cement rich layer to be placed and spread out in the mould manually. This layer received a single low energy blow after which the rest of the material was added and the total mix compacted together. We wanted the cement-rich skin to be 5mm thick, so approximately 10mm of un-compacted material was placed in the mould. The cement rich layer had a cement content of 10% and the remaining soil had the usual 5% cement. The material was compacted using a 60kg impactor dropped twice from 0.2m and a further 6 times from 0.4m, delivering approximately 1.65kJ.

Upon ejection the blocks were measured and then cured for 6 days. After curing they were air dried for one day and multiple indentation tests were carried out on the block surfaces. Only a small difference in the indentation tests could be noticed between the cement-rich side and the other sides of the block. This was enough; however, it was much easier to visually identify the cement rich layer on the block. The achieved P.D.D. of the two blocks were 1974 and 1965kg/m^3, quite acceptable for the energy transfer and comparable with 10MPa quasi-static compression.

The added complexity of manually placing the cement-rich layer in the mould would make this technique impractical during normal block production. We also do not know the performance of this variant to be able to compare it accurately with other CSSB. Further research would be necessary to determine if this variant would provide the benefits that we want without adding significantly to the machine complexity or the block production time.

It was noticed during the production of these block variants that each block exhibited a dimensional variation of less than ±0.5mm over the top surface, significantly lower than the ±3.0mm experienced on previous blocks. All of the block variants enjoyed special care in the material placement prior to compaction, which could be the reason for the improved dimensional tolerance. Such a small variation would be acceptable for interlocking block manufacture if it could be sustained during normal production. Interlocking blocks were suggested to be another good method of reducing the cement material for walling. Therefore, this finding justifies further research into improved material placement for incorporation into dynamic compaction.

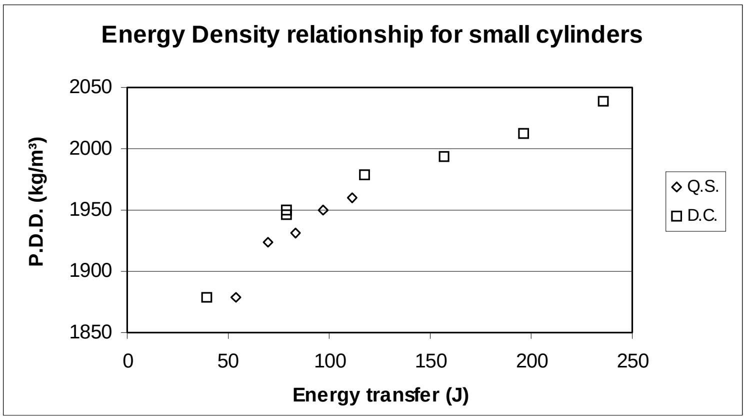
4.5 Comparison of dynamic and quasi-static consolidation

This section summarises the data collected from experiments conducted using the two different compaction methods. It aims to clarify the comparison of the effectiveness of the two methods using several measures of interest, namely P.D.D., energy transfer and block ejection force.

4.5.1 Achieved density for same energy transfer

Using the data that has been collected on small cylindrical samples compacted by quasi-static and dynamic methods we can compare the two methods of compaction. The graph in the figure below shows averages of sample sets of cylinders of the same soil compacted by quasi-static (Q.S.) and dynamic compaction (D.C.). It confirms the original premise that dynamic compaction is somewhat more effective at material consolidation than quasi-static compression.

Figure 4.16 – Comparison of energy transfer for small cylinder production



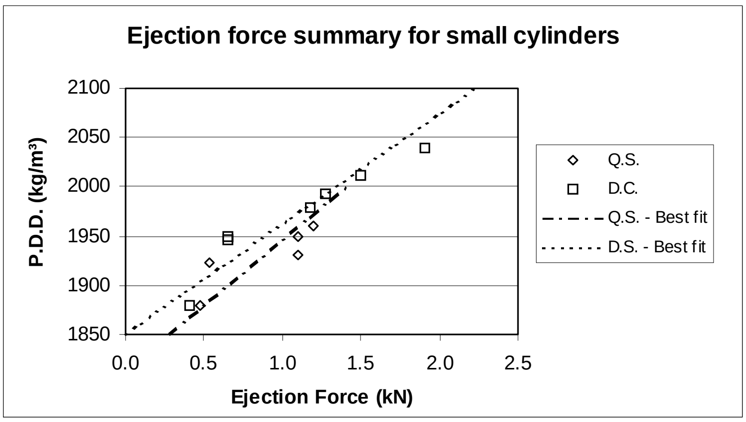
The graph plots data from 4-12MPa pressure and cylinders compacted with 8-24 blows and indicates the greater potential for compaction with dynamic over quasi-static. The application of extra blows delivers extra densification without the need for any machine modification, whereas significant machine modification would be necessary to increase a machine press from 4 to 12MPa or higher.

Early production of full-size blocks was conducted away from the optimum moisture content and this significantly reduced the achieved density for the energy transferred. Later block production indicated that a block could be manufactured with similar P.D.D. as a block compressed with 10MPa pressure using less than 1.7kJ of energy. This represents energy saving of about 20% over quasi-static compression (2.2kJ using soil-A). This also compares favourably to the estimated energy consumption of a 2MPa manual block press requiring 1.5kJ per block and very favourably with the 10MPa manual hydraulically-assisted press requiring 2.9kJ per block. We have therefore confirmed the original premise that dynamic compaction is more energy efficient in material consolidation than quasi-static, providing suitable production parameters are chosen and maintained.

4.5.2 Ejection force

With the results collected from the small samples it is also possible to analyse whether or not dynamic compaction offers any reduction in the ejection force of the compacted samples. This is interesting for the machine designers, as they will have to develop a system to provide the necessary force for block ejection. We have already established that the ejection force at small scale can be extrapolated to full-size blocks, so any findings at this scale can be assumed to apply at full-scale as well. The graph in the figure below shows a summary of the small cylindrical samples and their ejection force plotted against the compacted density. Due to the large variation in the numerical results between supposedly similar tests it is difficult to justify any practical difference between the two sets of data below. It was hoped that dynamic compaction would yield a small reduction in the ejection force for similar density samples and it is possible to see this marginal difference by applying lines of best fit to the data.

Figure 4.17 – Comparing ejection force for dynamic and quasi-static compaction



Such a small difference between the two methods of compaction does not present any real advantage of using dynamic compaction over quasi-static. We believe that much greater advantages can be found in reduced machine complexity as the next subsection explains.

4.5.3 Machine cost and complexity

We have established that dynamic compaction provides slightly more effective compaction for the same energy transfer, but does not improve other criteria such as ejection force. Are there any other advantages dynamic compaction can offer over quasi-static? The simple answer comes from the process by which compaction takes place. Quasi-static compression transmits between 30-70% (Gooding, 1993) of the load applied to the top of the block onto the sides of the mould. The overall machine must also be able to withstand over 100% of the maximum applied load without yield, deformation or failure. These requirements result in significant mechanical structures being applied for safe and reliable machine operation. Whilst low-pressure can be applied by a long lever or cam mechanism, high-pressure requires an additional hydraulic circuit. Hydraulic circuits are expensive and require maintenance for longevity and are typically inappropriate for low-cost applications in developing countries.

Experimental evidence has shown that high-pressure equivalent densities can be achieved by dynamic compaction with very thin walled moulds without any sign of yield or significant strain. This leads us to believe that the dynamic compaction process can be applied to full-size block making to produce high-pressure equivalent densities without the need for thick walled moulds or the complex hydraulic circuit. Removing these features from the machine design represents a large reduction in machine cost. The capital investment required for a dynamic machine would therefore be much less than a comparable quasi-static press, thus making it available to a wider market and more attractive for investment.

4.5.4 Other beneficial block characteristics

During the production of CSSB and their variants by impact compaction, several beneficial block characteristics were noticed. These may be of limited value but present some interesting features of dynamic compaction that have not been recorded during quasi-static compression. Gooding suggested that dynamic compaction delivered more uniform compaction, and this phenomenon has also been seen in the production of the full-size blocks through the indentation tests.

Another two features that have been identified as beneficial are to do with the surface characteristics of the block. During the cutting of the full-size blocks into cubes for compression strength tests it was noticed that the exterior skin of the block was harder than the core. This was further confirmed with the indentation test. The removal of the block from the ‘splitable’ mould does not cause the usual scraping and wiping effect normally experienced with ejection from quasi-static presses. The process of releasing the mould from around the block (something that is not appropriate with quasi-static compression) is delivering a visibly superior block surface. The combination of improved surface finish and increased surface hardness gives the finished block slightly better resistance to environmental attack and abrasion, truly a beneficial by-product of dynamic compaction.

4.6 Chapter summary

The results presented in this chapter have been very encouraging. We have also been assured that the experimental data collected is sufficiently accurate and repeatable to draw sensible conclusions from them. The inherent variation experienced during tests on quasi-static samples is very similar to the variation in impact compaction, from which we can conclude that the dynamic compaction process does not add any further variation. This small variation (±0.5%) is also present during full-size block manufacture.

We have established that dynamic compaction provides some 20% more energy efficient consolidation than quasi-static for each scale investigated. During block production small deviations (±2%) from the optimum moisture content will require additional energy to achieve desired consolidation. Compaction to 10MPa pressure-equivalent densities has been successfully achieved and many samples achieved even higher densities with additional blows. After choosing appropriate production parameters block P.D.D. was frequently over 2000kg/m^3, and exhibited 7-day W.C.S. of over 2MPa. From these findings we also re-calculated the relationship between P.D.D. and the W.C.S. for full-size blocks and found it to be only slightly different to the relationships discovered with the small cylinders.

The transfer of energy into the block via the falling impactor has a number of variables associated with it. Optimisation of the impactor mass, drop height and number of blows applied was investigated experimentally on small cylindrical samples. This indicated that the momentum transfer was not a critical parameter for compaction across the range investigated. This was assumed to be the same for full-size blocks as well and consequently the total energy transfer was monitored more carefully. Different impactor arrangements used during block manufacture indicated that a good solution was to use a 60kg impactor falling from 0.4m between 8 to 16 times.

Other aspects related to dynamic compaction were also investigated with some interesting findings. The practice of indirect compaction, (via intermediary billet) greatly reduces the potential for consolidation and should be avoided if possible. The losses of around 10% on density would result in unacceptably high strength losses of as much as 50%. The stiffness of the machine foundations was also found to have a practically significant effect on the final block properties. Increasing the delay between impacts was found to have a statistically significant effect on the blocks, but fortunately this was of little practical significance and any extra delay would have increased the production time unacceptably.

Our understanding of block manufacture by dynamic compaction has been greatly enhanced and will provide valuable guidance for machine design. It was discovered that thinner walled moulds are not only acceptable for dynamic compaction, but also yield slightly better consolidation compared with very thick walled moulds. A two-part thin walled mould was successfully implemented during full-size block production and overcame the problem of block ejection. Poor block tolerances were caused by a combination of poor impactor constraints and poor mould filling. These issues may need to be further assessed for inclusion into an appropriate machine design. Block variants were also successfully produced using impact, but the increased production time and poorer block characteristics recommend further research and improvements to the process.

The numerical data collected during these experiments have also given us an idea of the processes taking place during dynamic compaction. We now know the compaction curves for the material at different moisture contents and different impactor arrangements. This information can help us to suggest the mechanisms of impact. We believe that impact generates significant forces that cause consolidation, but the magnitude of these forces is still not known. Interesting findings concerning mould wall thickness lead us to believe that other mechanisms are acting during the compaction that are different to quasi-static compression. Closer inspection of the point of impact, its duration and effects now needs to be carried out.

5 Impact Mechanism

The literature review indicated that little was known about impact compaction and even less about impact compaction of confined soil. The results of experiments conducted in the previous chapter help us to make certain assumptions about the mechanisms involved in compacting soil by impact. The experiments described in this chapter have been conducted to investigate some of the fundamental mechanisms acting during an impact blow. Our motivation for conducting these experiments is twofold, firstly to improve understanding of the process of impact compaction and secondly to assess the magnitude of the forces delivered during impact and thereby assist with machine design. This chapter will be split into two sections. The first section develops a series of models for the compaction process and for impactor motion. The second section describes experiments conducted to measure certain features of dynamic compaction and assesses the models against the experimental evidence.

5.1 Models of compaction

The soils literature adequately describes the effects of soil compaction of soil without actually explaining any of the mechanisms that take place. Soil consolidation is achieved by bringing particles closer together and as a result driving out some gaseous material, and under extreme conditions, some liquid material as well. This section will develop models for three separate areas of interest; the force distribution during compaction, particle-particle interaction, and air/water dismissal. Eight conceptual models are presented below:

1. Force distribution during compaction,
    - Shock wave propagation to bottom and back
    - Compression transfer to top and sides
2. Particle-particle interaction
    - Sliding of particles past each other
    - Knocking off of asperities
    - Plastic deformation of lumps of clay
3. Air/water dismissal
    - Expulsion of air in the short duration of impact
    - Diffusion of air into water
    - Pressurisation of air in core followed by its slow diffusion out

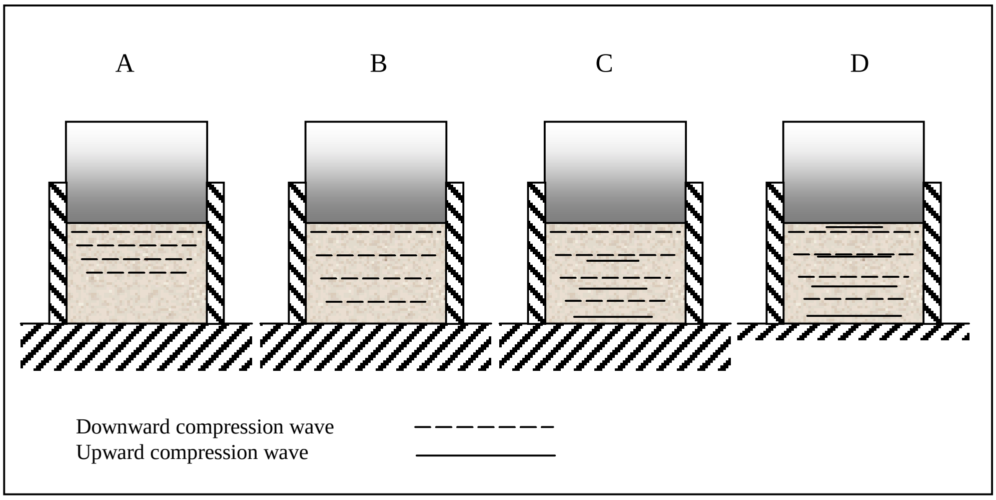
5.1.1 Force distribution during compaction,

It is already known that during quasi-static compression the sides and the bottom of the block mould feel only a fraction of the pressure exerted onto the top of the block, (typically 30-70%). We assume that the same is true for dynamic compaction, because the medium for the force transfer is the same, namely the soil. Whatever force is applied to the top will be felt in some measure on the sides and the base, but how the force is distributed during impact is still not understood.

Shock wave propagation to bottom and back – Experiments conducted using soft foundations indicated the phenomenon of shock wave propagation through the material during an impact blow. This was seen most clearly when de-lamination occurs, (i.e. when upper layers of the block have an internal tensile force applied that exceeds cohesive forces and material separation results). Such a phenomenon suggests that a shock wave impulse formed by the falling impactor is travelling through the soil.

The diagram in the figure below shows four different possibilities for compaction wave propagation through material confined in a mould. The horizontal lines in the material represent the wave front of the compaction at a succession of times. This wave reaches the bottom of the mould in C and D and reflects back up as a rarefaction wave upward through the material, depicted by the solid lines.

<u>Figure 5.1 – Compression wave propagation during compaction</u>



A – Has very low impact energy (similar to vibration) and only compacts the upper layers.

B – Has impact blows of higher energy that deliver shock waves as far as the bottom of the mould.

C – Has even higher energy impact blows and causes a reflection wave to bounce off solid foundations and travel back up some distance into the material.

D – Has elastic foundations and higher energy impact blows that causes a significant reflection wave travelling all the way back up the material causing de-lamination at the top of the block.

We can determine the speed of these compression waves if we know the speed of sound through the material. Sound waves travel through a material at a rate determined by the bulk modulus (G) and the material density (ρ) and using the following formula:

$$c = \sqrt{\frac{G}{\rho}} \qquad (2)$$

We can estimate the density of the material during compaction from the height of the block, but we need a method of determining the value of G for the material as well. Whichever method is used to determine G and the resulting speed of sound through the material should be verified experimentally in some way. The concrete industry uses a Pundit tester to estimate concrete strength from the speed of sound passing through it. Such a test would be acceptable to determine the speed of sound through the compacted material.

Compression transfer to top and sides – This model is similar to quasi-static compression model. It suggests that the force applied to the top surface of the material from the impact blow is transferred through the material along slip planes. If this force is large enough, the particles resisting the force give way and move closer together. Similarly to quasi-static the maximum forces are felt on the top surface and they reduce significantly as one progresses through the material and towards the bottom (since the growing friction of the vertical forces has been transferred to the mould sides). This model would suggest that compaction force would be smaller at the bottom of the block and therefore display a lower achieved density. This material characteristic is well known in quasi-static compaction, but has not been noticed during previous or current dynamic compaction research.

5.1.2 Particle-particle interaction

Sliding of particles past each other – Typical soils consist of large particles surrounded with smaller ones. The very smallest particles are clay, which have a flat plate-like structure with water molecules bonded to these plates. In the presence of additional water and/or force these plates will slip past one another. As the force is applied to the material (via impact or squeeze) these clay particles slid past one another enabling the larger particles (that they are coating) to move into a closer arrangement. This model seems to most accurately explain the effect of better consolidation from the addition of extra water as seen in both the soils literature and the dynamic compaction experiments.

The dynamic viscosity (μ) of water and air at 25°C are 0.001 Ns $m^{-2}$and 1.853×10^{-5} Ns m^{-2}. From this we can calculate a maximum likely shear stress (τ) for these fluids assuming a 1m/s velocity change (*du*) over 0.1mm (*dy*) using:

$$\tau = \mu \frac{du}{dy} \tag{3}$$

This yields a shear stress of 10Pa for water and 0.2Pa for air. These stresses are tiny compared with the shear strength of the solid component. Therefore we can conclude that any slipping is due to the very small shear forces between particles surrounded by air and water rather than shear planes through solid material.

Knocking off of asperities **–** This model may apply if the presence of clay or moisture is too small for sliding to occur between particles and the forces applied are large enough for material fracture. Sharp points on the particles may break off during the application of forces exerted by the impact blow. The load path through the material will be predominantly through point contacts between particles and these may crush or break under force. As compaction continues the number of point contacts increase until the force applied is sufficiently resisted without any further crushing and hence consolidation ceases.

If we assume the compressive strength of the rock particles is approximately 500MPa, this is significantly higher than the mean pressures that we are expected from dynamic compaction over the total surface of the block. If we were achieving a mean pressure of 10MPa there would need to be a 50 to 1 stress concentration for localised crushing to occur. Considering the wide range of particle sizes and close packing of them together, this seems highly unlikely and therefore we can assume that the forces are not physically affecting the solid particles.

Plastic deformation of lumps of clay **–** Clay will exist in the form of closely packed lumps that have not been broken down into smaller pieces during the soil mixing process. In the presence of water these lumps are quite soft and will deform under applied force. Initially these lumps may hold harder particles further apart but as the forces applied during compaction are exerted these lumps will deform and permit closer arrangement of the harder particles. These lumps of clay will have a shear stress dependent on the quantity of water present in them, but much lower than the solid rock material present throughout the soil.

5.1.3 Air/water dismissal

Expulsion of air in the short duration of impact **–** The soil comprises of three phases, solid, liquid and gas. For the applied pressures it can be assumed that the solid and liquid phases are incompressible compared to the gaseous phase. During the first blow the air volume reduces to approximately 65% of its initial volume. If the air was originally at 1 bar (or 0.1MPa) and the volume is reduced by 35% then (assuming no air loss or temperature change) the new air pressure is 0.15MPa. Substituting an adiabatic assumption for an isothermal one raises this pressure to 0.18MPa. During the first impact blow a small amount of dust is usually ejected from the mould along with the expelled air. We believe that this air loss constitutes a significant proportion of the volume reduction experienced by the block during the impact blow. It is possible that some of the air does not escape during the impact time and becomes trapped and compressed within the block. The above values indicate that the increase in pressure would be very small assuming most of the air escapes during the impact blow.

Diffusion of air into water **–** As pressure is applied to the mixture and particle-particle intimacy increases the mixture of air and water and pressure could cause some of the air to diffuse into the water. What then happens to the air when the pressure is removed is open for debate. The solid particles could keep the pressure on the overall matrix and keep the air dissolved in the water, placing the material into tension. Alternatively the air could slowly diffuse out of the water and out of the material long after compaction has been completed. The quantity of air that could be diffused into the water depends on the amount of water present, the applied pressure, the temperature and the amount of air already dissolved in the water. Whilst we cannot rule out the possibility that air may diffuse into the water we can suggest that the effects will be small for a number of reasons. There will only be a small amount of air under pressure throughout the block and the pressure applied to the air will also be small. We have already established that if none of the air escaped then the air pressure within the soil would increase to less than 0.2MPa. We also know that some of the air does escape so it is even more unlikely that air would be diffusing into the water within the soil during initial blows. During latter blows the pressure might be higher, but the volumetric change in the air is even smaller so the effects will still be limited.

Pressurisation of air in core with slow diffusion out **–** We believe that at some stage during the compaction air is being trapped within the block and becoming pressurised during further consolidation. At the end of compaction this trapped air will be at a greater pressure than the local atmospheric conditions. This could suggest that the air pressure in the pores increases during each blow and pressure equalisation occurs some period later as the high-pressure core slowly diffuses out of the material between blows. It could also suggest that as this pore pressure is increasing it could marginally hinder further consolidation until the pressure has equalised with the atmosphere.

5.1.4 Theoretical models for impactor trajectory during impact

The process of the dynamic compaction is assumed to include a combination of elastic, plastic and possibly viscous effects. In order to anticipate what sort of compaction was dominant in the different stages of compaction, a set of basic equations of motion was derived. These describe the motion for the different effects taken one at a time, (plastic, elastic and viscous) from which a possible position trace could be generated. Below are the theoretical derivations of plastic, elastic and viscous models of impactor retardation.

Plastic deformation **–** constant retardation a = -*k*

$$x = -\frac{kt^2}{2} + at + b = pt^2 + qt + r \qquad ①$$

$$\text{and} \quad v = \frac{dx}{dt} = 2pt + q \qquad ②$$

(i) at $t = 0$, $x = 0$, inserting into ① gives $r = 0$ ③

(ii) at $t = 0$, $\frac{dx}{dt} = v_0$, inserting into ② gives $q = v_0$ ④

(iii) at $v = 0$, $t = T$, inserting into ② gives $p = \frac{-v_0}{2T}$ ⑤

(iv) However at maximum indentation ($v = 0$), $x = X$,

inserting ③④⑤ into ① giving: $\therefore X = \frac{1}{2} v_0 T$ (4)

Elastic deformation – retardation is proportional to penetration $\therefore m\ddot{x} = -kx$

$x = A\cos\omega t + B\sin\omega t$ ①

where $\omega = \sqrt{\dfrac{k}{m}}$ is constant

and $v = \dfrac{dx}{dt} = -A\omega\sin\omega t + B\omega\cos\omega t$ ②

(i) at $t = 0$, $x = 0$, inserting into ① gives $A = 0$ ③

(ii) at $t = 0$, $v = v_0$, inserting into ② gives $B = \dfrac{v_0}{\omega}$ ④ $\therefore x = \dfrac{v_0}{\omega}\sin\omega t$

(iii) at $v = v_0\cos\omega t = 0$, $t = T$, giving $\omega = \dfrac{\pi}{2T}$ ⑤

(iv) However, at maximum indentation (v = 0), x = X, inserting ③ ④ ⑤ into ① gives: $X = \dfrac{v_0}{\omega}\sin\omega T$ (5)

Viscous deformation – retardation is proportional to velocity $a = -cv$

$x = P + Qe^{-ct}$ ① and $\dfrac{dx}{dt} = -Qce^{-ct}$ ②

(i) at $t = 0$, $x = 0$, inserting into ① gives $Q = -P$ and $\therefore x = P(1 - e^{-ct})$ ③

(ii) at $t = 0$, $\dfrac{dx}{dt} = v_0$, inserting into ② gives $Qc = -v_0$ ④ $\therefore P = \dfrac{v_0}{c}$ and $\therefore c = \dfrac{v_0}{P}$

(iii) at maximum indentation (v = 0), t = T, $\therefore X = P$ and x = X inserting into ③ gives $x = X(1 - e^{-\frac{v_0}{X}t})$ ⑤

(iv) Relationship between T and X is $T >> \dfrac{X}{v_0}$

1. If pure plastic deformation occurs then the relationship between T and X is

$$T = \frac{2X}{v_0}$$

2. If pure elastic deformation occurs then the relationship between T and X is

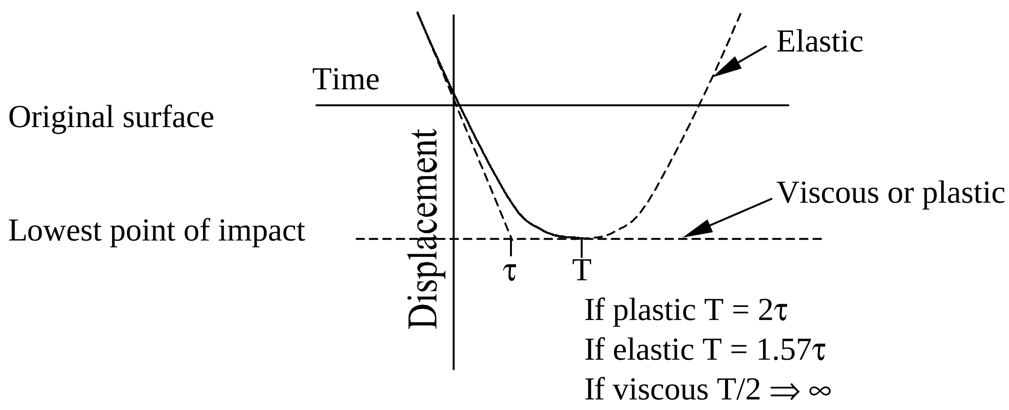
$$T = \frac{\pi}{2}\frac{X}{v_0}$$

3. If pure viscous retardation is dominant then the relationship between T and X is

$$T >> \frac{X}{v_0}$$

The graph below shows the possible displacement/time trace for the falling impactor as contact with the surface is made and compaction of the material results. The solid curved line represents the trace of the falling impactor whilst the dashed line indicates the original velocity at impact extended to cross the lowest point of impact to determine τ.

<u>Figure 5.2 – Theoretical displacement analysis of impactor</u>



It was hoped that if an actual trace of the motion of the impactor could be gained then this trace could be analysed with reference to the theoretical traces. This would help to determine the dominant effect in the different stages of compaction and perhaps lead to a deeper understanding of dynamic compaction. If we can analyse the position of the impactor accurately then we should also be able to analyse the position of the top surface of the block during the compressive part of the impact.

5.2 Experimental measurement of impact

Earlier in the project it was assumed one real advantage of impact compaction was that the forces delivered to the block were smaller than with high-pressure quasi-static compression. It was of both academic interest and economic interest to determine whether this assumption was correct or not. Academic because the actions of an impact blow onto the surface of a confined soil sample had yet to be analysed. Economic, because lower forces justify the use of less material in the mould design and general machine structure.

Before attempting to accurately monitor the position of the impactor during a series of impact blows, we estimated certain characteristics from known equations of energy and motion. From experiments conducted earlier we can estimate the actual impactor drop height from relative impactor positions before and after each blow. This data gives the distance travelled and the deformation achieved by the applied blow. The impact sequence can be divided up into a series of sections:

The impactor lift: h_i = height lifted to impactor stop,

i = blow number

During impactor free-fall: $v^2 = 2gh_i$,

$E = 1/2mv^2$,

$a = g\ (9.81 m/s^2)$

Contact with material surface: $F_C = ma$, (where 'a' is <u>not</u> constant)

Retardation of impactor and compaction of material: $v = 0$,

$u^2 = 2gh_i$

Elastic restitution of material: $e = \frac{v_2^{'} - v_1^{'}}{v_1 - v_2}$ where v_2 and $v'_2 = 0$

Impactor bounce: $E_b = mgb_i$,

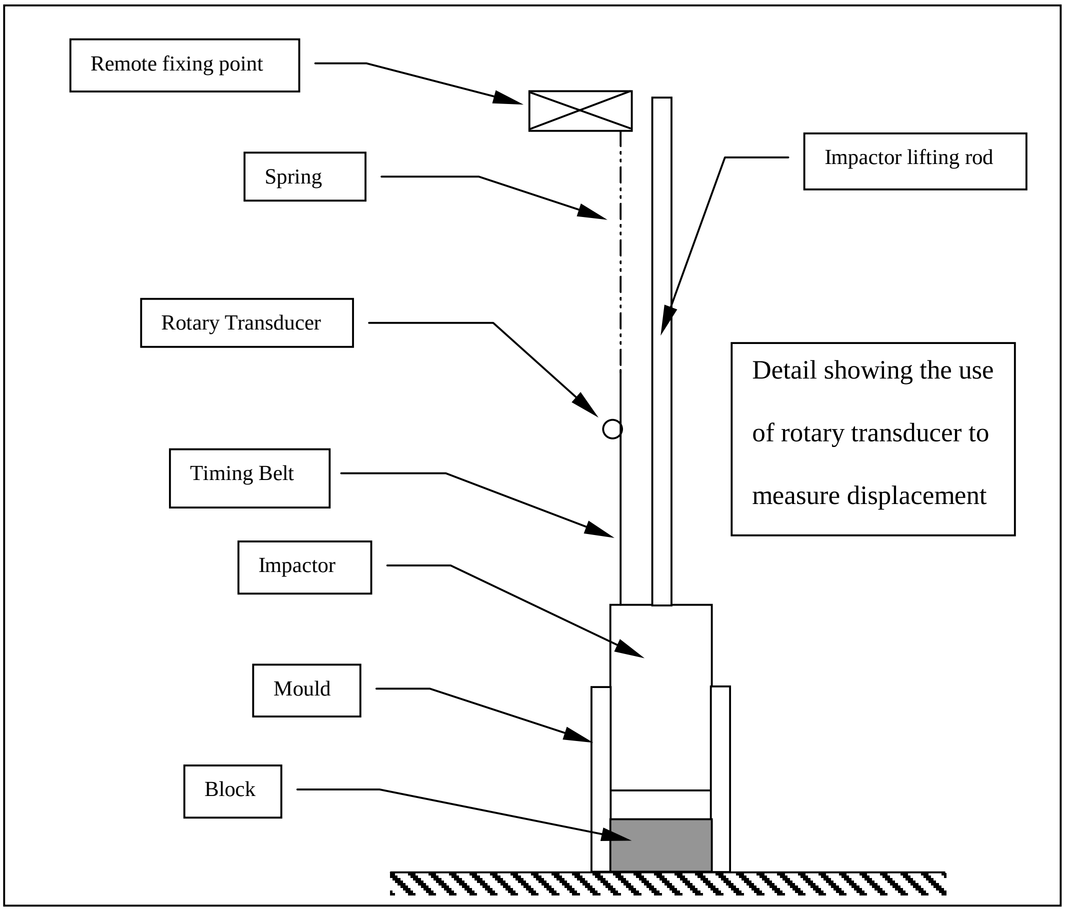
b_i = impactor bounce height

Experimentation was conducted on dynamic compaction of soil-B with 6.5% moisture and using a 36.8kg impactor falling through approximately 200mm. Therefore the impactor velocity at impact would be approximately 2m/s and the impact energy would be around 74J.

Several different methods could be used for monitoring the dynamic blow. Remote measurement could be used via a laser or sonic pulse monitoring absolute position. Alternatively a mechanical device or sensor that was attached to the impactor in some way could also monitor the location (e.g. via a rotary transducer) or acceleration (via an accelerometer) of the impactor. For practical and economic reasons it was decided to use a rotary transducer and monitor the relative position of the impactor during the compaction cycle. An accelerometer was also used, but it was only rated up to 25g and consequently could only be used to indicate the point of maximum acceleration rather than measure the magnitude of it.

The rotary transducer was connected to a toothed wheel and mounted onto the impactor guide. A timing belt passing over the toothed wheel had one end connected to the impactor base and the other end connected to a series of springs before being fixed to a remote part of the rig. This arrangement enabled the timing belt to move freely up and down past the rotary transducer whilst also staying sufficiently taught to accurately measure displacement both on the upward and downward strokes of the impactor. A diagram of the arrangement is shown below. The tension in this timing belt is negligible compared with the weight of the impactor.

Figure 5.3 – Diagram of sensor position for impactor analysis



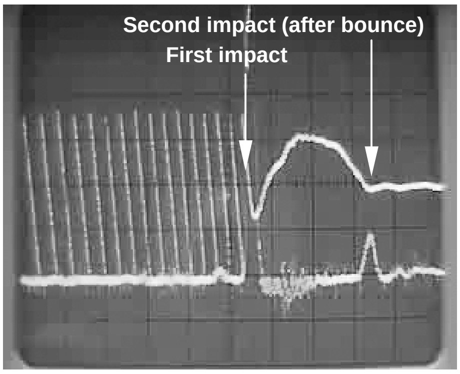
A digital decoder was connected to the rotary transducer to give an 8-bit number output from the transducer and this was intended to be transmitted directly into the parallel port of a computer. Unfortunately serious interfacing problems were encountered in capturing the digital data from the rotary transducer. After many weeks of trying, this method was shelved and another system of analogue analysis using a storage oscilloscope and digital video camera was implemented instead.

The resulting video was then analysed frame by frame to determine the actual position of the impactor relative to the impactor's starting position on the oscilloscope trace. This procedure was incredibly laborious and generated results of only passable numerical accuracy. Consequently it was only carried out on traces taken from the 1st and 38th blow delivered to a sample of soil. Traces from other blows were only analysed at the impact point determining the amount of compaction achieved, the impactor bounce height and the elastic displacement of the material.

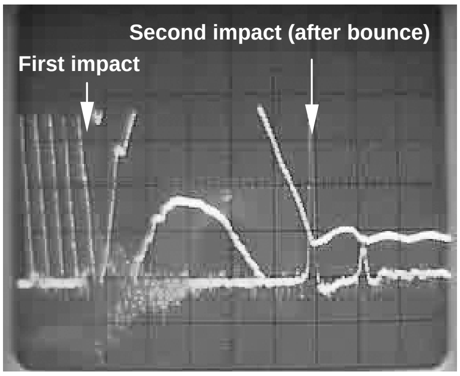
5.2.1 Impactor position, velocity and acceleration

Below are snapshots taken from the compaction video of two separate blows delivered to a test sample. On the left of the snapshot one can see the descent of the impactor indicated by the almost vertical lines running from the top to the bottom of the screen. Eventually contact is made with the sample and the impactor comes to a stop before bouncing backwards, (indicated by the hump). The flat line on the right side of the snapshot gives the final resting position of the impactor.

Figure 5.4 – Signal traces from rotary transducer and accelerometer during impact



5th Blow

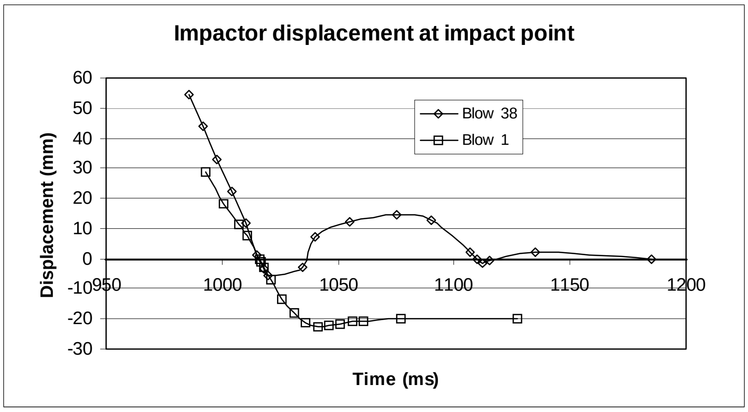


29th Blow

Spikes on the second line on the snapshots (the accelerometer trace) indicate the peak acceleration at impact both for the initial impact and for the subsequent bounce(s). It is clear that during the 5th blow the accelerometer is experiencing significant shock from the impact blow well in excess of its working range of 0.5 volt (vertical scale 1 div = 0.5V = 250m/s^2). The shock becomes even more significant during latter blows. The rotary transducer was calibrated for displacement using a different system than the recording system and this resulted in an error of a factor of two throughout the data recorded. Once the error factor was found, then the data could be adjusted and the corrected results are reasonably close to the theoretical calculations for the experiments, hence making them of satisfactory accuracy for experimental interpretation.

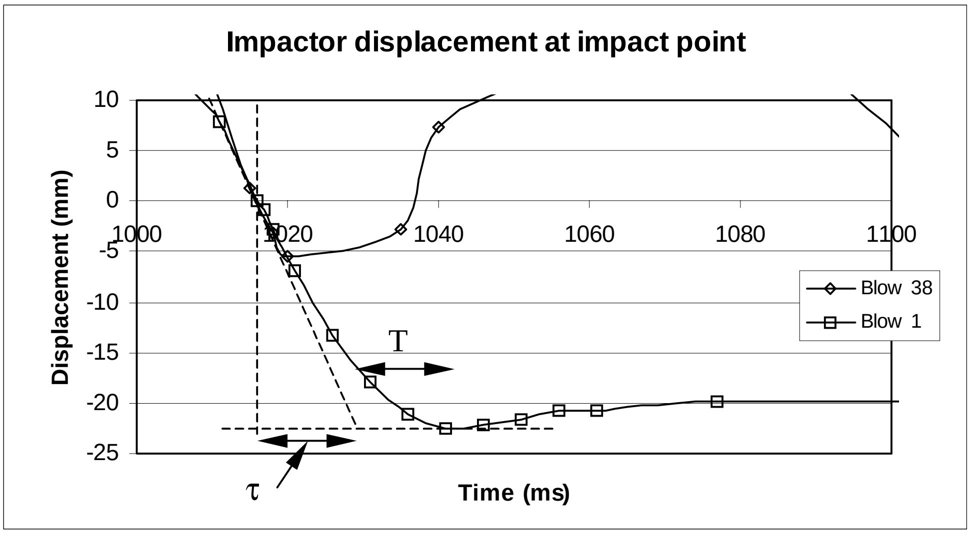
The following data comes from another block that was manufactured by impact compaction with careful analysis of the video traces received from the experimental equipment described above. The results of the two position traces from the 1st and 38th blow can be seen in the graph below. For both of the traces the approximate soil level prior to the impact has been indicated as zero displacement and from this the level of compaction or the elastic deformation can be identified. The data presented has also been time shifted to superimpose the two traces so that they coincide at their respective point of impact. The results demonstrate the significant difference between the initial blow applied and the much later blow where densification per blow has become very small.

Figure 5.5 – Graphical representation of impactor displacement



We can take a closer look at the impact region of the graph and analyse it with respect to the models generated earlier. The graph in the figure below shows the graphical interpretation of the trace. It is unfortunate that these numerical results do not seem to correspond very well with the theoretical models for impactor motion. This can be seen with the initial blow and where the impactor initially comes to rest more than 20mm below the original surface. The theoretical data suggested that for a completely plastic material deformation $T = 2\tau$ and if completely elastic $T = 1.57\tau$. The dashed lines drawn onto the graph indicate the theoretical lines for determining T with respect to τ. By inspection we can see that $T < 2\tau$, but also less than 1.57τ.

Figure 5.6 – Close up of impact point



The graphical trace indicates at least three things. One, the curvature of the graph increases with displacement, (favours elastic over viscous interpretation). Two, $T<1.57\tau$ indicates some plastic or viscous action. Three, Rebound is small indicating plastic or viscous action. During the 38th blow the evidence is also a little confusing. Latter blows would be expected to be predominantly elastic as any plastic deformation has reduced to almost zero. However, the above graph indicates that for the 38th blow $T \varphi \tau$. Perhaps these results could be interpreted in the following way. Initial blows are predominantly plastic (T is large) but as the sample becomes more compacted the plastic element decays and an elastic component becomes noticeable (T is smaller). This does in fact correspond with the theoretical data as 2τ (plastic) is larger than 1.57τ (elastic). Perhaps the numerical accuracy of the data received doesn't warrant any deeper or further analysis than this.

The changes that occur to the compaction process can also be monitored from the data received from the compaction video. The figure below shows the impactor displacement for three separate stages of an impact. The plotted variables are:

Compaction – permanent change in block height from the applied blow

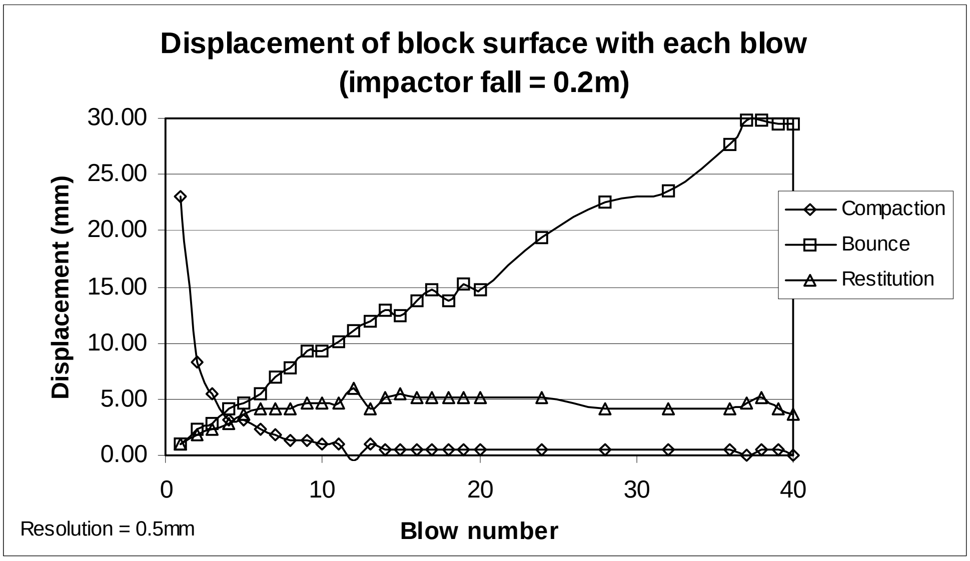
Restitution – assumed elastic deformation of block during impact, defined as the recoil height of block surface from maximum indentation to final steady state

Bounce – height of impactor bounce after impact relative to final block surface (assumes negligible compaction from subsequent bounce impact)

The graph shows some very interesting phenomenon that has not been seen before. We can see that the compaction graph complies with the pattern of dynamic compaction as seen already, which gives us assurance that the measurement method is working OK. However, what we haven't seen before is the elastic region of the impact and the impactor bounce height relative to the block surface. It seems that there is a limit to the elastic deformation of the material, possibly dependent mould stiffness rather than the block material itself. This limit of elastic deformation stabilises at about 5mm after the first few blows. It should also be remembered that the impactor energy is almost constant, especially after the first few blows.

Another more striking feature of this data is that the bounce height of the impactor increases linearly after each blow and only seems to level off during the last few blows. This result combined with the almost constant elastic deformation of the block gives us a good clue about what is happening within the material. As the material becomes compacted the elastic restitution increases with each blow. Therefore subsequent blows achieve a greater bounce height than the previous blows do. The elastic restitution is dependent on the materials that come into contact and their respective velocities. Generally the elastic restitution is related to the material hardness, and we believe that the block is becoming harder with compaction and therefore this fits in with the data quite well.

Figure 5.7 – Impactor position analysis for complete block production



Up until the 20th blow a marginal compaction could be measured for each blow. After this the compaction is measured after every four blows to ensure a measurable compaction within the resolution of the equipment. It can be seen that the increase in compaction per blow drops to virtually zero after 20 blows, yet the bounce height seems to rise steadily. This phenomenon suggests that the elasticity of the material is increasing with each blow.

5.2.2 Changing material properties during compaction

We already know that the density of the material changes during compaction, but we now have good reason to believe that the overall material stiffness is also changing during compaction. This seems plausible as the material is increasing its resistance to further consolidation with similar energy blows and the impactor rebound height is increasing. We know the mechanical properties for the air and water and their respective fractions during the compaction sequence. We can also assume a certain overall stiffness of the material from the elastic restitution and rebound height of the impactor.

We can apply a parallel stiffness model or a series stiffness model to the composite material of air, water and rock. If we select the parallel stiffness model the stiffness of the material will be dominated by the rock, whilst the series stiffness model will be dominated by the air. We believe that the air within the block is playing a significant part in the compaction so we will apply the series stiffness model first.

If we replace stiffness by elastic bulk modulus we can estimate the elastic bulk modulus of the material using the following equation: $\frac{1}{G'} = \frac{\lambda}{G_a} + \frac{\gamma}{G_w} + \frac{1-\lambda-\gamma}{G_r}$

Where γ and λ are the volumetric fractions of water and air during a sequence of impact blows.

By using $c = \sqrt{\frac{G}{\rho}}$ and working backwards from the speed of sound through air and water and their densities we can estimate the values of G for air and water to be 0.13MPa and 2.0GPa respectively. We have a range of 20 to 150GPa for the Young's modulus (E) for rock taken from an Ashby diagram (Department of Engineering, 1996). Depending on the constraints this can be converted to bulk modulus using either $G = \frac{3E}{8}$ (tri-axial) or $G = \frac{E}{3}$ (uni-axial). This gives us a possible range for G of 6.7GPa to 56.3GPa. If we take a midrange value of 30GPa and calculate G' for the material at the beginning and end of consolidation we get a range of 0.28MPa to 0.78MPa. Knowing the final density as 1880kg/m³ we calculated the final speed of sound through the material as 20m/s, (far less than the speed of sound through air alone). We then tested the speed of sound though a similar freshly compressed block using a pundit tester and after calibrating the device a speed of 490m/s was recorded. This suggests that the speed of sound through the block is dominated by the speed of sound through the small fraction of air and the series model is inaccurate by at least an order of magnitude.

With the parallel model we assume that the material is stacked in parallel and calculate G' using $G' = G_a\lambda + G_w\gamma + G_r(1-\lambda-\gamma)$. This model yields a range for G' between 14GPa and 21GPa. If we again attempt confirmation by calculating the speed of sound through the material we get a maximum speed of 3342m/s, (grossly dominated by the speed of sound through the solid). From this we can assume that the mechanism by which sound travels through a composite material follows a model other than the parallel or series stiffness model. One would expect that the sound would travel through the solid material, hindered by the point contacts and interfaces with the water and air that surround them.

We can propose one further model that suggests that the total time through the material is the sum of the times through the solid, water and air taking the proportions rock, water and air as a fraction of the whole distance travelled. Taking the fractions of the total volume of the finished block and the speeds of sound through rock (estimated using G as 30GPa), water and air, using: $c' = c_a\lambda + c_w\gamma + c_r(1-\lambda-\gamma)$ we get an overall speed of 2620m/s. Unfortunately, as this model depends on the accuracy of G for the rock we cannot suggest that this model is superior than the parallel model despite yielding a better value for c'.

These investigations suggest that there is some link between the increasing consolidation affecting the block bulk modulus. The ranges for G' are numerically inadequate because they are based on a wide range of G for rock. Using the speed of sound through a *cured* block that was made yields a value for G' at around 10GPa. However, assessment of the Young's modulus on a freshly quasi-statically compacted block still constrained in the mould gives a value of 0.7GPa. Converting this to bulk modulus results in a rather low value of 2GPa, similar to that of water. The curing process will make the block stiffer and therefore increase the bulk modulus significantly so an initial value of 2GPa increasing to 10GPa is not unreasonable. Unfortunately we have not been able to establish a suitable model to determine the value of G' during the compaction procedure. All we can say is that as the material becomes compressed the rebound height increases and therefore the stiffness of the material also increases. Without an accurate value for G for the rock material we cannot verify our models or the results attained.

5.2.3 Maximum acceleration experienced by impactor

Early calculations conducted by (Montgomery, 1997) utilised an estimated stopping distance and time to estimate the acceleration and hence the force applied to the surface of the block. With the data that was collected from the rotary transducer a more accurate estimate could be made for the stopping distance. From the known impactor velocity prior to impact (calculated from the drop height) and the distance in which the impactor came to a stop the acceleration could be calculated.

By ignoring the horizontal scale on the traces (defining the time) and just looking at the height changes from the vertical scale it was determined that during latter blows the impactor came to a stop in 5mm from a velocity of 1.8m/s (drop height of 0.19m). By assuming ideal plastic deformation and hence constant rate of change of velocity we can determine the acceleration, (using $v^2 = u^2 + 2as$ where v = 0 u = 1.8m/s and s = 0.005m), giving a constant deceleration of 324m/s².

For *plastic* deformation model use: $v^2 = u^2 + 2ah$ which gives a value of a = <u>324m/s²</u>

If deceleration is proportional to penetration (i.e. *elastic*): $a = -kx = v\, dv/dx$

$k = (1.8/0.005)^2 = 129{,}600$

Max acceleration = $0.005k$ = <u>648m/s²</u>

If compaction follows *viscous* model then: $a = -cv = v\, dv/dx$

$c = V/X$, $a_{max} = cV = V^2/X$

Max acceleration = $1.8^2/0.005$ = <u>648m/s²</u>

Maximum acceleration during elastic or viscous deformation would be about twice as large at around <u>650m/s²</u>.

These values do not take into account the bounce achieved by the impactor, that drive the acceleration experienced by the impactor even higher. If the impactor bounces upwards with an initial velocity of 0.9m/s then the total change in velocity is 2.7m/s. If the compaction distance is 0.005m and the elastic restitution distance is 0.006m then s = 0.011m and the maximum constant acceleration is 331m/s^2. Again this value could be as much as twice as large for elastic or viscous effects.

5.2.4 Losses in the system

During very late blows no significant densification is achieved with each blow. It can therefore be assumed that no useful work is being done to the material and all the impact energy is being lost through a number of mechanisms.

Kinetic energy **–** energy restored to the impactor causing it to bounce and vibration energy dissipated through the floor and foundations

Heat energy **–** hysteresis losses from elastic displacement of material and mould

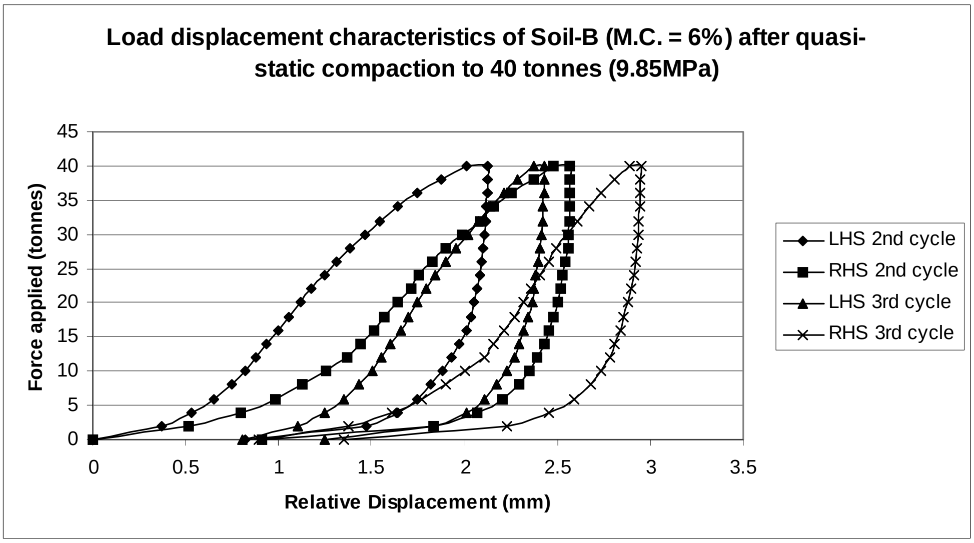
Sound **–** energy lost through the generation of noise

Unfortunately the only mechanism that we can easily measure is the kinetic energy restored to the impactor. The rebound height of the impactor after impact gives an indication of the elastic energy required generating a restoring force sufficient to make the impactor bounce. We can assume that the energy attained by the impactor using E_b=mgb_i is equal to the elastic energy delivered by the material into the impactor. Using initial bounce velocity of 0.9m/s yields a final bounce height of 0.04m requiring 15J of energy for a 36.8kg impactor. Initial impactor energy is around 75J so approximately 20% of the energy is lost during impactor bounce. The rest of the energy is lost through a combination of vibration dissipation, hysteresis and noise.

We have experimental evidence for the hysteresis losses incurred by quasi-static compression of full-size blocks from tests conducted on *soil-B*. The elastic deformation from impact compaction is higher than with quasi-static compression so it is reasonable to assume that the hysteresis losses would also be larger.

The data presented in the figure below is from the compression of a full-size block of soil-B compressed to 40 tonnes and then recompressed a second and third time monitoring the displacement of the two ends of the compression plate during the cycles. From this graph we can estimate the hysteresis losses experienced in the compression of the material to 40 tonnes. Calculation of the energy lost through hysteresis is the total energy input less the elastic restitution energy restored. For the block featured below the hysteresis losses were 16J for the second cycle and 31J for the third cycle. Please notice that the displacement achieved by the application of 40 tonnes is only about 2.5mm rather than the 5mm elastic displacement experienced during an impact blow.

Figure 5.8 – Hysteresis effects on compression of full-size blocks



These hysteresis losses are not insignificant and could apply to dynamic compaction as well. Furthermore the losses experienced by elastic deformation during dynamic compaction of twice that recorded by quasi-static suggests that the loss of 60J is not out of the question. Noise generation and machine vibration are other possible outlets for energy losses that we are unable to easily isolate and determine the magnitude of.

It is improbable that these losses are present during very early blows as very little elastic deformation occurs initially. From this we can suggest that the impact initially delivers most of the impactor energy into compaction and then as the elastic restitution element increases the energy begins to be lost through impactor bounce and hysteresis within the material.

5.2.5 Assessment of forces for machine design

Now that we have reasonably accurately measured the relative position of the impactor during an impact blow we can make some assumptions and try and extrapolate the values to give estimates for the forces applied. Three different models were proposed elastic, plastic or viscous, and the maximum possible accelerations were calculated for each model. We need to extrapolate these results to yield possible values for a larger impactor being dropped from a greater height.

In the plastic model the acceleration is constant and therefore the resistive force is also constant. We know the 36.8kg impactor when dropped from 200mm penetrated the block during a latter blow by 0.005m. This was not entirely plastic, but lets assume that it was for a moment. Lets also assume that the resistive force of the material does not change during the impact, (consolidation does not occur). The indentation distance now depends on the impactor energy divided by the resistive force $\Delta = \frac{mgh}{F_p}$. So increasing the impactor drop height by a factor of two and the mass from 36.8 to 60 will result in a larger indentation by a factor of 3.26, but the same maximum force.

In the elastic model the material acts like a spring, so the higher impactor energy will change the indentation Δ and therefore maximum force as well. Using the energy of the impactor: $mgh = k\frac{\Delta^2}{2}$ to give $\Delta = \sqrt{\frac{2mgh}{k}}$ and therefore, $F_{\max} = \sqrt{2mghk}$ such that only m and h are variable. Increasing the impactor mass and drop height now increases the indentation by a factor of √3.26 or 1.8. With greater indentation the force is also increased by a factor of 1.8.

In the viscous model the maximum force is dependent on the initial velocity of the impactor which has now been increased by a factor of √2. Calculating the increase in indentation is more complex because it depends on both the increase in velocity and the increase in impactor mass. Hence $\Delta = \frac{mv_0}{k}$ so if the mass increases by 1.63 and v_0 has increased by √2 giving a combined increase of 2.3.

The table below summarises these relationships and extrapolations and leads us to suggest that the range of possible forces that could be applied is between 12kN and 43.2kN. Crudely taking an average for the three models yields a force of 30kN. Converting this to a pressure on the top of the block yields only 0.74MPa.

Table 5.1 – Extrapolation of compaction forces

	Indentation depth Δ (mm)	Maximum Force (kN)
Plastic Model		
36.8kg falling 200mm	5 ‡	12 †
60.0kg falling 400mm	5 × 3.26 = 16.3	12 ×1 = 12
Elastic Model		
36.8kg falling 200mm	5‡	24†
60.0kg falling 400mm	5 × 1.8 = 9	24 × 1.8 = 43.2
Viscous Model		
36.8kg falling 200mm	5‡	24†
60.0kg falling 400mm	5 × 2.3 = 11.5	24 × √2 = 34

‡ - measured value
† - calculated value

We still believe that only a fraction of this force is felt at the mould sides. The literature suggests that the maximum force experienced on the sides of the mould is about 70% of the force applied to the top. We also need to take into account the change in the area that the force is applied to. The top plate is 0.0406m² and the area of the mould side that we wish to design has a width of 0.29m and a height of 0.1m giving a wall area of 0.029m². Assuming the pressure remains the same throughout the material, the force applied on the side F_s can be calculated using $F_t A_t = F_s A_s$ to be $1.4F_t$ which virtually cancels the 70% reduction suggested above. Consequently the force applied to the sides of the mould are approximately 30kN. It is now possible to use this figure to confirm the performance of the mould during the tests and apply the data to machine design.

6 Machine design and development

The motivation for research into dynamic compaction of soil blocks was the need to solve a specific practical problem. The pioneer in the dynamic compaction of soil blocks, A. Groth (1987), went on to make a machine and built houses in Botswana with the finished blocks. Gooding (1993) made significant improvements in the understanding of dynamic compaction and suggested some parameters for machine design. Montgomery (1997) took those parameters and proved the potential of the process in the laboratory for full-size blocks. The experiments conducted during this Ph.D. have further improved the understanding of dynamically compacted production of full-size blocks. The next stage was to develop a suitable prototype for field trials and dissemination. This chapter describes the design methodology, the application of experimental results to machine design, the modifications made to the mould and the way that prototype models of Lego® were used to aid design selection.

6.1 Approach to a production machine

The next stage in the design process was to draw up a set of specifications for the machine. The development of specifications can be a cyclic process with several iterations performed before a final set is chosen. The specifications outlined in this section derive from the understanding of the dynamic compaction process, the required block characteristics and the limitations of machine construction in developing countries. The specifications outlined here can be split up into three different sections. One section deals with the requirements for easy machine manufacture. The second section is concerned with machine operation and use. The final section confirms the desired characteristics of the blocks produced by the machine and discusses methods that achieve them.

The Test Rig that was used for the experiments reported in previous chapters, is different both in form and function from a production machine. The Test Rig required a greater degree of flexibility than is necessary for production. Moreover, machine productivity was not a major concern during experimentation. Whereas a production machine needs a high production rate and its design needs to facilitate that.

6.1.1 Design for ease of manufacture

Machine to have few moving parts **–** Soil can act as an abrasive if permitted to come between moving metallic parts of a machine. It is therefore important to design the machine with as few moving parts as possible. Those moving parts essential to its function should be located where the likelihood of soil contamination is small. The use of rolling element bearings should be avoided, as these will be especially prone to degradation from the presence of soil.

Simple to manufacture and maintain **–** Many developing countries already have a surplus of complex machinery that cannot readily be maintained. We do not want to be adding another machine to this category. The design of the machine should therefore take into consideration the level of technical competence and tooling availability in the area where it is to be used. Through personal experience and communication with other researchers in machine development, a basic level of skill and tooling has been identified. If the machine can be locally manufactured then the necessary maintenance and repair work could also be performed locally. The machine needs to be manufactured using basic power tools such as a manual metal arc (stick) welder and a hand held angle grinder. These two tools can be found in many manufacturing centres in developing countries. Processes such as milling, grinding and even drilling are less common and require more specialised tooling and operator training, hence they should be excluded from the machine production if possible.

Low-cost alternative to hydraulic block press – The aim was to meet the need for a low-cost machine that can produce a comparable block to that from a hydraulically assisted press. The removal of the hydraulic circuit, thick-sided moulds and heavy-duty bearings will dramatically reduce the overall cost of the machine. But this is only the start of potential cost reduction from machine design. Machine tolerances should be as large as possible to remove the need for some jigs and fixtures during machine production. Specific parts that need to be purchased, like hinges, should be kept to a minimum. Wherever possible parts should be manufactured on site reducing the costs and improving the potential for local maintenance. Greater emphasis needs to be placed on the function rather than the form of the machine.

6.1.2 Design for ease of use

Machine portability – We intend to reduce the transportation of soil and therefore promote an on-site building material production unit that utilises very local or on-site soil to make blocks. The machine will therefore need to be easily portable as a complete unit or at the very least it will need to be separable into different parts for moving from one site to another and reassembled with relative ease. This portability requirement of the machine should limit the weight of any single part of the machine to less than 100kg.

Low personnel requirements **–** Block production requires about 2.5kJ of human energy to compact each block. The rate of block production will therefore depend on the power output of the production team. The application of good ergonomic design and team rotation of the most arduous activities will help to maximise the productivity of the team. It is estimated that a team of three persons could operate the machine continuously to produce at least 60 blocks per hour (mean power output of 42W).

Safety and ease of use **–** Dynamic compaction uses a heavy mass that falls onto the top of the block in a mould. Falling masses present a significant hazard and this machine should include adequate protection for its users and for bystanders. Improved safety can be achieved through good working practices, training and built-in safety mechanisms.

6.1.3 Confirming the block specifications

Block size and shape **–** The standards outlined in (Centre for the Development of Industry, 1998) define 6 types of blocks based on the standard parallelepiped shape. Some include perforations, horizontal and vertical indentations. It is not possible to produce every type with a single machine, but some machines can produce several different types with minimal modifications. Such a capacity should be incorporated into the machine design. For example, a block mould can be modified to include a frog relatively easily. Additional features on the block make the machine marginally more complex, but can significantly improve the block characteristics and reduce material consumption.

High-density block production **–** Chapter 3 showed that the achieved density of the compacted block is closely related to its compressive strength. For the purposes of the machine design we have taken the requirement that the block has a wet compressive strength after 7-day curing of 2MPa. In order to achieve this strength a projected dry density of around 2000kg/m³ is necessary. From this density we can estimate other necessary parameters from the experimental results, such as the ejection force.

Versatility in material usage **–** One of the limitations of making blocks out of soil, is the specific range of soils that are should be used. Block compaction via impact can accommodate a wider range of soils, giving it greater site versatility. This can be further enhanced by machine versatility using different impactor arrangements and number of blows.

6.2 Interfacing dynamic compaction with machine design

Now we have a slightly better understanding of the process of dynamic compaction and the mechanisms involved during consolidation. From our experience in the production of small cylinders and full-size blocks we can reduce the ranges of certain machine design parameters. This section derives suitable parameter values from the experimental findings.

6.2.1 Optimisation of energy transfer

Previous research (Gooding, 1993) has already established that the application of neither one or two very high energy blows nor a very large number (e.g. >64) of low energy blows is as effective as a modest number of medium energy blows. This optimisation study was repeated during this research using the small cylinders. The results indicated that over the range investigated (4 to 32 blows), there was a little variation (<1%) in the achieved density and a modest variation (13%) in the resulting strength for the energy transferred.

The results presented in Table 6.1 are for small cylindrical samples that each received a total energy transfer of 157J via a range of impactor masses, drop heights and number of blows. The 7-day W.C.S. and the P.D.D. shown are the average of three samples produced at each arrangement.

Table 6.1 – Small cylinder production using constant energy transfer

Number of Blows	Mass of impactor kg	Drop height m	P.D.D. kg/m³	7-day W.C.S. MPa
4	10	0.4	1980	1.62
8	5	0.4	1992	1.73
8	10	0.2	2017	2.02
16	2.5	0.4	2003	2.26
16	5	0.2	1993	2.17
32	2.5	0.2	2003	1.93

From the table above we can see that for each arrangement the P.D.D. is within ±1% of the target of 2000kg/m³. As the inherent variability of the block density is also around 1%, we could conclude that 6 combinations of impactor mass, drop height and number of blows are equally satisfactory. However, the 7-day W.C.S. varies by slightly more than the inherent variability of 10%. The data indicates that the W.C.S. is highest between 8 to 16 blows and drops off at 4 or 32 blows. We will therefore limit the blow number (n) to between 8 to 16. Extrapolating these compaction parameters to produce a full-size block with a soil mass 40 times larger, needs to be done with care. Direct extrapolation of the energy used would suggest that about 6.3kJ of energy is required. However we know from Chapter 4 that only 1.8-2.4kJ is sufficient to adequately compact a full-size block to 2000kg/m³.

Other considerations need to be applied during extrapolation that affect the ergonomics and productivity of the proposed production machine. Higher values of n will reduce the productivity of the machine as each blow takes 2-3 seconds to apply. We would not want to be lifting a mass of over 80kg, even with some form of mechanical lever. We have found that a 60kg impactor worked sufficiently well during experiments on the Test Rig. The lifting height for the impactor needs to have an upper limit of 400mm otherwise the lifting mechanism becomes un-ergonomic. More complex lifting mechanisms add to the cost and size of the machine. Higher lift heights generate higher impact velocities that may also generate detrimental negative pressure rebound waves.

Using the above upper limits for impactor mass (M = 80kg) and drop height (h = 0.4m) and knowing the maximum energy (2.4kJ) required making a block with P.D.D. of 2000kg/m³, we can calculate the minimum number of necessary blows to be 8. If only 1.8kJ is required then this reduces to only 6 blows. From this we can select suitable design values for the machine to be M = 60kg, h = 0.4m, n = 8-10 to achieve a target of 2000kg/m³. However, if de-lamination occurs at 0.4m then the drop height can be reduced to say 0.3m without increasing the number of blows too significantly (n = 10-14). This gives the machine a degree of flexibility to cope with different circumstances without further modification.

6.2.2 Improved impactor constraint

During the experimentation it was noticed that the top surface of the block had an intolerably high variation in its slope. This was believed to be a result of a combination of the following: the impactor falling at a slight angle, the base plate of the impactor being incorrectly aligned with the base of the machine and poor placement of soil in the mould. Originally the impactor of the Test Rig was a solid block of reinforced concrete with a metal plate at the bottom welded to the reinforcing bar. Initial tests with this indicated that the concrete was suffering from fatigue and beginning to crack. This prompted the change to a cylindrical metal impactor, but in so doing the impactor alignment became more difficult.

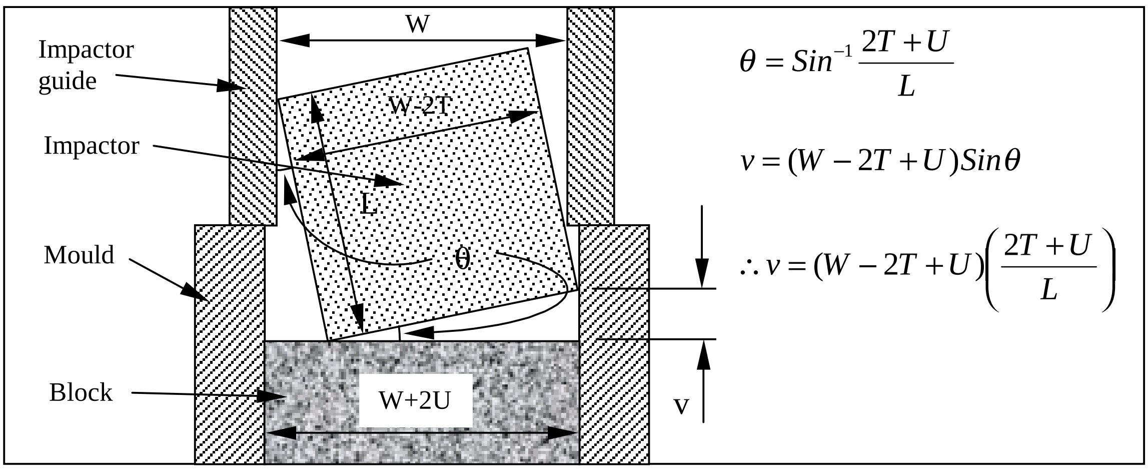
Part of the problem was that a rope pulley some 5 meters above the ground was the only lifting point for the impactor. Even with a 400mm linear bearing at approximately 2 meters off the ground it was virtually impossible to constrain a 60kg impactor successfully over a 400mm free fall. Better impactor constraints could have been implemented, but not without extensive rebuilding of the rig.

The original design for the impactor and impactor constraint could still be acceptable if the concrete was contained within a skin of steel. We need to determine the maximum permissible clearance between the impactor and the impactor guide so that the maximum angle at which the impactor can fall will not produce an unacceptable variation in the block height. This surface variation arises from the impactor rotating in the guide very slightly in both planes of constraint and thus is the sum of two components.

According to (Centre for the Development of Industry, 1998) the acceptable height variation across a block is ±2mm. The interior dimensions of the mould is 0.29m by 0.14m, and clearly to avoid any chance of the impactor hitting the mould sides, the interior dimensions of the *impactor guide* should be smaller than this, say no bigger than 0.288m by 0.138m. The impactor itself will be smaller still in order to give a clearance between the impactor guide and the falling impactor.

The variation (v_x) caused by rotation about the x-axis and (v_y) caused by rotation about the y-axis should sum to not more than 4mm. The diagram shown below indicates how these variations can be calculated using the length of the impactor (*L*), the width of the impactor guide (*W*), the tolerance (*T*) between the impactor and the impactor guide and the tolerance (U) between the impactor guide and the mould. If we take L as 500mm and W_x as 288mm for the x-axis constraint and W_y as 138mm for the y-axis constraint we can calculate the maximum acceptable tolerance to be 1.8mm.

Figure 6.1 – Impactor constraint diagram



These calculations suggest that the impactor should be about 1.8mm smaller on all sides than the impactor guide, i.e. 284.4mm by 134.4mm. For design purposes we will select 285 by 135mm as the dimensions of the impactor.

6.2.3 Ergonomics and productivity

Having now selected a suitable design of impactor we now wish to establish the method of energy transfer to the impactor to lift it to the desired height. The lifting mechanism may provide some mechanical advantage or may even be mechanised to reduce the human effort required. However the energy requirement remains constant and the more complex the mechanism the more potential there is for losses in the system. Ergonomic data {Gee, 1997} suggests that the aerobic energy output of a human is between 70-175 watts (W) for light intensity work, but this value would be lower in a hot environment.

We need to be applying a maximum of around 2.5kJ to each block and we wish to produce at least one block each minute. This equates to a man power requirement of 42W, easily within the range of a single person. However the force required lifting a 60kg mass is 600N, and the mass will be moved through 0.4m during approximately two seconds. This results in a power requirement during the lift phase of each impact cycle of approximately 120W. It is particularly difficult for the human body to apply such force and power and then cease them suddenly, as would be necessary to drop the impactor. This presents a design problem that can have a number of different mechanical solutions:

- Single pulley and two persons pulling on the rope (each exerts 300N through 0.4m)
- Single pulley and one person pulling on a lever attached to the rope (exerts 300N through 0.8m)
- Double pulley system and one person pulling on the rope (exerts 300N through 0.8m)
- Double pulley system and one person pulling on a lever attached to the rope (exerts 150N through 1.6m)
- Double pulley system and motor driven capstan operated by one person

The solution that was selected for the Test Rig was to use a double pulley system and a capstan driven by a high voltage DC motor. This may not be convenient or appropriate for the Production Prototype machine, and this will need to be assessed when the machine design is disseminated. A suitable system will need to be developed locally, that matches the available resources where the machine is going to be used.

6.3 Design of the mould

This section explains some of the changes that were made to the design of the mould as a result of experimental work. The Test Rig was designed with the Production Prototype in mind, so many of the essential parts of the Rig closely resemble the prototype design. Assessment of the mould design used in the Test Rig has indicated where it is in need of modification prior to incorporation in the Production Prototype.

6.3.1 Confirming mould stiffness and strength calculations

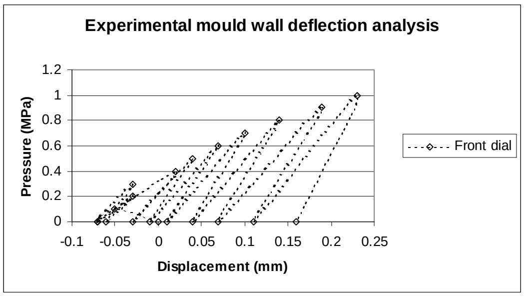
The Test Rig mould was designed on the presumption that a maximum pressure of 5MPa is applied to the top of a block. This reduces to a pressure of approximately 3.5MPa on the side of this block, which equates to a force of 200kN distributed over the sides of the mould during compaction. We further assumed that the mould side could be modelled as a beam with encased ends supports. Adequate mould stiffness had been assumed to be the primary concern and the design deflection was restricted to be less than 1mm. A spreadsheet was drawn up to determine an appropriate arrangement of ribs for the mould sides. The mould side was selected to be 0.29m wide and 0.2m high with a material thickness of 0.005m, its height necessarily greater than the finished block height (90-100mm).

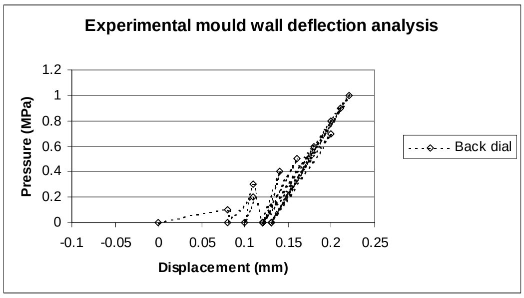
The calculations led to the selection of four 40mm wide ribs placed evenly around the mould. The ribs had the same thickness as the mould sides (5mm) to reduce the number of material sizes required for mould production. Four ribs were selected because they would provide stiffness all over the side of the mould rather than in just one plane. Four was considered to be a low enough number to permit sufficient access to the base of the ribs for welding to be carried out. This mould design led to a calculated maximum central deflection of 0.9mm from a distributed load of 200kN. This mould did not plastically distort during the dynamic compaction tests on full-size blocks.

With the data collected from the dynamic compaction analysis, the mould design detailed above can now be checked. The different dynamic compaction measurements from Chapter 5 suggested that the force delivered to the top of the block during an impact blow could be around 30kN. The maximum stress in the mould had not been calculated previously, and although the mould remained undistorted during block production we still want to double check our calculations with this new force estimate. This force of 30kN was found to give a maximum stress of 109MPa in the mould side, about 40% of the yield stress for M26 steel, giving a factor of safety of about 2.5. We would have preferred 3 or 4, but we can still suggest that this is OK because we have ignored the additional mechanical constraint provided by the joint between the mould side and the base of the mould. This joint will increase the strength of the mould side and therefore raise the safety factor to acceptable levels. This lower force (of 30kN) reduces the side deflection of the mould to 0.13mm or 0.19% of the block width, which is excellent. Now we can be sure that the original mould will perform adequately in terms of both yield stress and deflection displacement.

A further test was conducted by putting the mould in a machine press to test the wall deflection when a measured force was applied to a batch of soil inside the mould. The deflection was monitored using two dial gauges positioned at the midpoint of the block (50mm above the base of the mould). The soil surface was cyclically loaded and unloaded in 0.1MPa increments up to 1MPa. The deflections observed are shown in the figure below. Greater displacement was noticed on the front dial gauge because the front of the mould was the removable section of the mould and would therefore move slightly prior to material deflection. The graphs indicate that the displacement experienced is around 0.22mm at 1MPa. Our calculations had indicated that a force of 30kN (equivalent pressure of 0.52MPa) should yield a displacement of 0.13mm. Therefore our computation (0.25mm/MPa) and experimental (0.22mm/MPa) are in good agreement.

Figure 6.2 – Mould deflection under 1MPa pressure





From these experiments and analysis we can now confirm that the mould design that was developed for the Test Rig is a suitable design for incorporation into the Production Prototype. It performs adequately on strength and stiffness and uses a tolerable amount of metal (11.2kg) to achieve this.

6.3.2 Further mould design developments

Early in the development of the Test Rig it was noted that an integral mould was unacceptable for use with dynamic compaction. In a traditional block press the mould is integral with the machine, having its four sides fixed and the top and bottom plates moving to compress the soil. It was not possible to apply this design to dynamic compaction, as the bottom plate would need to withstand the shock forces applied by the falling impactor. Moreover it would be mechanically very difficult to safely organise block ejection upwards toward the temporarily raised impactor. Finally the benefits of impact would be undermined by having to exert large forces to eject the newly formed block.

A different design of mould was therefore developed to enable compaction to occur onto a flat solid surface and the block removed from the side of the mould rather than from its top or bottom. This design involved breaking the perimeter wall of steel into two parts locked together through some mechanism. Figure 6.2 below illustrates the idea via a plan view of the mould showing the locking mechanisms and the two parts of the mould that come together. Figure 6.3 is a photograph of one half of the finished mould as used in the Test Rig.

Figure 6.3 – Plan view of the two-part mould design

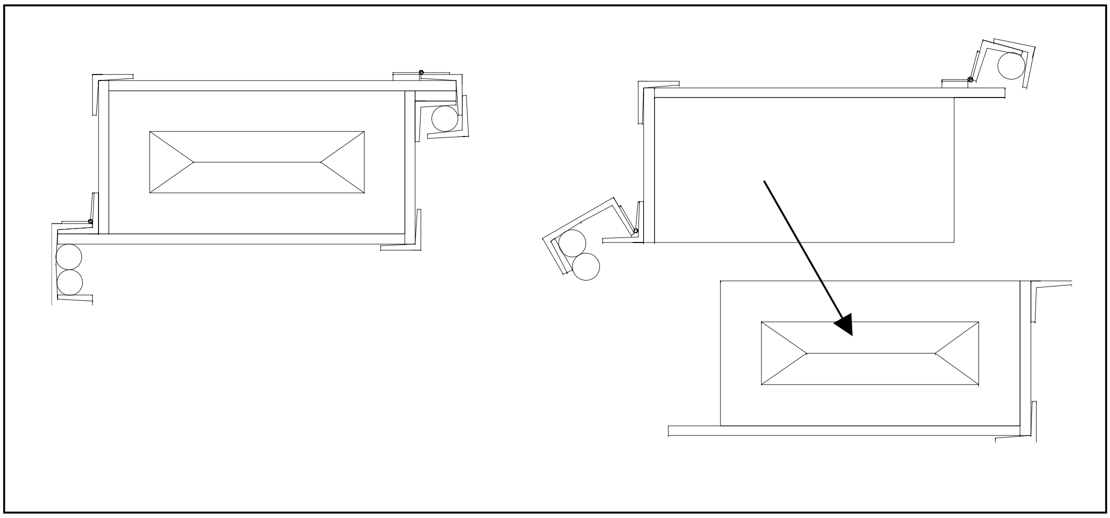


Figure 6.4 – Photograph of the finished front half of the mould

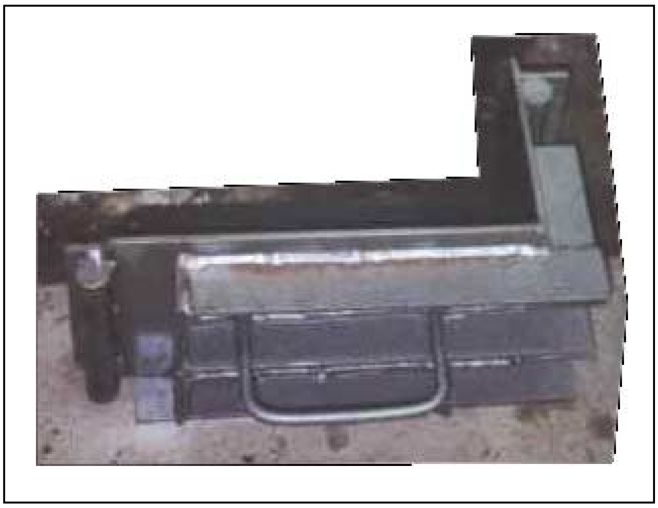
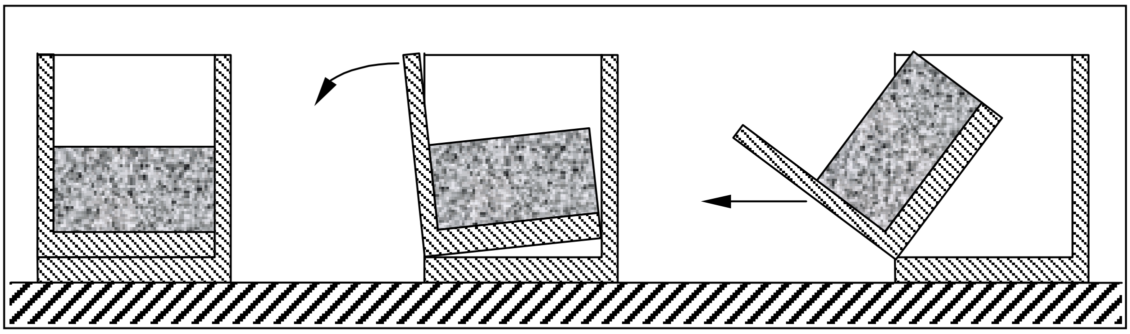


This two-part mould was a novel approach to block ejection and presented some new problems. Overcoming the adhesive forces between the moist compacted soil and the smooth steel mould walls was an exercise that required gentle persuasion. Blocks could only be successfully ejected from the mould by using a slow steady force: impact or jerking action resulted in the block becoming cracked and unsuitable. Furthermore the drag experienced by the block along the sides of the mould would often mar the corner edges upon ejection.

We have established that the initial mould design is adequate for dynamic compaction. There may be problems with fatigue that may need to be addressed during long term testing, but that is outside the scope of this work. The main issue with mould design used in the Test Rig that still needs to be addressed is a better system of block ejection. We know the magnitude of the forces involved in block ejection from our earlier experiments using cylindrical moulds. The ejection forces measured can be converted into the force per unit area of material in contact with the mould. The highest ejection force recorded during these tests, (1.5kN acting on a surface area of $0.0078m^2$), equates to an ejection force per unit area of 200kPa, a value considered excessive.

As viewed from above the Test Rig mould design used two ‘L’ shaped parts that came together to make the rectangular section required for the block, but block edges were getting damaged too easily during ejection. The proposed design for the Production Prototype has one ‘C’ shaped part of the mould fixed to the bed of the machine and a flat front with an attached base that can be drawn out of the machine from the front with the block on top of it. The figure below shows a cross-section through the mould illustrating the proposed method of block removal.

Figure 6.5 – Proposed mould design for improved block removal shown in end elevation



The advantage with this method is that a peeling action is used to remove the block from the back face of the mould as the front part is rotated slightly. Then this is followed by a pulling action to draw the block and front/base out of the rest of the mould. This way the majority of the block is supported by the base throughout the ejection process and should therefore reduce the damage caused to the corners. In order to design this mould we need to know the resistive forces that need to be overcome during the block ejection.

Unfortunately assessing the forces applied to this design of mould is not straightforward. The ejection force necessary for block removal needs to be split into two separate parts. Firstly the adhesion of the soil block to the mould walls usually dependent on the clay content, moisture content and smoothness of the mould walls. And secondly, the frictional shear force between the soil block and mould walls, where the frictional shear force depends on the normal force applied onto the surface.

In quasi-static compaction a large fraction of the force exerted to the top is felt on the sides of the mould. Some of this lateral force remains after the force from the top is removed as elastic strain in the mould. This elastic strain exerts a normal force that generates a high frictional shear force between the block and the mould walls. The process of splitting the mould into two parts releases any elastic strain in the mould and therefore reduces the normal force to almost zero. The remaining force that still needs to be applied is to overcome the adhesion between the compacted material and the mould walls. This adhesive force is most easily overcome through a peeling action rather than a shear or direct pulling action.

Experiments were conducted at different scales to assess the maximum ejection force required to eject a compacted block with density around 2000kg/m³. During these experiments the peak force was recorded as the quasi-static ejection force was applied to the compressed block. This peak force drops off rapidly once the block begins to move within the mould walls (i.e. the adhesive force has been overcome). In the Brepak operation manual (Webb & Lockwood, 1987) one is instructed to "jerk" the block ejection lever downwards to free the block from the side walls, to overcome the adhesive forces perhaps. The data in the table below summarises the recorded ejection forces for the different compression machines used and from the mould wall area calculates the shear friction stress in each occasion.

Table 6.2 – Shear friction stress summary for different compression machines

Compaction device	Mould wall area	Ejection force	Shear friction stress
400kN press	0.0774m²	15kN	195kPa
Brepak (400kN)	0.0774m²	(2kN)‡	(25kPa)
100kN press	0.0023m²	1.1kN	480kPa

‡ - Estimated force applied to block after "jerk" operation

If the same jerk action is used with the design of mould described in Figure 6.4 then the adhesive forces can be overcome and the remainder of the ejection force required will be coming from the ends of the block that are wiping past the ends of the mould. Assuming that the frictional shear stress is the lower 25kPa (despite the open mould) this would result in a maximum ejection force of 625N. Such a force can be applied with a short lever inserted between the front handle and the front of the mould. To ensure that the base of the mould can withstand the hinge moment of the force distributed across the base plate, it has been increased in thickness to 10mm.

6.4 Prototype model exploration and design selection

Six different models were made using Lego® over the duration of the project. Lego® is not the ideal modelling medium, but it did assist greatly in the development of several concepts that were adopted in the final machine design. The models were generally created to explore specific design questions raised. The following paragraphs describe the different versions of the models created and explain why different features were either included or rejected in the final design. Table 6.2 below summarises those features.

Mark I – This model was produced in response to the need for a machine design for the work conducted by Montgomery in 1997. It incorporated a flywheel driven rotary actuator that lifted a lever arm with the impactor attached to it. The rotary actuator lifted the arm upwards raising the impactor until the rotary actuator moved out of the way of the lever arm causing it to fall back onto the surface of the block. A parallel linkage ensured that the impactor was constrained to fall in a vertical plane and directly into the mould. The design was rejected because of the problems in mould and impactor alignment, flywheel and rotary actuator complexity, overall machine size and cost.

Mark II – This design was based on the crank slider mechanism, or inverted piston arrangement. A crank arm at the top of the machine rotated with the assistance of two flywheels. The connecting rod between the crank and the impactor (piston) had an elongated slot on the impactor end to accommodate the different block heights during compaction. The design employed a series of roller bearing guides to constrain the impactor to fall into the mould. Whilst this design was compact and relatively simple, it was top heavy from the flywheels and the roller bearing added unacceptably high levels of complexity and cost.

Mark III – Marks I & II did not include any satisfactory method for mould filling or block ejection. These were not trivial issues and the modelling process identified some problem areas that needed to be considered. The design used in Mark III used a rope and pulley system to lift the impactor that was constrained by running along vertical bars connected to the machine. Two extra features of the design were the inclusion of a mould filling system using side access and the lifting of the mould to eject the finished block. Experience had suggested that the static impactor provided insufficient force to successful de-mould a compacted block, so a locking mechanism to keep the impactor stationary relative to the moving mould still needed to be added. The letterbox-style single-sided access point for mould filling was a nice idea but involved several moving parts in areas of high soil contamination and would have therefore been difficult to manage successfully.

Mark IV – This design adapted Mark III to include a lever mechanism to lift the impactor and a further mechanism to assist the lifting of the mould whilst keeping the impactor position fixed to eject the block. Mould filling was now accomplished by a dual hopper system filling the mould via larger side chutes. Overall this was an attractive system but the complexity of having the impactor guided within another guide (for the mould) was deemed too complex and awkward to use.

Mark V – The real breakthrough with this design was the incorporation of a two-part mould that could be opened from the side permitting the finished block to be removed from the front of the machine. The novel mould design was used with a single point pulley lifting system for the impactor constrained between vertical guides. A single point chute mould filling system was included to improve access to the machine front and to reduce complexity. A safety mechanism was also included in the mould design so that when the mould was open the impactor could not fall into the open mould space. The only complex component of the design was now the mould and this was seen to be a tolerable compromise.

Mark VI – This last design attempted to incorporate into the Mark V design a degree of automation in the lifting and dropping mechanism. The mould design was also slightly modified to make it easier to operate. Instead of an overhead pulley system a more elaborate system of levers and guides similar to those used in Mark I were included. The design was to be a manually assisted counterweighted lever that was lifted upwards with the impactor until a certain point where the impactor would slide off the lever and drop into the mould. The lever could then be pulled back down and re-engage it with the impactor for another lift cycle. The system also included an upper locking off point so that the impactor could be securely placed prior to mould opening.

After the conceptual modelling of the different design ideas, more detailed design could commence. The Lego® models indicated where problems might be encountered and these would need to be addressed in the detailed design. Between the production of two block making test-rigs and the Lego® models it was hoped that the final selected solution would be an acceptable design for dissemination.

Table 6.3 – Summary of features of different prototype models

Mark	**I**	**II**	**III**	**IV**	**V**	**VI**
Lifting Mechanism	Rotary actuator	Lifting crank	Rope & pulley	Lever, rope & pulley	Rope & pulley	Counter-weighted lever
Dropping Mechanism	Rotary actuator	Falling crank	Rope release	Lever release	Rope release	Rotary actuator
Impactor Constraint	Parallel link	Roller bearings	Linear bearings	Sliding	Sliding	Sliding
Soil Filling	N/A	N/A	Side slot	Double side chute	Single side chute	Single side chute
Mould Design	Straight sided	Straight sided	Straight sided	Straight sided	Two Part	Two Part
De-mould Mechanism	N/A	N/A	Egg laying	Lift mould	Open mould	Open mould
Basis of Test Rig				✓	✓	
Basis of Production Prototype					✓	

The final design that was selected was Mark V with the additional modifications made to the mould as detailed in the previous section. Mark VI was considered to be too complex for dissemination at this stage in the design development. Its features could be incorporated at a later date if desired or deemed necessary.

The final Lego® design attempted to incorporate everything necessary for machine operation in one complete unit. However, in the interests of simplicity only the dynamic mechanism and mould have been incorporated in the Production Prototype. This is the minimum necessary to produce blocks and is detailed in the following paragraphs and diagrams. The other features necessary for machine operation can be determined locally, e.g. the lifting mechanism for the impactor. This leaves the machine design open to interpretation, adaptation and improvisation, which is more appropriate for a developing country.

The configuration used in the Lego® model Mark V was adapted to make the Test Rig. Since this design has proved to be successful, the design proposed for Production Prototype is very similar. Modifications were made to the impactor constraint and the mould as a result of the tests conducted on the rig. Minor modifications were also made to the soil loader as it was too small to contain enough soil to make a complete block with a single charge. The impactor guide was also extended upwards to permit greater travel of the impactor, and to provide greater support when the impactor was raised to permit mould filling.

Other details of the design, such as the impactor guide support, are not essential to the functioning of the machine but are advisable additions to the design. Another feature that had been included in the machine design is the safety mechanism within the mould. Whilst the machine will perform adequately without this, its addition makes the machine much safer to use. The pictures of the CAD models shown in the following figures illustrate the different features of the final design.

Figure 6.6a – CAD model of the mould

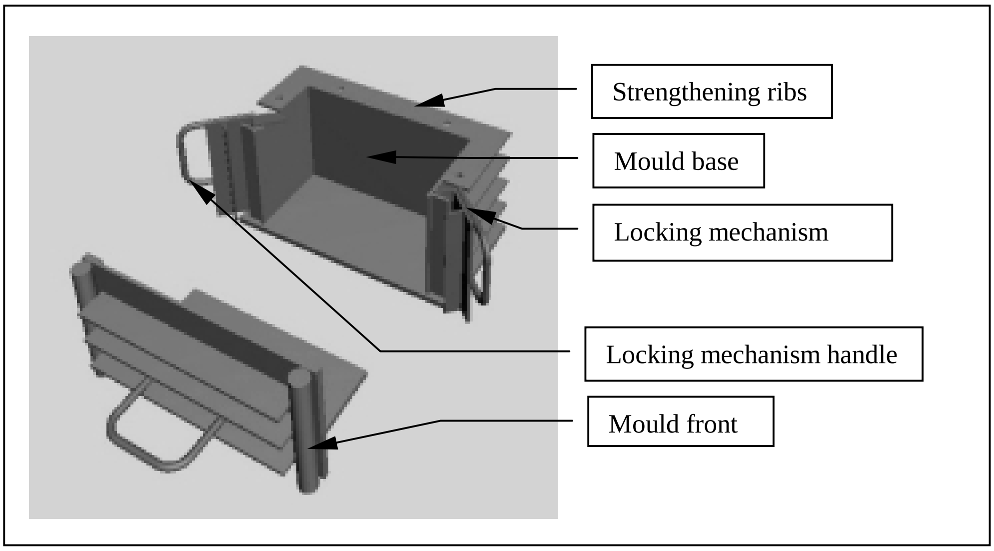


Figure 6.6b – CAD model of the final design

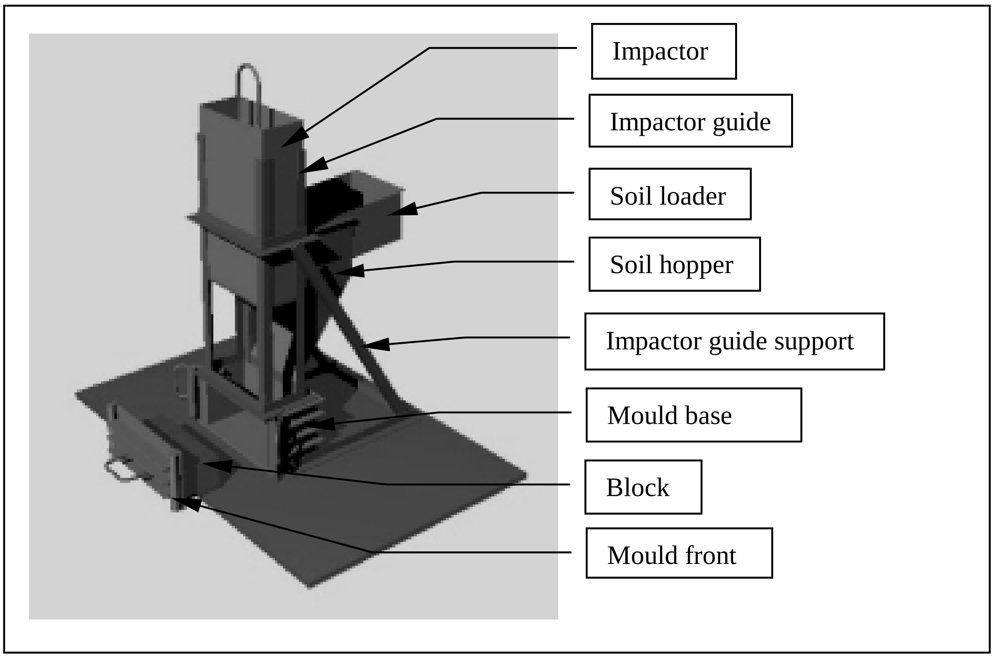

Figure 6.6c – CAD model of the mould safety mechanism

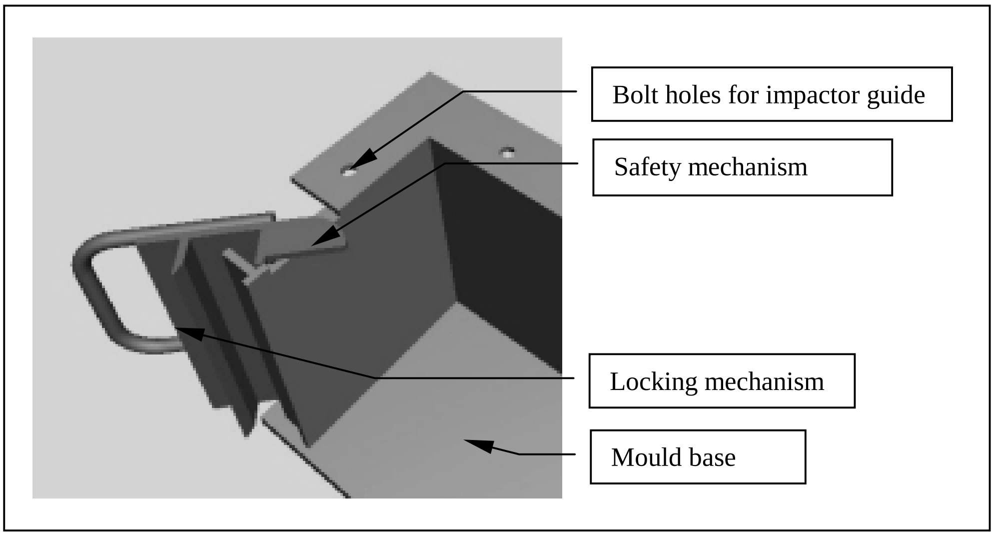


A complete set of drawings was generated from this model clearly showing the different parts of the machine. Scaled versions of these drawings can be found in Appendix D. The dimensional accuracy required for the design was limited to ±0.5mm. The use of the CAD modelling package has helped identify many of the problems in the dimensional accuracy of the design. The different parts are separately modeled and then assembled. The assembly process immediately highlights any problems in the model. This is a very useful tool and gives us greater confidence that the final design will perform as we expect.

6.5 Production guidelines

In the interests of completeness we will now present a brief set of Instructions for Machine Use (for block manufacture). This will help us to also confirm that all major components of the machine are suitably designed and will also be useful for the field testing process described in the following chapter.

6.5.1 Machine foundation selection

The process of dynamic compaction has always required a firm foundation onto which the impact blows can be delivered. It was not known how significant the stiffness of the foundations was until tests were carried out on full-size blocks. Apart from reducing the potential consolidation achieved by each blow, an elastic foundation can also have the detrimental effect of increasing likelihood of material de-lamination, and a more elastic foundation will reflect higher energy shock waves.

The calculated flexural rigidity (EI) (per meter width) of the strong floor used for dynamic compaction experiments was 272MNm^2. A less firm foundation was also created by suspending a 20mm metal plate above the strong floor. This metal plate had a calculated flexural rigidity (per meter width) of 0.133MNm^2. Those blocks produced on the softer foundation were about 10% less dense than those compacted on the strong floor. This is a modest difference in terms of density resulting from a 2000-fold decrease in the flexural rigidity of the foundations. This suggests that the achieved block density is quite insensitive to changes in the foundation flexural rigidity, which is good.

A more noticeable and damaging side effect observed when using the more elastic foundation is that de-lamination of the block is more common. This leads us to suggest that compaction should take place on the most solid and firm foundations available. This may involve the production of a suitable foundation where the machine is set up incurring greater expense, but helping to ensure a better quality block free from any compaction defects.

6.5.2 Block production instructions

These instructions assume that acceptable procedures are already being used for soil preparation and block curing. They list in order the actions that need to be carried out during block production.

1. Lift impactor to locking height, insert bar between the impactor bottom and the upper cross member of the impactor guide, lower impactor onto the bar and ensure it is held safely in position
2. Open and check mould, clear it of any debris and close it again, ensuring the locking mechanism is functioning properly
3. Add the measured quantity of soil to the soil loader
4. Rotate the soil-loader so that the contents fall down the soil hopper and into the mould
5. Lift the impactor slightly and remove the bar
6. Gently lower the impactor onto the surface of the soil
7. Lift the impactor to the desired height, (this can be done visually using points marked on the impactor guide), and drop the impactor onto the surface of the soil
8. Confirm that the impactor did not hit the edge of the mould by listening for the sound of metal hitting metal
9. Continue to apply the required number of blows

10. Lift impactor to locking height, insert bar between the impactor bottom and the upper cross member of the impactor guide, lower impactor onto the bar and ensure it is held safely in position
11. Open mould by releasing the two locking mechanisms
12. Using the ‘rotate and pull motion’ draw the block out of the mould
13. Lift the finished block from away from the front part of the mould
14. Place the block in the curing area
15. Clear the mould of any loose soil and close the mould
16. Repeat items 3 to 15 to make another block
17. An indentation test should be conducted on a number of blocks in each batch to confirm adequate consolidation is occurring
18. Density measurements should also be made frequently as a part of the production feedback

We now have sufficient information and detailed design to share with a collaborator and to begin the process of design dissemination and field trials. The next chapter deals with this next exciting phase of the project.

7 Technological dissemination and field trials

Having established the potential of dynamic compaction theoretically and experimentally we need to conduct field trials of the process in a more representative environment. We wish to assess the Production Prototype for suitability for manufacture in a representative workshop, to test it for short term durability, productivity and ergonomic acceptability, to make any necessary design refinements and to assess the characteristics of produced blocks. The nature and scope of this work cannot be carried out in the UK so an overseas partner was needed to help provide the necessary facilities and environment for field trials to be conducted. In order to improve the readability of this chapter, the first person will be used to distinguish between work carried out by the author and the collaborators.

7.1 Overseas collaboration

Potential partners were identified in Botswana, Ethiopia, India and Tanzania who were all interested in the technology and were prepared to assist in some way. However, it was decided that the Indian partner had the best mix of facilities, expertise and local connections for machine production, development, testing and dissemination. We were extremely fortunate to find a collaborator with strengths in all these areas and who was also willing to collaborate with us without any additional financial assistance.

Our collaborator was Development Alternatives (DA) which is based in India with its head offices located in Delhi. It was established in 1983 as a non-profit corporate organisation and to date has been involved in a number of different areas of sustainable development. It has worked on the application of several technologies in the fields of :

- Construction: Compressed Earth Block, Ferro-cement roof channel, Micro-cement roof tile
- Textiles and paper: Manually driven “powerloom”, Recycled hand-made paper production
- Energy: Biogas electricity generation plants, charcoal briquette production machines
- Water: Portable water testing kits, check-dam construction

The main ethos of DA is to identify locally sustainable practices that generate income and to encourage collaboration between entrepreneurs and local communities in the deployment of these practices. DA has had many successful projects in different regions of India and is always interested to hear of a new technology that may be suitable for sustainable development. When we expressed our wish to collaborate with them in the development of a new type of block machine they were interested enough to accept the challenge and meet the primary practical needs of the project. We were reasonably convinced that the team at DA could manufacture our machine (called ‘Block Impacterre’) and also provide very useful development suggestions from their experience in block machine manufacture. Their connections with other organisations and knowledge of possible sites for building trials would also be very useful for further technological dissemination.

A 4-week visit was set up and suitable funding for the project was obtained. Engineering drawings of the machine were sent out about 4 weeks before the scheduled visit. Two copies of the machine plans were sent under separate cover by mail to DA. The arrival of the plans was confirmed and further communication was done through e-mail.

7.2 Experience with machine

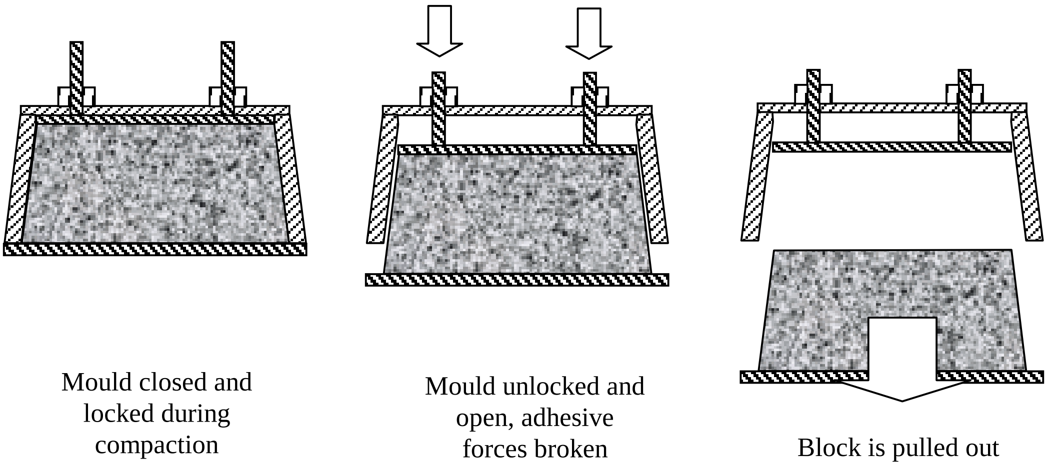
Upon arrival in India contact with DA headquarters was made and from there I went to the workshop where the machine was being produced. I had anticipated that further machine production would be necessary, but it was with great surprise and delight that I found the machine was ready for assembly and testing. This section will summarise some of the machine modifications and block production issues faced during the testing.

The machine was fully built but some of the finer details had been omitted. These were not a major problem, but would need attention eventually. The impactor for example had not been filled with concrete, but with sand. This proved to be a poor solution and the sand was replaced eventually by concrete. The machine foundation was a large metal plate about 20mm thick that unfortunately had protrusions on the underside causing the machine to bounce during each blow. This produced a foundation similar to the soft foundations that were experimented on in the UK. The dimensional tolerance of the machine construction was generally within the ±0.5mm that was recommended. However, the design of the impactor guide was not completely understood and consequently the mould dimensions were very slightly smaller than the internal impactor guide dimensions. This resulted in the impactor hitting the side of the mould on its descent, thereby slightly damaging the mould and causing less energy to be delivered into the block.

Another issue that was immediately brought to our attention was the problem with de-moulding. This was a design fault rather than a manufacturing problem. It was quickly apparent that the proposed de-moulding procedure of the “rotating and pulling” the front of the mould was not going to work successfully. It seemed that the adhesive force between the block and the walls of the mould was higher than anticipated. Several blocks were made and great difficulty was experienced in removing them from the mould, furthermore most had major defects. The proposed solution was to redesign the mould to include a slight taper to assist block ejection. A further proposal was to install a plate mounted on linear bearings on the back face of the mould to push the finished block out the mould rather than try pulling it out. These suggestions were based on the team’s understanding of other block making machines that they had worked on.

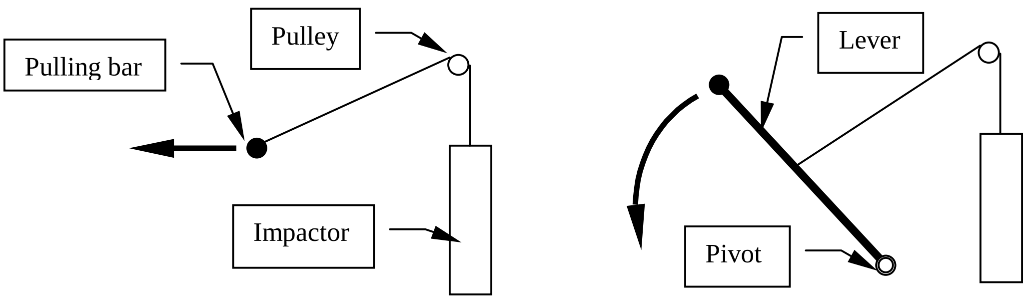
The diagram in the figure below shows a plan view of the modified mould design illustrating the concept of using the taper in the mould to release the adhesive forces between the block and the mould walls. Once the bond is broken then the block can be pulled out from the front of the mould with ease.

Figure 7.1 – Tapered mould design with ejection mechanism (plan view)



The original sand-filled impactor was not weighed, but with the single overhead pulley and rope arrangement three people were needed to lift it. Two people could not exert the necessary force to lift the impactor for a sustained period and so a third person was introduced to help. A bar was attached to the end of the rope to give each operator something to grasp and to ensure that the three operators were operating in unison. The figure shown below illustrates this lifting mechanism and the adapted lever system described below.

Figure 7.2 – Modified lifting mechanism for the impactor



This lifting system was later modified to include a lever that provides a 2:1 lever ratio and reduced the necessary force so that only two operators were necessary. The concrete impactor mass when it had been cast was approximately 66kg. This could still be lifted and dropped using the rope pulley and lever system by two operators.

Generally the concept of dynamic compaction was well received. Our collaborators hoped that the main advantage of this method of compaction would be the improved surface finish of the block. This was one of the major problems with CSSB and initial trials indicated that dynamic compaction offered a superior block finish compared with other block presses. The team was also impressed with the level of compaction achieved by the machine and was hopeful of its potential.

7.3 Machine assessment and block analysis

Once the modifications were made to the machine, block manufacture and testing could be conducted. The main aim of the block manufacture was to test the block characteristics and to compare these with the characteristics achieved by other available block machines. Two other machines were at the DA workshop that could be used to manufacture CSSB, one was a diesel-driven hydraulic press and the other a manual lever-operated press.

7.3.1 The testing procedure

In order to make a meaningful analysis of the blocks produced by the different machines, they all need to made in similar ways and analysed using the same tests. A suitable sample of soil was available on site and this was used to make all of the blocks, we will call it soil-I. A particle size distribution analysis was carried out on soil-I and the results can be found in the Appendix A. A constant quantity of cement (5% by weight) was mixed into each of the batches of soil. During testing the same quantity of water was added to the mix each time, however moisture content analysis indicated a slight difference in the moisture content for each batch of material. The blocks were produced on the three machines using their best machine settings. The pressure applied using the manual machine (Balram or BAL) and the hydraulic machine (Hydraform or HYD) could not be modified, however the level of compaction delivered by the dynamic compaction machine (Block Impacterre or BI) depends on the number of blows applied and the impactor drop height. These two variables were kept as constant as possible during the tests. The blow number did not vary by more than ±1 blow and the impactor drop height unfortunately varied between 350-450mm.

Once the blocks were manufactured they were then carefully weighed to ±25g and measured to calculate their volumes. An indentation tester similar to the one used in the UK had been made in India and this was used on the surfaces of the blocks to determine the uniformity of the blocks. It was also used to gain the necessary data to calibrate the indentation tester from the compressive strength of the blocks. The finished blocks were then cured under plastic for 6 days during which they were sprinkled with water regularly. At the end of day 6, half of the blocks were put underwater, while the other half were placed in an oven for 24 hours at 105°C. At the end of their time in the oven or under water, they were then re-weighed and re-measured to calculate their respective wet and dry densities. All the blocks then had the indentation test repeated on them before they were crushed in a compression machine, noting the maximum load before failure. The results of these tests can be found in Appendix H.

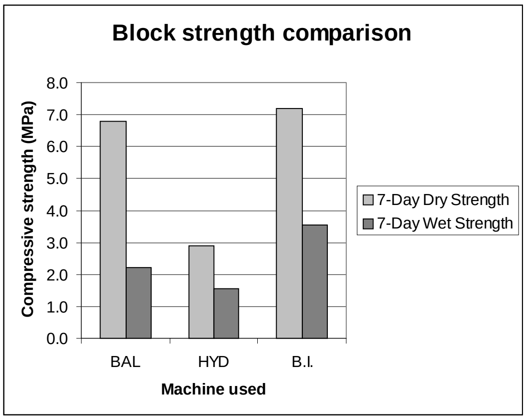
It was not possible to conduct all of the desired testing during the 4-week visit. Consequently, during the testing procedure a member of the team from DA observed the testing and carried out some of the tests personally. That way future tests should be conducted in similar manner and with similar levels of accuracy. The data from these tests were then sent back to the UK for further analysis and inclusion into the thesis report. This data can also be found in Appendix H.

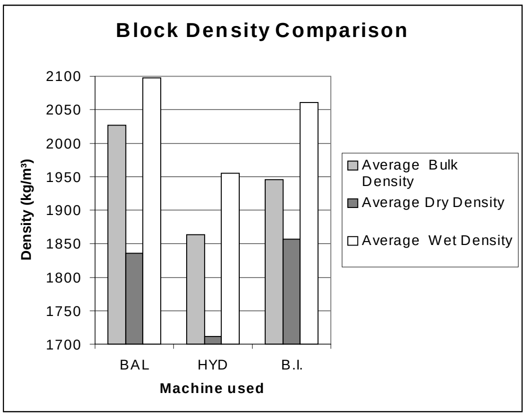
7.3.2 Initial machine comparison

We now wish to compare the output of the three different machines and draw some initial conclusions. The most obvious criterion for block comparison is the wet compressive strength (W.C.S.). We believe that density is a good surrogate for strength and the indentation tester also indicates possible strength of the material, but initially these methods were not calibrated for the soil and the conditions, so we must only use the W.C.S. measure.

The results of the wet and dry compression tests and the density calculations for the bulk (freshly ejected), dry (oven dried) and wet (soaked) density of the blocks from the three machines can be seen in the figure below.

Figure 7.3 – Initial results for comparing block machines





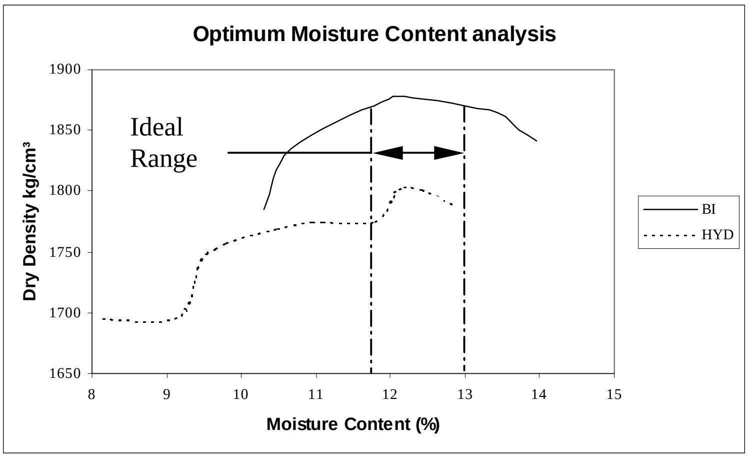
Although these are only the initial test results it can be seen that the BI blocks have performed significantly better than both the BAL and HYD blocks. Part of the reason for the difference is the different moisture contents used in the different machines. Testing of the soil after mixing indicated that the average M.C. for BAL was 12%, HYD was 10% and BI was 8%. The M.C. for BI was lower than desired and we would have expected even better block characteristics with higher water content.

The team at DA estimated that the cost of building Block Impacterre would be similar to the Balram (£500) as it contains similar quantities of material and has similar machining complexity. The block production rates for the BI was estimated to be between 60-100 blocks per hour. Unfortunately the block performance results do not provide conclusive evidence, as there were unavoidable differences in the production using the different machines. Furthermore, we do not know the inherent variability of the production methods used so it is difficult to conduct statistical analysis on these results.

7.3.3 Further block production and testing

After returning to the UK more blocks were produced using the *Block Impacterre* and the *Hydraform* machines in India. Unfortunately the block production and analysis regime was not exactly the same as the initial tests and consequently cross comparison will not be possible. However the larger numbers of block produced do provide a much better data set for statistical analysis. A new mixture of raw material containing soil-I (65 or 63%) and sand (30%) was used during the block production instead of the 95% soil-I used initially. Cement content was either 5% or 7% by mass and the optimum moisture content for *density* was established for both machines experimentally (shown in the figure below). DA further modified the BI machine to include an impactor stop to ensure a constant drop position for each blow.

<u>Figure 7.4 – OMC analysis of two machines</u>



Unfortunately the data received from the blocks made during these tests was not recorded in a way that identified individual blocks adequately. Many blocks had their density calculated and the indentation test conducted on them and several of these were crushed, but there is no obvious way of determining what density the crushed blocks had. Consequently the density and indention tests will have to be analysed in isolation from the W.C.S. results. Further confirmation of the indentation test performance and the density/strength relationship would have been beneficial, but this is not possible with the data received.

The data in the following two tables summarise the results of block production using Block Impacterre and Hydraform. For each machine two groups of blocks were made, Group A (batches 1-4) had 5% cement, Group B (batches 5-8) had 7% cement. The data shows the average P.D.D. and the average indentation diameter (ϕ) for each cement content used. The variation in the moisture content observed during different batch production has also been included for completeness and to check the reliability of the production method. Statistical analysis has been conducted on the data to determine the significance of changing the cement content on the P.D.D. and ϕ.

<u>Table 7.1 – Density and indentation results of Block Impacterre blocks</u>

Group (10/batch)	Cement Content	M.C.		P.D.D. (kg/m³)		Indentation ϕ (mm)	
		Average	C. of V.	Average	C. of V.	Average	C. of V.
A (1-4)	5.0%	10.85%	4.32%	1890	1.92%	17.4	11.46%
B (5-8)	7.0%	10.36%	1.97%	1863	2.04%	18.3	13.23%

Statistical analysis						
Comparing	Standard Deviation of pop'n	Standard Error of means	Standard Error Difference	Difference Of Means	DOM/SED	Significance Normal Distribution
M.C.	0.0047	0.0023				
	0.0020	0.0010	0.0026	0.0048	1.90	94.26%
P.D.D.	36	6				
	38	6	8.31	27.43	3.30	99.90%
Indentation	2.0	0.3				
	2.4	0.4	0.50	0.92	1.86	93.72%

The analysis shows that for Block Impacterre blocks there is an almost 95% probability that the ranges of moisture contents used for the two groups are not from the same population, indicating a change in production method. This helps to account for the 99.9% probability that the P.D.D. achieved are not from the same data set either, (i.e. they are *statistically* significantly different). This is because even a small variation in the moisture content can change the P.D.D. by a noticeable amount. However, the results do not indicate that there is a commercially significant difference in the sets of blocks produced as their P.D.D. are within ±1% of each other.

Table 7.2 – Density and indentation results of Hydraform blocks

Group (10/batch)	Cement Content	M.C.		P.D.D. (kg/m^3)		Indentation ϕ (mm)	
		Average	C. of V.	Average	C. of V.	Average	C. of V.
A (1-4)	5.0%	10.99%	6.09%	1769	2.47%	18.4	9.25%
B (5-8)	7.0%	11.18%	2.76%	1764	0.56%	18.7	5.63%

Statistical analysis						
Comparing	Standard Deviation of pop'n	Standard Error of means	Standard Error Difference	Difference Of Means	DOM/SED	Significance Normal Distribution
M.C.	0.0067	0.0033				
	0.0031	0.0015	0.0037	0.0019	0.52	39.70%
P.D.D.	44	7				
	10	2	7.09	4.63	0.65	48.44%
Indentation	1.7	0.3				
	1.1	0.2	0.32	0.27	0.86	61.02%

By contrast, in the case of Hydraform blocks, the data shows that there is no statistically significant difference between the two groups in the moisture content used. Having established that the production method is not significantly different we can assess the difference in the P.D.D. and ϕ. The results show that there is no statistically significant difference in the P.D.D. or ϕ. From this we can conclude that the additional cement has not affected these two output measures significantly.

The data presented in the two tables above give us more material for machine comparison. It appears that the P.D.D. achieved by the *Block Impacterre* machine is higher than the density achieved by the *Hydraform*. This can be confirmed as statistically and practically significant for the 5% cement batches. Unfortunately there is a statistically significant difference between the moisture content used in the two machines for the 7% cement batches that makes further comparison inconclusive. On average the *Block Impacterre* delivers a 6% increase in density above the *Hydraform* machine. Such an increase in density will also yield an increase in the compressive strength that is of great practical significance (possibly 60%).

Despite the large variation in the indentation diameters (ϕ) recorded, there is a statistically significant difference between the results collected from blocks made by each machine. Again, only the 5% cement batches can be analysed. Not only is the difference in ϕ noticeable *statistically*, the difference also displays the correct phenomenon that a denser block yields a smaller value for ϕ. For *Block Impacterre* a P.D.D. of 1890kg/m^3 yields a ϕ of 17.4mm, whilst for *Hydraform* a P.D.D. of 1769kg/m^3 yields a ϕ of 18.4mm. This demonstrates that the indentation tester provides meaningful results, but its sensitivity to changes in P.D.D. is too small for practical application. We would prefer a sensitivity of about 1mm/25kg/m^3 rather than 1mm/120kg/m^3. This could be achieved by changing the cone angle of the indentation device and/or increasing the weight of the falling mass striking the indentation pin.

We also received results for the strength of the blocks produced by both of the machines. Blocks were crushed in batches of five to determine their 7-day and 28-day W.C.S. for both cement contents used. This data has been summarised in the table below indicating the average W.C.S. for each configuration. In every case the recorded strength of the Block Impacterre blocks exceeded the Hydraform blocks and the average ratio of BI strength : HYD strength is 1.425. However only three out of the four comparisons (5% cement 7-day, 5% cement 28-day & 7% cement 7-day) show a statistically significant difference. The 7% cement 28-day BI specimens have a number of irregularities. Firstly, the C. of V. is unusually high, 23.8% instead of around 10%. Secondly, the blocks are weaker than the 5% cement specimens; they should be stronger with more cement. Thirdly, their measured density is about 2.5% lower then the 5% cement blocks, a difference that could result in a 25% loss of strength. These factors point to some error in the block production for the batches used to gain the 7% cement 28-day strength data for BI.

Table 7.3 – Strength analysis of blocks produced by different machines

Batch (n=5) Soil-I with 30% sand Machine	Cement Content (%)	Curing Period Days	Average W.C.S. MPa	C. of V. (%)	Ratio of W.C.S BI / HYD	Statistically Significant >95%
Block Impacterre	5.0	7	4.6	10.1		
Hydraform	5.0	7	3.2	6.4	1.44	Yes
Block Impacterre	7.0	7	5.6	10.2		
Hydraform	7.0	7	3.8	2.9	1.46	Yes
Block Impacterre	5.0	28	6.4	10.3		
Hydraform	5.0	28	3.7	1.0	1.72	Yes
Block Impacterre	7.0	28	5.8	23.5		
Hydraform	7.0	28	5.4	5.8	1.08	No

Statistical analysis						
Comparing W.C.S.	Standard Deviation	Standard Error	Standard Error Difference	Difference Of Means	DOM/SED	Significance Normal Distribution
5% cement	0.47	0.21				
7-days	0.21	0.09	0.23	1.41	6.13	>99.99%
7% cement	0.57	0.25				
7-days	0.11	0.05	0.26	1.77	6.85	>99.99%
5% cement	0.66	0.30				
28-days	0.04	0.02	0.30	2.69	9.09	>99.99%
7% cement	1.36	0.61				
28-days	0.31	0.14	0.62	0.43	0.69	50.98%

The strengths recorded here are noticeably higher than those experienced during initial tests using only soil-I, (see graphs in Figure 7.3). It would appear that the addition of sand to the soil significantly improves the strength of the material as it increased the average BI block 7-day strength from 3.6MPa to 4.6MPa and the average HYD block strength from 1.7MPa to 3.2MPa. The inherent variability of the strength (±10%) seems to be consistent with the previous tests so we can presume that the tests have been conducted in a satisfactory manner. It is a shame that the BI blocks inherent variability is so much higher than the Hydraform bocks, but this is probably due to the very different compaction mechanism employed during consolidation. The variability of ±2% on density and ±10% on strength is an acceptable range for experimental analysis.

The strengths demonstrated by the BI blocks are all much higher than the original specifications of 2MPa strength after 7-days. If we assess these blocks using the Indian standard for masonry walling (28-day W.C.S. of 3.5MPa) we find that they all comply. Furthermore, all of the BI blocks achieve this strength after only 7 days. The general trend exists that the 28-day W.C.S. is about 25% higher than the 7-day W.C.S. In order to achieve a 3.5MPa strength at 28-day one wishes to achieve at least 2.5MPa at 7-days. Again, all of the blocks above comply with this. Recent work on CSSB durability conducted by (Kerali, 2001) shows that 28-day W.C.S. of 3.5MPa is an acceptable standard to ensure adequate durability. Therefore we can say that these blocks have adequate strength and durability.

7.4 Dissemination overview

Apart from gaining the practical experience in the field with the technology in a more representative environment, the field trials also gave us more experience in the process of technology dissemination. From an academic perspective this is valuable to us as it helps to provide and promote technology in ways that will be more accessible and appealing to those who will derive most benefit from it.

One of the big problems with technological dissemination is transferring information. This is a problem for both the end user communicating their real needs and desires to the research body and also for the researcher sharing their work with those would most benefit from their research. During the visit to India there was the opportunity to speak directly with those who were more actively involved in supplying technological solutions to local needs. From these conversations it was found that current CSSB technology was not cost effective and with a poor track record CSSB was considered a second-rate material. Those who can afford to, build used burnt brick rather than CSSB. This poor perception of the material was not obvious from the information available to us at the start of the project. We knew that CSSB didn’t perform as well, but we didn’t know that it already had a bad name, which would be difficult to overcome.

The technological advancements that were proposed during the project all took a poor material and made it slightly better. There was no major breakthrough in terms of material performance, only cost reduction and material savings were realised. These improvements alone would not be enough to sway people from a tried and trusted less expensive material (burnt brick) to CSSB. A switch seems much more likely if burnt brick was much scarcer as it is in the region of Bangalore in India. CSSB technology has been much more successful there due to a lack of appropriate alternatives.

Getting people to change their minds about techniques or products requires clever marketing and communication. However, successful marketing tools are not easily applicable to this level of technology and propagated in areas of poor communication. The team at DA suggested that an effective method of getting new technology accepted is to initiate it with a middle-class group rather than with the very poor. Something perhaps initially expensive, but desirable and cutting edge, which is a modest challenge with a low-cost mud brick machine. The Hydraform machine presents a high tech solution at a high price and leaves no possibility of local artisanal replication or even maintenance. However, if the Block Impacterre was initially marketed as a high tech solution that provides the same sort of product as the Hydraform machine but for a much lower price, that would make it more attractive. As the new-technology is accepted by the more prestigious and wealthy it becomes much more desirable to the poor. Now, the low complexity of the Block Impacterre machine leaves the potential for artisanal copying and maintenance if some marketable high-tech features are left out, without greatly compromising the machine performance.

Another issue that was not obvious from the information available in the literature was that environmentalists in India consider the use of soil for building a bad practise. Whilst in the United States earth building has become more acceptable for environmental reasons, in India the use of soil for building reduces the soil that could be cultivated for crops. Instead environmentalists recommend the use of waste materials such as fly-ash from power stations. This material has been used successfully with the Hydraform machine to make blocks with a compressive strength of 30-40MPa. This impressive product is only hampered by the poor availability of the fly-ash material in areas away from the power stations, and the fact that Indian annual production of fly-ash is only a small fraction of the annual tonnage of walling materials used in the country.

We have demonstrated that the dynamic compaction technique is superior to quasi-static compression both during experiments and field trials. With the information gained from the overseas collaboration there are still outstanding questions about the economic viability of the new technology, its acceptance among the low-cost building market and it's environmental implications. For the purposes of this research we are only able to investigate the economic viability of the technology compared with the other machines available. The next chapter analyses machine productivity and block viability.

8 Commercialisation and feasibility study of impacted blocks

We now have details of the characteristics and performance of dynamically compacted blocks and the machine used to make them. We wish to quantitatively compare these with those of a suitable competitor to conduct a feasibility analysis. This chapter is split into three sections. The first investigates the features of the machines used in India to produce CSSB (including the Block Impacterre developed during my research). The second section normalises the material produced by each machine to a suitable standard and compares the requirements of each machine to produce adequate CSSB. The final section summarises these findings and suggests how feasible the dissemination of *Block Impacterre* into the block-making market would be.

8.1 Machine analysis and comparison

We wish to compare the machines used during the production of CSSB using a number of different criteria. Three criteria that are easily assessed for each machine are its respective cost, production rate and energy consumption. A further criterion for assessment is the wet compressive strength of the material that each machine produces with similar raw materials. Our data for this criterion is divided up into the results gained when I was in India, (which included the investigation of three machines) and the comparative analysis of only Block Impacterre and Hydraform conducted by collaborators after I returned to the UK. The Hydraform machine in its various models is a market leader in several countries. Due to problems with some of this data only the 7-day wet compressive strength has been included in this analysis.

The table below presents the summary of the different criteria for machine comparison. Some of the values presented have been estimated in good faith using the experience of the collaborator. Several values for the 7-day wet compressive strength have been presented. These highlight the difference between the machines when sand is added to the soil mix for CSSB production and also the improvement obtained.

Table 8.1 – Machine comparison

Machine name	Balram	Hydraform	Block Impacterre
Origin	India	South Africa	Warwick University
Machine cost (2001) £1 = Rs 70	Rs 36,000 £510	Rs 200,000 £2860	(Rs 35,000) (£500)
Production rate Blocks/hr	120-180	50-100	(60-100)
Energy consumption per block	0.75kJ	180kJ	3.7kJ
Average 7-day W.C.S with 5% cement, 95% soil (3 samples)	2.2MPa	1.6MPa	3.6MPa
Average 7-day W.C.S with 5% cement, 65% soil, 30% sand (5 samples)	N/A	3.2MPa	4.6MPa
Average 7-day W.C.S with 7% cement, 63% soil, 30% sand (5 samples)	N/A	3.8MPa	5.6MPa

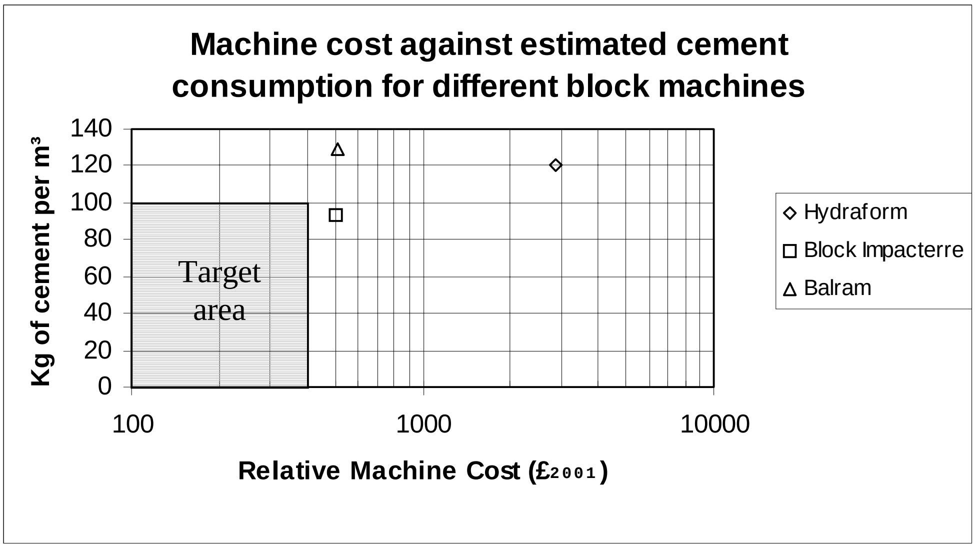
Figures in parenthesis are projected

Block Impacterre performs adequately in terms of production rate and energy consumption, and delivers better results on W.C.S. due to increased material consolidation. *Hydraform* has an excessive energy requirement because of the diesel engine used to power the hydraulic press, something that neither *Balram* nor *Block Impacterre* suffer from being manually operated machines. The assessment indicates that on the combined basis of machine cost, production rate and W.C.S. the Block Impacterre machine is the best performer.

A comparison of different machines was presented in Chapter 2 and identified the target area of a lower-cost machine with a lower cement demand. By applying the data from Chapter 7 and making certain assumptions, we can recreate that comparison for the three machines used in India. We have attempted to normalise the CSSB block performance from each machine by adjusting the cement content. The initial test using only soil and 5% cement indicated that 5% cement was sufficient for *Block Impacterre* to achieve 3.5MPa. But both *Hydraform* and *Balram* required a boost in cement to comply with this standard. Consequently we have selected a cement content of 7% for these two machines. From these figures and the block densities that each machine produces we can calculate the cement requirement per cubic meter of walling material using only soil and cement.

The graph below presents this data for the three machines. Whilst *Block Impacterre* does not achieve the target (<100kg cement per m^3 and < £400 per machine) originally suggested, it is the closest machine to it by a fair margin. Furthermore, a 20% reduction in the cost of *Block Impacterre* would bring the machine into the target area. *Balram* requires a significant reduction in its cement demand as well as a similar reduction in machine cost. *Hydraform* is too far away from the target area to be a possible contender.

Figure 8.1 – Re assessment of CSSB machines using recent data

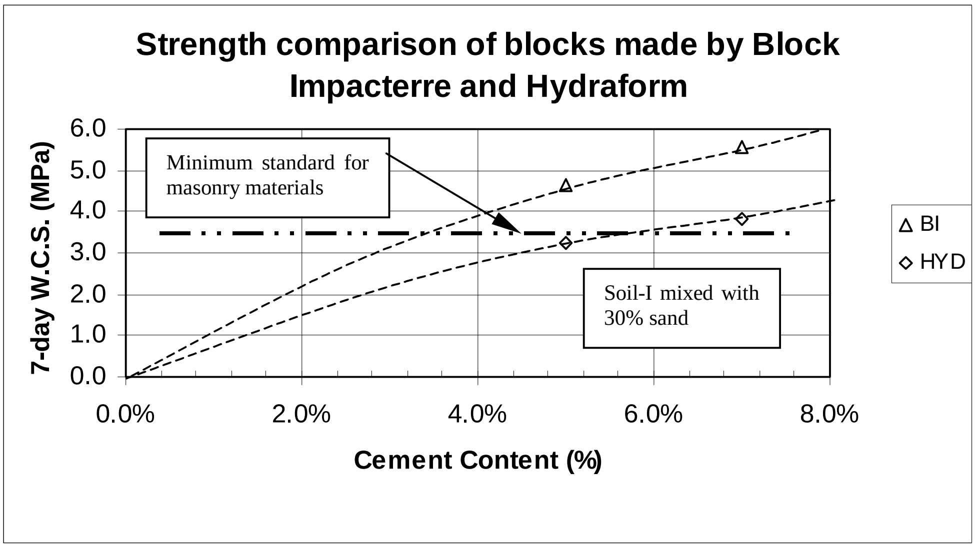


8.2 Material analysis for performance

It has been necessary to use material performance as a criterion for machine comparison. We now wish to assess the material produced by these CSSB machines to see their potential for meeting the needs of low-cost building materials in tropical regions. The building regulations in India require a minimum 28-day wet compressive strength of 3.5MPa for all masonry walling. (Kerali, 2001) recommends a similar figure for durable CSSB walling blocks. We will adopt this as the comparative strength of the materials produced by different machines instead of the 2MPa chosen for the analysis in Chapter 2.

The graph shown in the figure below projects the 7-day W.C.S. for different cement contents for the Hydraform and Block Impacterre. We know the general relationship between strength and cement content from our experience with CSSB, so we can approximately predict from the results gained in India the necessary cement content required for either machine to produce CSSB with a 7-day W.C.S. of 3.5MPa. The material used here includes 30% sand, permitting a reduction in the cement content of the CSSB.

Figure 8.2 – Block strength using different machines and cement contents



From this graph we can project that a block manufactured from soil-I with 30% sand by *Block Impacterre* requires about 3.5% cement to achieve the desired strength, whilst *Hydraform* needs closer to 5.5%. If sand is not used then the machines require 5% and 7% cement respectively to achieve the same standard. We can now use these figures to conduct an analysis of the CSSB production using these two machines and the different raw materials available.

In Chapter 2 and Chapter 3 a comparison of low-cost building material and CSSB variants was presented. Using a similar strategy and assumptions it is possible to calculate the respective energy consumption and cement requirement for walling made with these machines and different raw materials. Any requirement for sand in the CSSB production makes on-site production marginally less suitable. The analysis indicates that *Block Impacterre* uses less cement and less energy than *Hydraform* per square meter of walling produced. Furthermore, with *Block Impacterre*, the addition of sand to the soil yields a cement demand of less than the original target of 15kg/m². Even without the sand the analysis indicates that a normal CSSB requires only 17.5kg/m² instead of the originally calculated 18.7kg/m² in Chapter 3.

Table 8.2 – Comparison of CSSB walling material from different machines

Machine	**Dimensions ($l \times b \times h$)**	**Note**	**Energy**	**Cement**	**Suitability for production**	
					'Locally'	**On-site**
	Mm		MJ/m^2	kg/m^2	Ranking	(1 = best)
Block Impacterre (with 30% sand)	290 × 140 × 90	1	309	14.0	2	3
Hydraform (with 30% sand)	215 × 221 × 116	2	529	22.8	3	4
Block Impacterre (without sand)	290 × 140 × 90	3	273	17.5	1	1
Hydraform (without sand)	215 × 221 × 116	4	466	29.0	2	2

Notes

0. All cement is assumed to have been transported 100km, all sand transported 25km and all material has a 7-day W.C.S. of 3.5MPa.
1. High-density (1925kg/m³) solid blocks manufactured on-site from local soil mixed with 30% sand and 3.5% cement, laid with 10 mm of soil/cement mortar (20% cement) and no render.
2. Medium-density (1775kg/m³) solid blocks manufactured on-site from local soil mixed with 30% sand and 5.5% cement, dry stacked with no external render.
3. High-density (1925kg/m³) solid blocks manufactured on-site from local soil mixed with 0% sand and 5% cement, laid with 10 mm of soil/cement mortar (20% cement) and no render.
4. Medium-density (1775kg/m³) solid blocks manufactured on-site from local soil mixed with 0% sand and 7% cement, dry stacked with no external render.

8.3 Feasibility study

The analysis in the previous two sections have demonstrated that dynamic compaction of CSSB using the *Block Impacterre* provides reasonable reductions in machine and walling cost without compromising the material properties of the finished block. It is possible to financially analyse these machines if we assume their respective working life to be 4 years for 240 days a year. We know the productivity of the machines from earlier analysis and their cement demand for adequate material properties. Taking a cost of cement as £0.05/kg (Rs 3/kg) we can draw up a projected total cost/m² of material produced using each machine.

Table 8.3 – Projected costs of walling for machines during lifetime

Machine and material	Cost (£)	Block production	Cost/m² (£)
Hydraform (soil)	2860	768000 blocks (1)	1.60
Block Impacterre (soil)	500	461000 blocks (2)	0.91
Hydraform (soil, 30% sand)	2860	768000 blocks (1)	1.29
Block Impacterre (soil, 30% sand)	500	461000 blocks (2)	0.74

(1) Average of 100 blocks per hour for 8 hours a day, 240 days a year for 4 years.
(2) Average of 60 blocks per hour for 8 hours a day, 240 days a year for 4 years

It appears that the *Block Impacterre* delivers a 40% reduction in walling costs compared to the *Hydraform* with or without sand in the blocks. The running cost of the machines and their respective maintenance has not been included in the analysis. Assuming that both machines use the same labour force the *Hydraform* also requires diesel to operate and more complex maintenance than the *Block Impacterre*. These factors would push the running costs of the *Hydraform* up higher. From an economic viewpoint, it appears that the process of dynamic compaction is superior to high-pressure quasi-static compression.

Proving that the process and machine is cost competitive is unfortunately insufficient to claim its future success in the market of low-cost walling. Certainly such significant savings would prompt many to try the new technology and this is most certainly what we hope would happen. However, the relative success of the *Hydraform* machine compared to the *Balram* may indicate that a mechanised machine is looked upon as better investment for entrepreneurs. The *Block Impacterre* was never designed to be part of the high-tech market, but was designed to fit into cottage industry type of environment. The problem with a low-tech and low-cost machine may be the limited resources for marketing, advertising and dissemination that is available for that type of product.

9 Conclusions and recommendations

The research conducted during this Ph.D. has increased our understanding in several areas related to the production of low-cost building materials. This chapter aims to draw together the different aspects of block manufacture, machine design and analysis of impact compaction. It is split into four sections and each section makes recommendations for further work. The first section details the investigation of CSSB potential and acceptability. The second section extends this to include the work conducted on dynamic compaction of CSSB. The third reports the analysis of the mechanisms behind dynamic compaction and the implications for CSSB production. The final section includes the findings of overseas field trials and feasibility study of the application of dynamic compaction to CSSB block production in a developing country.

9.1 Acceptability and potential of CSSB

The use of earth as a building material is well known and its highly variable performance is well documented. Specific research in the production of building blocks over the years has revealed certain features of the material. Generally un-rendered low-cement (<6%) and low-density (<1800kg/m^3) CSSB exhibit an unacceptably low tolerance to humid conditions and will deteriorate during less than 10 years. This deterioration is typically in the form of spalling of the exterior surface.

By increasing the cement content, and/or the density, the stability of the material is greatly enhanced and becomes more acceptable for use in humid areas.

Performance of the CSSB is usually defined by its wet compressive strength. Literature suggests that a CSSB that exhibits a 28-day wet compressive strength of 2MPa is considered a first class material (Houben & Guillaud, 1994). Previous research into CSSB production indicated that for suitable soils doubling the cement content more than doubles the wet compressive strength. It has also been noted that a 10% increase in density can approximately double the wet compressive strength. Higher cement content generates a more expensive material, but if a significant increase in density could be realised then the cement content could actually be reduced without harming the performance of the material. From this the potential of improving the performance for stabilised soil and more specifically CSSB has been identified.

There are other reasons for promoting the use of CSSB for low-cost walling. Several sources have indicated that environmentally unacceptable practises are currently involved in the delivery of low-cost walling. The use of clamp-fired brick and river sand is proving to be unsustainable in the long term and resources necessary for their production are becoming scarcer. CSSB has been identified as a more environmentally and socially acceptable alternative, if its production and use is carefully controlled.

An assessment of several different types of building materials indicated that high-density CSSB was the only material that consumes a modest amount of cement and has a low-energy requirement in its production and subsequent erection. Different block variants were also explored and these indicated that taller, interlocking and hollow blocks had the most promise for further reducing the cement requirement of the material.

Testing of the finished CSSB involved a crushing test using sophisticated equipment and destroying the CSSB. The CSSB achieved the desired strength of 3.5MPa after 28-days. Unfortunately a suitable non-destructive test was still unavailable. The relationship between the density of the compacted material and the compressive strength showed potential as a method of strength estimation. Unfortunately this technique requires a careful production regime and calibration for each mixture of soil, cement and water. As this was not seen to be a practical solution an indentation tester was developed instead, which provided an indication of densification and the block strength. Readings could be taken at any point in the production cycle as a comparative measure of block performance. It could indicate large changes in block characteristics without the need for destructive testing. The limits of its accuracy were about 0.5MPa, so only changes in block characteristics larger than this could be identified. Improved resolution of the device could be achieved by modifying the shape of the indentation tip.

9.2 Performance of dynamic compaction

The application of dynamic compaction to stabilised soil was initially investigated using small cylindrical samples. The results of the investigation were then extrapolated to the production of full-size blocks. Trials at the smaller scale confirmed previous findings that dynamic compaction is more energy efficient in consolidating soil than quasi-static compression. This finding was not however replicated during the production of full-size blocks until their moisture content was raised from 6% to over 9%.

It was originally assumed that the lower moisture content suggested by the cement literature was more acceptable than the less handlable blocks with the higher water content. Trials indicated that the concrete literature did not apply to the production of stabilised soil and a much higher water content could be used successfully. The experimental evidence showed that adjusting the moisture content to achieve the greatest consolidation was an effective method of improving the strength of the material. This finding was consistent with the “optimum moisture content” defined in the soils literature.

Previous CSSB production guides suggest relatively basic systems for monitoring and controlling the moisture content, (drop test) and the quantity of material used to produced each CSSB, (volumetric measurement). After seeing how a small variation (2% drop) in the water content can have a pronounced effect on the block properties (50% drop in strength), it would be much better to implement an improved system of moisture control. Careful weighing is difficult to achieve in the field, but a small-scale compaction test may provide a suitable alternative for moisture content optimisation. The material measurement currently done by volume should be done by mass instead. The calculated density of the compacted material can be used as a method of feedback after block ejection only if an adequate system for mass measurement is incorporated in block production. Such systems are currently not in use, but the development of them would be beneficial in the field of CSSB production.

The process of dynamic compaction was investigated and compared with the equivalent quasi-static compression process. Both methods of consolidation exhibited similar levels of variation, ±1% on density and ±10% on wet compressive strength. The low variability of density was helpful in determining the optimum parameters for the dynamic compaction process. Earlier studies indicated that a heavy impactor with a low velocity provided marginally more effective material consolidation. Experiments conducted on small scale confirmed that this was true, and these findings were extrapolated to full-size. Full-size blocks required a higher energy transfer and therefore required a more massive impactor. A practical upper limit for the impactor mass was suggested as 80kg and 60kg was found to yield satisfactory results. The drop height of the impactor also had an upper limit because of the generation of a destructive reflection wave at high impactor velocities. It was found that a drop height of 400mm was acceptable on a firm foundation, but if a reflection wave was generated the drop height should be reduced.

Analysis of the potential of CSSB indicated that different block variants had potential for further reducing the cement and hence cost of the walling material. Two of these variants were tested using dynamic compaction, the cement-rich skin block and the hollow block. Unfortunately neither variant was very successful. The strength of the hollow block variant was too low for building purposes (0.6MPa). This was because the material density at the bottom of the block flange was quite low, as indicated by the indentation test. The potential of this type of block produced via dynamic compaction is uncertain and requires further work. Different methods of soil placement in the mould and different shaped voids may help deliver a more uniform density throughout the block. The method for producing the cement-rich skin variant was too complicated for normal block production. A more automated system could be implemented but this variant yields only a small saving in cement and other variants hold more promise.

9.3 Analysis of impact compaction

We perhaps understand a little bit more about the process of soil consolidation after the experiments conducted on dynamic compaction. We have been able to determine that the closer arrangement of particles is primarily due to shock wave propagation through the material. The presence of free-water in the mixture aids this process significantly as the particles slide over one another into closer proximity with each other. The impact compaction drives out air from the mixture in this re-arrangement process at such a rate that some of the air becomes temporarily trapped and possibly compressed. This trapped or compressed air very slightly hinders further compaction, but not at a level of practical significance.

Careful monitoring of displacement during the impact cycle itself has revealed some interesting phenomenon in the process. From these findings it is possible to conclude that the method of dynamic compaction follows some sort of combined elastic-plastic-viscous model. Initially this model demonstrates high plastic deformation, low energy loss and low hysteresis. As the compaction process continues the model changes to include increased losses, a decreasing plastic component and the development of an elastic component. Towards the end of the possible compaction the plastic component diminishes to zero, high energy loss is experienced through hysteresis and a small elastic component causes impactor bounce.

The discovery that the losses are so significant may seem like a disadvantage to the dynamic compaction process. The most effective compaction occurs during the very first few blows, but it is the latter blows that give the desired levels of compaction necessary for a high-density CSSB. These extra blows only require a small amount of extra time and therefore it seems reasonable to apply many of them. The large number of blows (>30) used for monitoring the impactor motion would not normally be experienced during normal block manufacture. Typically the number of blows would be smaller than this and could be stopped when further blows delivered little extra compaction rather than none at all.

The relative displacement was monitored during the impact cycle to gain an impression of the mechanisms behind impact compaction. An accelerometer was also used to determine the point of maximum acceleration, as the methods used for measuring the accelerations experienced by the impactor were unreliable beyond 25g. Calculations from the stopping distance applied to plastic, elastic and viscous models showed that the maximum accelerations experienced by the impactor were around 65g.

These accelerations experienced by the impactor were converted into forces delivered by the impactor, which were in turn experienced by the mould. These forces were a small fraction of the forces required for high-pressure quasi-static compression yet achieved similar and often better levels of consolidation with a tolerable number of blows (<16). A 10MPa hydraulic press would deliver about 400kN of force to the top of a block. Dynamic compaction was delivering about 30kN of force and also only for a short duration of 5-10ms.

The application of this dynamic lever in the compaction of CSSB provides another significant advantage over quasi-static in the potential use of a two-part mould rather than the very stiff 1-part mould required for quasi-static pressing. Significant forces (5kN) are required to overcome block friction and adhesion to the mould walls. These would be much reduced if the mould could be split into two parts after compaction. Dynamic compaction offers this possibility as the forces on the mould are much smaller and are very short in duration. The need of a large mechanical lever to eject the finished block would partially negate the advantages that dynamic compaction presents in machine design. Dynamic compaction removes large levers and forces applied to the block, so this novel method of mould design needs to be incorporated to maximise the advantages of the production process.

Trials of the two-part mould in the laboratory were a reasonable success. Blocks had to be ejected with care because of the adhesion between the block and the corner of the mould. The adhesion often resulted in small corners being left behind in the mould. After laboratory testing of the two-part mould and the necessary analysis for mould strength and stiffness from the data on the impact forces, the mould was slightly modified. The modified mould design used a different method of block removal, but the same two-part arrangement that was successful with dynamic compaction.

9.4 Feasibility study of dynamically compacted CSSB

The experiments in the laboratory indicated the potential success of dynamic compaction over quasi-static compression of CSSB. These findings needed to be confirmed in a more representative environment and consequently an overseas collaborator was sought out. A development organisation in India was the most promising of the different possible collaborators that we had correspondence with. They were able to comply with our requests for machine manufacture, future testing and possible dissemination if deemed successful.

Using a modest amount of machine tooling and expertise, a dynamic compaction block maker (Block Impacterre) was built in India. The team estimated the cost of machine production and block productivity was predicted following initial trials. Blocks produced were tested whilst I was there and further testing was conducted after I returned to the UK. The testing measured the performance of the material produced by Block Impacterre and a high-pressure competitor (Hydraform). From these findings it was possible to make a comparative analysis of walling material produced by both machines.

The study indicated that Hydraform could produce walling during its projected lifetime at a rate of £1.60/m^2. Block Impacterre with its improvement in consolidation and hence lower cement requirements and much less expensive machine could produce walling costing only £0.91/m^2. This represents a monetary saving of over 40%. The addition of sand to the soil mix makes the added cement even more effective and therefore enables a greater reduction in cement whilst still maintaining the same strength. The addition of 30% of sand reduces the cost of walling to £1.29/m² and £0.74/m² for the Hydraform and Block Impacterre respectively, still representing a saving of over 40% using the dynamic process compared with quasi-static compression.

This analysis indicates that the process of dynamic compaction offers a significant incentive to switch from an alternative low-cost building material to dynamically compacted CSSB. However, such a switch is not guaranteed just because of a significant monetary incentive. Other factors need to be considered in order to assess if this material and this process will be successful. Communication with Indian building advisors suggests that CSSB is not cost effective if burnt brick is available. Typically a burnt brick in Delhi costs about £0.04 whilst a CSSB costs about £0.08. The 40% reduction in cost will go some way to bringing these two materials closer together, but the perceived poor performance of CSSB will drive away some potential customers. However, in areas where burnt brick is not available and consequently CSSB has a reasonable following already, the dynamic process of CSSB production should have significant potential. Further trials are necessary in such an environment along with pilot schemes to help disseminate the technology into communities with a need for low-cost walling.

The work carried out during this Ph.D. has been directed towards meeting a need for low-cost housing. It initiated with a concept that impact compaction provided a better alternative to material consolidation than slow squeezing. The research has taken this initial premise through stages of conceptualisation and laboratory testing during which time the understanding of the process has been improved. Test results confirmed the initial potential of the process and this prompted machine design and dissemination for use in developing countries. The additional collaboration and field trials conducted on the finished machine have been very promising. Finally the analysis of the potential of the machine and its product has given the Ph.D. all aspects of research through to product dissemination. This has made the work both interesting and highly rewarding and will hopefully be useful to others in the future.

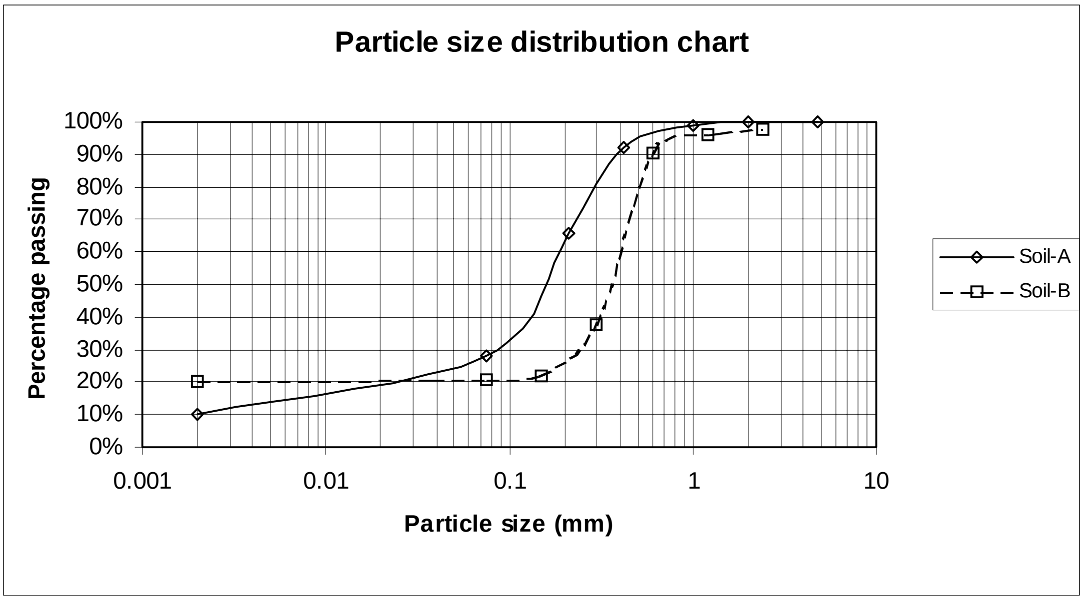
Graphical results of sieve analysis



Mixing of soil-B

The raw materials for the laboratory soil was generally mixed dry to ensure that the cement present in the mix would not start to hydrate until a known amount of water was added. This enabled large quantities of soil-B to be weighed and mixed waiting for further processing. Typically the dry mix was weighed out on a set of Avery Scales rated to 50kg to the following proportions:

Oven dry builders sand	15.2 kg
Kaolin clay grade-E	3.8 kg
Cement	1.0 kg
Total	20.0 kg

This results in a 4:1 mixture of sand to Kaolin clay and an overall percentage of cement equal to 5% by mass.

The dry quantities were placed into plastic bags and mixed together when necessary in a steel drum with a lockable lid. Due to the high level of fines present in the mixture the sealed drum was necessary to keep the dust levels down and to also to ensure that the fines added remained in the mix rather than becoming airborne.

Water was added to the weighed out samples in a batch size of one and the water was mixed using a Hobart mixer. The mixer motor had been condemned, consequently the mixing paddle has to be turned by hand via the main crank shaft and gearbox through an attached handle. The handle was rotated at a rate of around 60 revolutions per minute and the mixture was mixed for at least 3 minutes. The mixture had always taken a uniform colour at this time and further mixing was not only exhausting, but also seemingly unnecessary.

Some tests required soil-B without any cement present and the quantities were mixed together in the electric drum mixer and mixed with water in the correct quantity. The finished mix was then placed into plastic bins and used when necessary ensuring the mixture was never left open any longer than necessary to extract a quantity of soil.

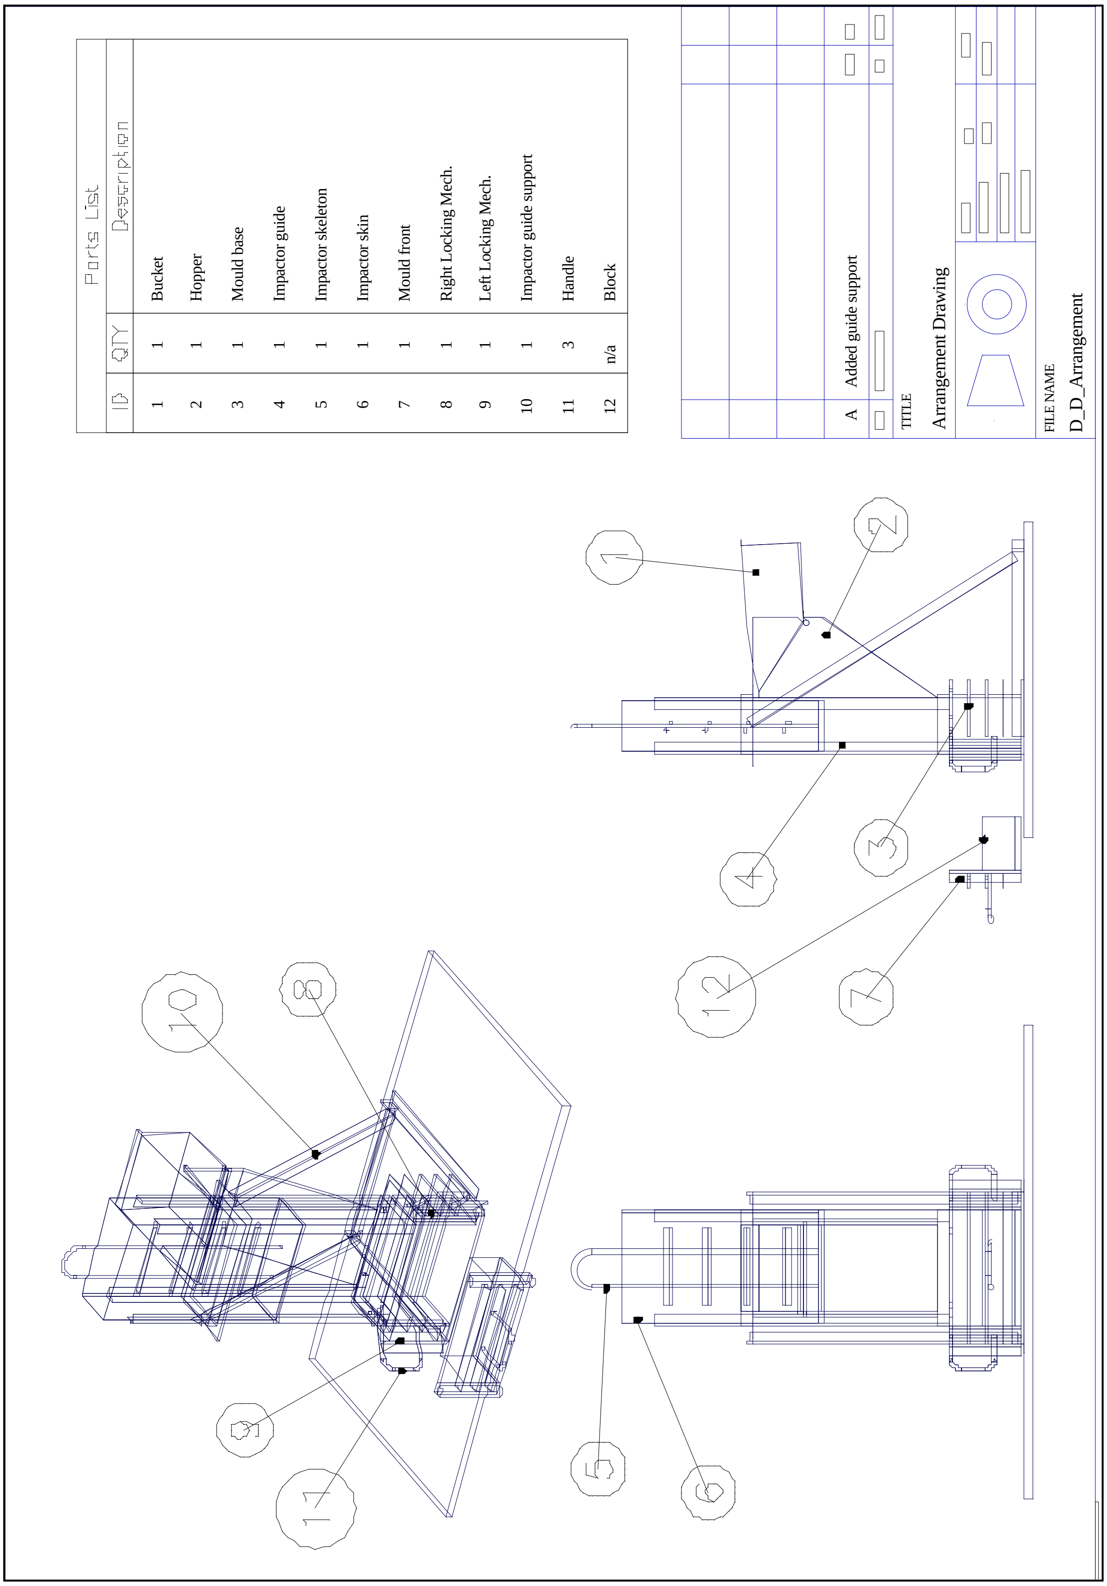
Appendix D - Machine drawings

The following pages contain 9 drawings that have been copied from the CAD program used to make them, (Pro-Desktop 2000i²). The original drawings were sent to India for them to manufacture the machine before the overseas trip. All of the following drawings have been scaled to fit onto the page and consequently are not displayed at the scale indicated on the drawing. The first drawing in this collection is the Arrangement drawing that identifies the different components of the machine. The following table summarises each of the drawings with reference to this arrangement drawing and identifies them with the part number that is used.

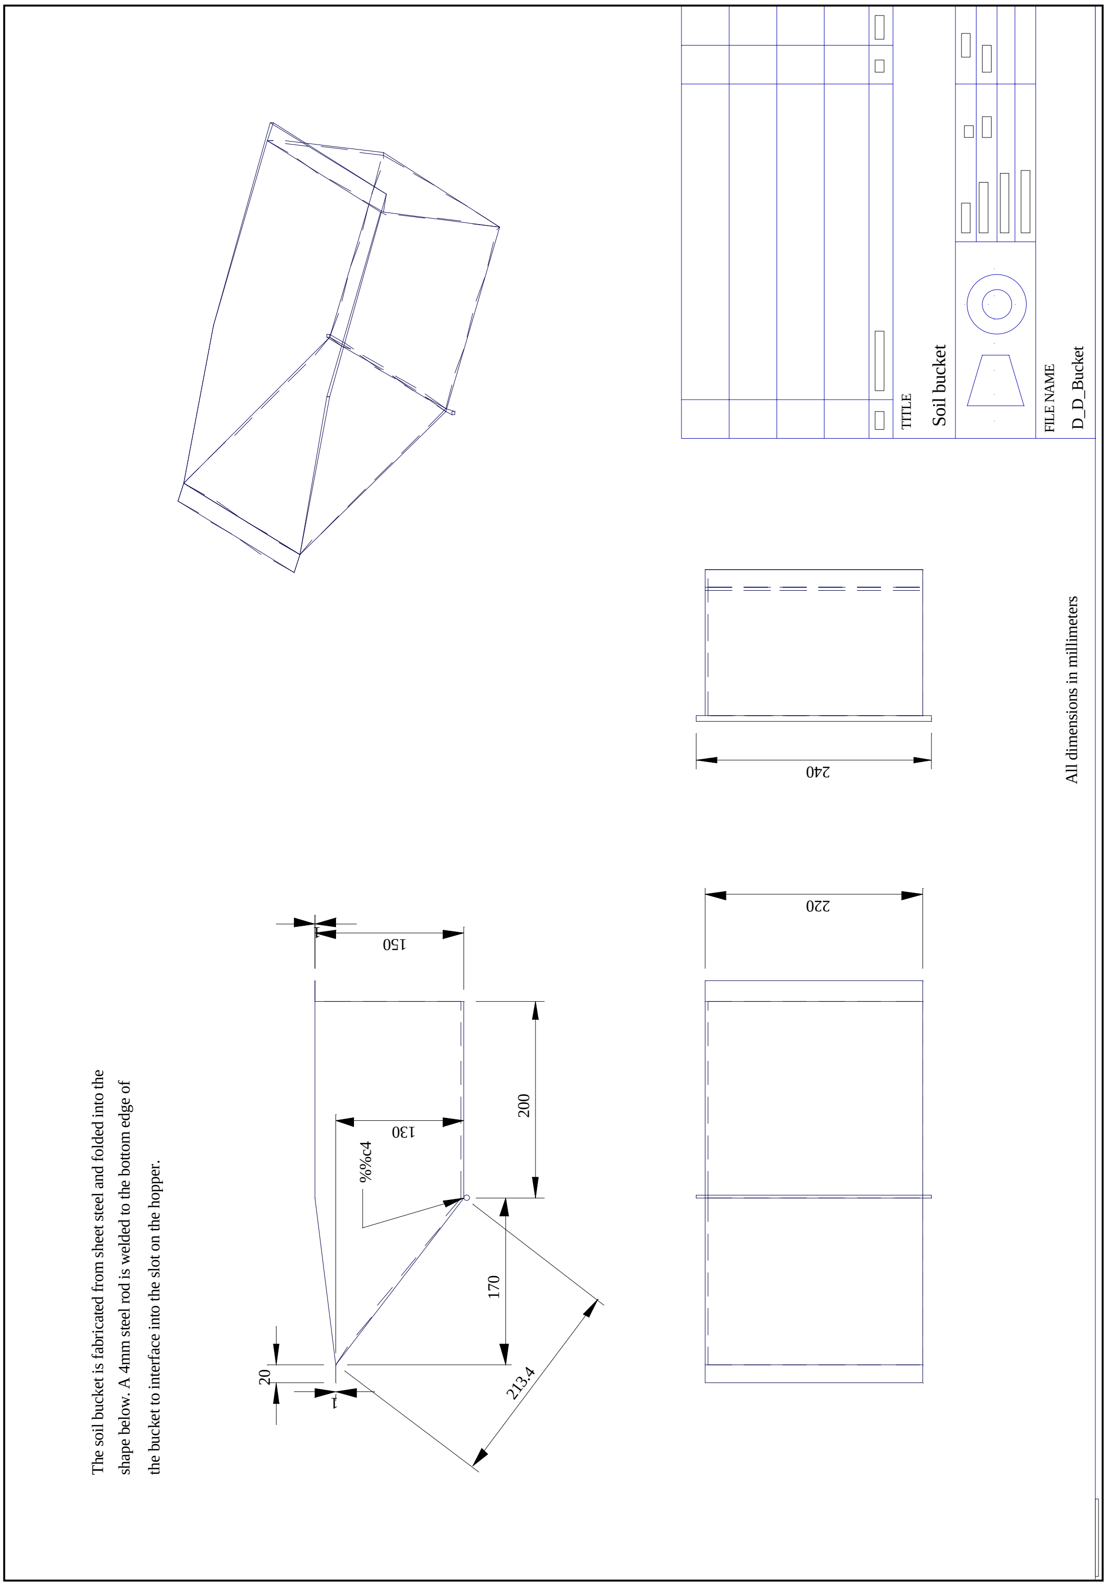
Part No.	Drawing name
1	D_D_Bucket
2	D_D_Hopper
3	D_D_Mould base
4	D_D_Impactor guide
5, 6	D_D_Impactor
7	D_D_Mould front
8, 9, 11	D_D_Locking handles
10	D_D_Impactor guide support

Note: the conversion process has caused some of the text on the drawings to be lost. Also the symbol '∅' has been replaced by '%%c'.

D_D_Arrangement



D_D_Bucket



The soil bucket is fabricated from sheet steel and folded into the shape below. A 4mm steel rod is welded to the bottom edge of the bucket to interface into the slot on the hopper.

Abstract

This dissertation aims to design a waterwheel for very low head sites in rural Scotland to provide domestic electricity supply. The dissertation uses MathCAD to design a stream wheel and Excel to design the vessel that the wheel is fixed to. Options for the gearbox and generator are briefly considered.

During research it became clear that one of the major challenges facing waterwheel development is a lack of scientific analysis and the general perception that waterwheels are anachronistic and irrelevant. To illustrate the potential of waterwheels three case studies are included; a new wheel in the developing world, a mill renovation in the UK and an old wheel that still powers a working mill.

Keywords: undershot waterwheels, stream waterwheels, basic barge design, basic catamaran design, microhydropower,

Glossary of Terms

Archimedian Screw- age old technology used to lift water from lower heights to irrigate fields. Currently being developed in reverse to produce electricity. Patent owned by Ritz Attro (www.ritz-attro.de)

Gantt Chart- graphical representation of the stages of a project against the estimated time taken to complete each stage.

PERT Chart- chart showing chronological order of the stages of a project, illustrating which stages rely on previously completed components.

Kyoto Protocol- a summit on climate change held in Kyoto in 1997 saw 160 nations sign up to this Protocol laying down targets for greenhouse gas emissions reduction.

Undershot wheel- a waterwheel powered by the kinetic energy of water running below the centre, which pushes the blades around.

Overshot wheel- water enters the wheel near the top and falls into buckets, turning the wheel using the potential energy of the water.

Breastshot wheel- similar to an overshot wheel the water enters about halfway up the height of the wheel.

MathCAD- computer program allowing users to input equations, functions and matrices, alter variables and perform mathematical processes such as integration, differentiation etc. quickly

Head- the difference in the water height either side of the waterwheel

Zuppinger or Poncelet wheel- undershot wheel with curved paddles that use both kinetic energy and, by channelling the water into curved blades potential energy. This leads to higher outputs and greater efficiencies.

Glossary of Terms

Renewable Obligation (Scotland) Bill- government bill introduced in 2002 forcing electricity suppliers to buy 10% of their supply from renewable sources

Critical flow- point at which the flow of the water changes from being streamline to turbulent, signalling the use of different equations, theories and testing procedures

Supercritical flow- beyond the critical flow here flow is turbulent with a Froude number of 1

Froude Number- ratio of the force on an element of fluid to the weight of the element. In mathematical terms $Fr = velocity \div (gravitationalcons\tan t \times characteristiclength)^{0.5}$

Nomenclature

π = Pi ~ 3.14

cos= Cosine function

x= Angle of blade arm at centre of waterwheel relative to the vertical

xL= Angle of blade arm at the centre of waterwheel relative to the vertical at the point of the blade leaving the water.

x1= Angle of blade arm at centre of waterwheel at point of blade beginning to leave the water

Current= Speed of the water horizontally

Vc= Component of the current acting in the blade's direction

Vb= Rotational velocity of the blade

Vr= Relative velocity of blade

Cd= Coefficient of drag

f = Width of blade

d = Depth of blade

L= Distance from centre of waterwheel to bottom of blade

y = Distance from centre of waterwheel to top of blade

Nomenclature

a(x)= Diagonal distance from centre of waterwheel to water line

D(x)= Depth of blade in water

A(x) = Surface area of blade in water

p = constant representing the proportion of velocity the blade picks up from the current

t = Time taken for one blade to complete one revolution

Larm= Lever arm from centre of waterwheel to the centre of the submerged area of blade

F(x) = Force on one blade moving from a vertical position to the point that the blade leaves the water

M(x) = Moment at waterwheel centre created by blade moving from a vertical position to the point the blade leaves the water

WorkDone= Work done on one blade from entering to leaving the water
N= Number of blades

TotalWorkDone= Total work done for entire wheel from entering to leaving the water

PowerAbsorbed= Total amount of power absorbed by wheel during one revolution

Side A= breadth of barge multiplied by the depth of the barge

Side B= length of barge multiplied by depth of barge

Nomenclature

q= distance from point of triangular barge end to the nearest side of barge rectangle

side F= breadth of the watertank multiplied by its depth

side E= length of the watertank multiplied by its depth

1 Introduction

1.1 Recent concerns over global warming and an over reliance on fossil fuels have led to an increased political, academic and public interest in renewable energy. The Kyoto Protocol sets strict standards for countries to limit their carbon emissions and research alternative energies.

1.2 Three viable areas of renewable energy have emerged- solar power, wind power and hydropower. This dissertation focuses on hydropower for a single domestic supply in rural Scotland.

1.3 Microhydropower refers to the production of 300 kW or less using turbines, waterwheels or Archimedian screws (1). With its low head and flow requirements, relatively low cost, "fish friendly" slow rotation, and ease of construction the waterwheel is experiencing a revival. They are especially relevant to small residential projects where the long payback period of turbines is prohibitive (1) and for developing countries, where maintenance and fabrication has to be simple. Three case studies are included in the literature review here to demonstrate waterwheels in use today.

1.4 This dissertation evaluates the typical energy usage of a hypothetical three bedroom household of two adults and two children and then models the dimensions and properties of the waterwheel required to produce this output. The wheel is to be situated on an open small river where there is no head difference and the flow velocity is approximately $2ms^{-1}$.

1.5 The waterwheel is fixed to a type of barge or catamaran. This allows the wheel to move with the change in water level insuring a reliable power output and removes the cost of building a separate channel or weir. It is assumed that the waterway is not travelled on by boats.

1.6 Scotland has been chosen as there is a plentiful supply of water and rainfall and a number of island and highland communities, who would benefit from small scale power generation, as connection to the grid is expensive and unreliable.

2 Literature review

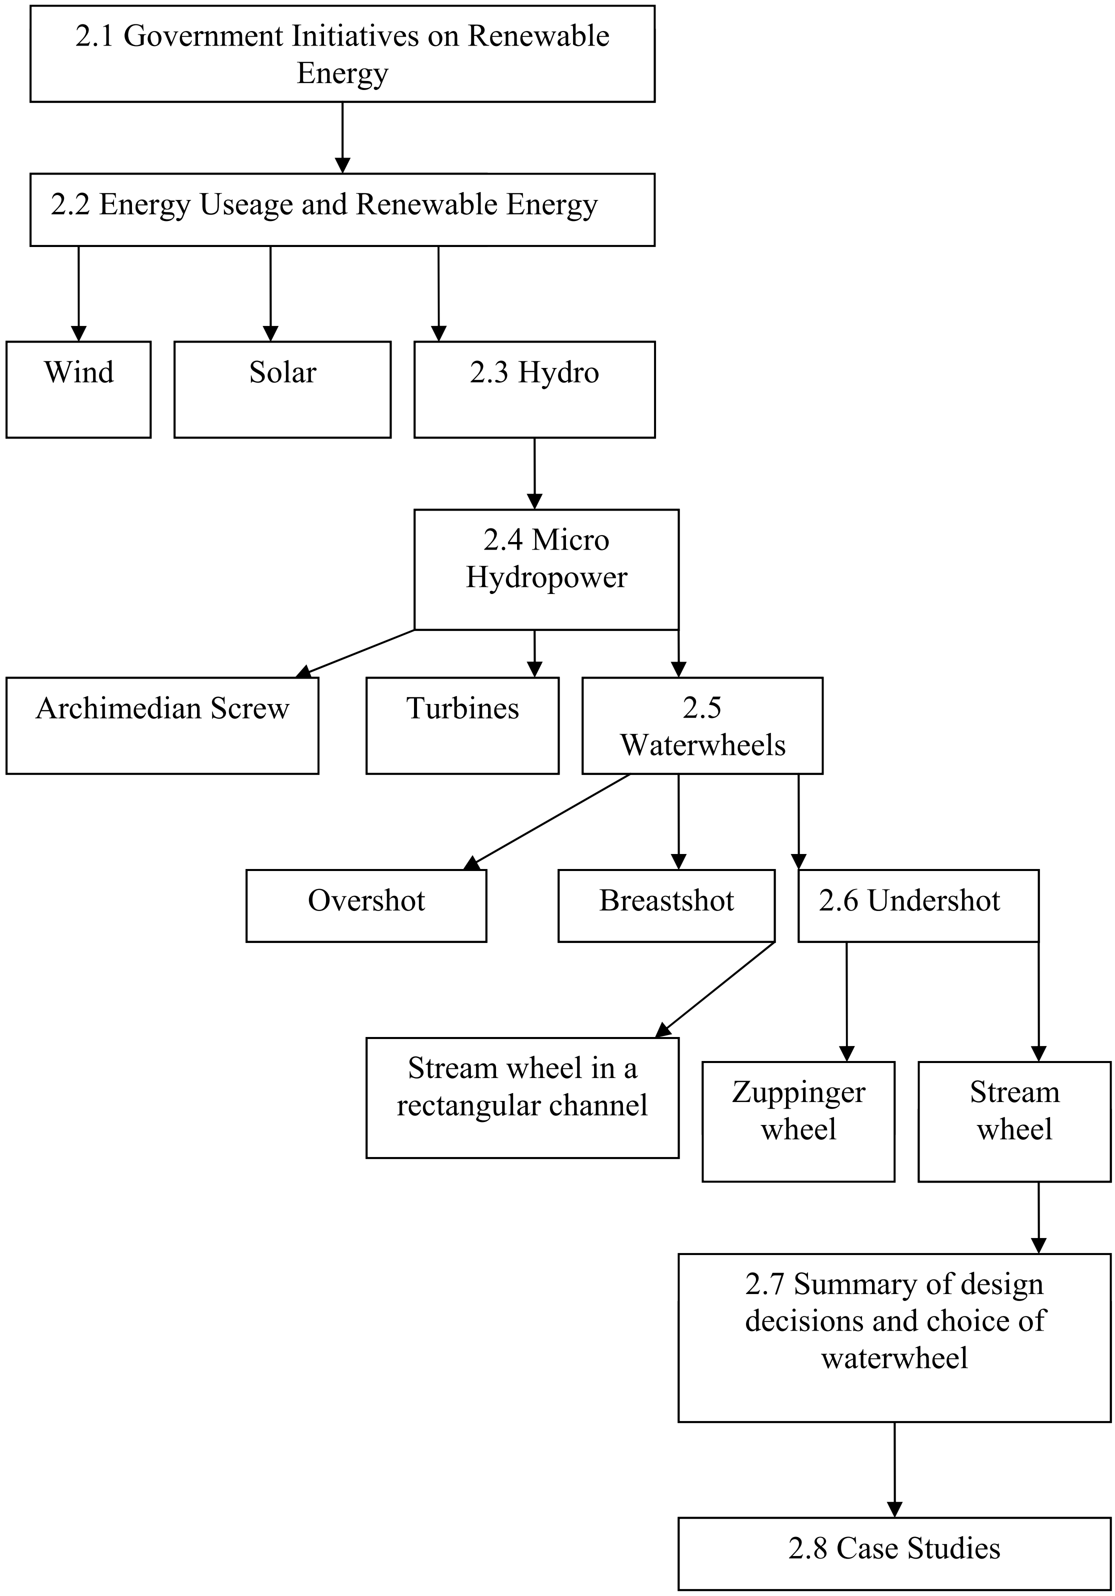

Fig. 1 Diagram showing process of research involved in the Literature Review

2.1 Government Initiatives on Renewable Energy

The UK government pledged under the 1997 Kyoto Agreement to cut greenhouse gas emissions by 12.5% during 2008-2012 leading to a 20% reduction on 1990 emission levels by 2010, in 5 years time (16). According to the 2003 Energy White Paper “Our energy future- creating a low carbon economy” the government aims for a 60% reduction in greenhouse gas emissions by 2050. (16).

2.11 In 2003 only 2.7% of the total energy used came from renewable sources. The Energy White Paper aims to increase this figure to 10% by 2010. This will mean approximately 10,000 MW of electricity from renewable sources, which is roughly equivalent to 3,000-5,000 wind turbines (16).

2.12 In Scotland the Renewables Obligation (Scotland) bill was passed in 2002 forcing the licensed electricity suppliers to begin investigating renewable energy sources and purchasing a percentage of their energy from renewable sources (16). This will hopefully lead to electricity suppliers offering higher buy-up prices for renewable energy, making small scale renewable installations able to pay for themselves.

2.13 The Scottish Climate Change Programme signs Scotland up to generating 18% of its energy from renewable sources by 2010, increasing that to 40% by 2020 (17), with a range of measures, new bodies and funding to promote energy efficiency, renewable energy research and raise public awareness.

2.2 Energy Usage and Renewable Energy Types

Man requires energy at a basic level for heat and light. In primitive times burning wood provided warmth, cooking facilities, light and a place of gathering. Over the last 2000 years man has developed more sophisticated machinery for heating, lighting and entertainment; however the burning of fossil fuels has continued leading to the current situation of climate damage and few alternatives to fossil fuels.

2.21 In the latter part of the last century concern over the rapidly depleting fossil fuel supplies focused world leaders to meet and set Co_2 emission limits. Renewable energy is defined as energy that "is derived from an inexhaustible (wind, sun, sea) or replaceable (waste products, crops) source" (12).

2.22 Inexhaustible resources include:

- **Wind Power**- differences in temperature across the globe cause differences in air density setting up winds that can be used to turn turbines generating electricity.

- **Solar Power**- the sun's energy can be used in photovoltaic cells, where a reaction causes electricity production or in a thermal or solar air heating system where water or air are warmed for heating.

- **Hydropower**- the hydrological cycle draws water from the sea into clouds, releasing rain onto high ground that then flows back to the sea along rivers, streams and tributaries. The flow of this water can be harnessed to turn the blades of a turbine, waterwheel, or the motor of an Archimedian Screw (1)

2.3 Hydropower

At the smaller end of the scale hydropower is classified as:

- **Picohydropower**- up to 10kW
- **Microhydropower**- 10kW-300kW
- **Small Hydropower**- 300kW-1000kW
- **Mini Hydropower**- above 1000 kW

(Taken from 13)

Within this dissertation the intention is to power one domestic dwelling in the UK making the power banding microhydropower.

2.21 Currently supplying only 0.8% (1456 MW) of the total energy consumption in the UK Hydropower has been much underrated, with hydroelectric capacity in this country being estimated at 4,244 MW. (14) The map below (Fig. 2) shows the high concentrations of hydroelectric installations in Scotland and Wales, areas with greatest head differences (15). Large scale dams are seldom built now as they are costly to maintain and their construction has huge environmental impacts, such as water diversion, altering of river slopes and infrastructure creation, all of which disturb aquatic ecosystems (18).

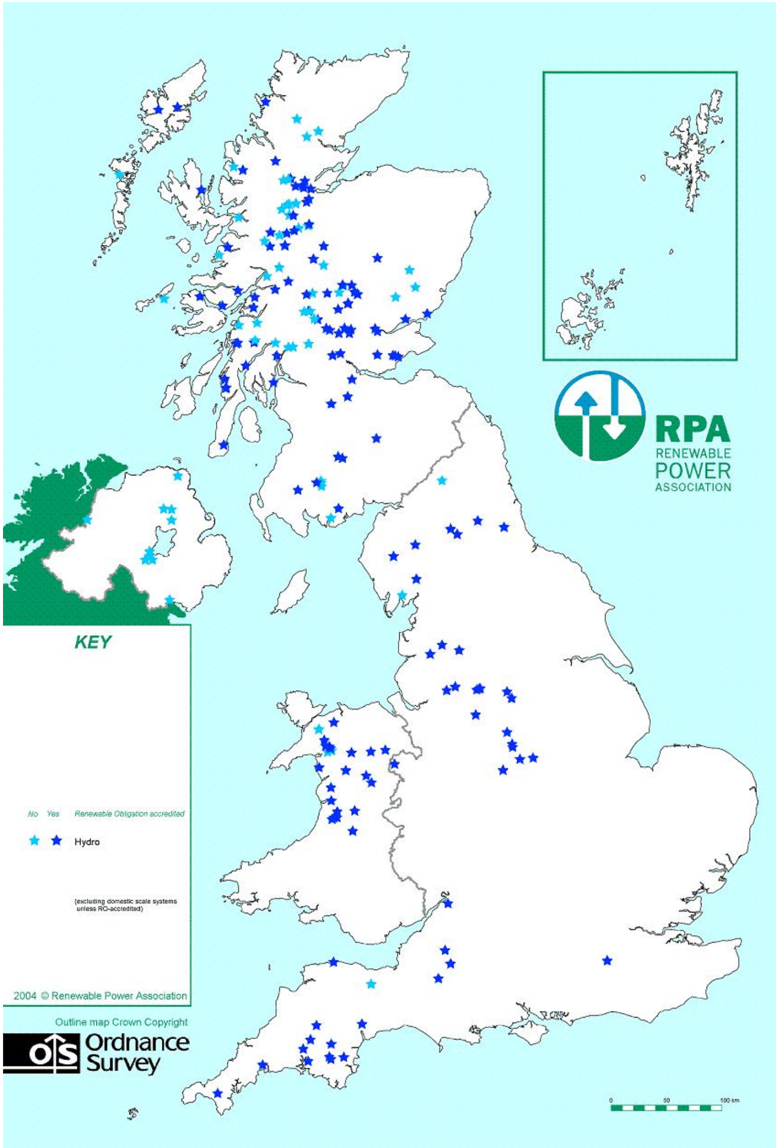

Fig. 2 Map of Hydroelectric Plants in the UK as of end 2004. The dark blue stars signify sites that have been renewable obligation certified and light blue stars are yet to gain certification. (Taken from 15)

2.4 Microhydropower

No clear estimates are available for microhyropower potential in the UK but some experts point to the 20,000 abandoned weir and watermill sites across the UK that could produce between 600 MW and 10,000 MW of power (2). Both the Department of Trade and Industry and the Scottish Executive seem to acknowledge the role that micro hydropower has to play-

" If small-scale hydroelectric power from all of the streams and rivers in the UK could be tapped, it would be possible to produce 10,000 gigawatt hours…. per year- enough to meet just over 3 per cent of our total electricity needs and making a significant contribution to the Government's renewables target…." Department of Trade and Industry, 2005 (14)

"There are…. an increasing number of proposals for small run of river hydro projects and these projects,…..will ensure that hydro will continue to play its part in Scotland's renewable energy mix." Scottish Executive Business and Industry, 2004 (19)

2.41 Yet despite this acknowledgement there has been little encouragement or official research into microhydropower since the "Small Scale Hydroelectric Generation Potential in the UK" Report by the Department of Energy in 1989. Frustratingly this only considered sites of more than 25 kW potential (and so ruling out waterwheels whose average power rating is 17.1kW) and with head differences of over 2m, immediately ruling out undershot and breastshot waterwheels (10). The report also discounted remote sites, with no grid connection as being uneconomical. These are exactly the kind of sites, where connection to the grid is too costly, that would benefit from the reliable independence that microhydropower can provide.

2.42 The publication of "The Layman's guide on how to develop a small hydro site" in 1997 by the Commission of European Communities (21) did promote microhydropower to the public indicating costs, environmental impacts and basic site evaluation methods. This type of document has encouraged a whole group of "do-it-yourself hydro developers" (22) who have experimented independently with different heads, waterwheel types and generation systems.

2.44 Microhydropower can be generated using:

- **Turbines**- Water is funnelled into enclosed systems of blades rotating about the x or y axis. (See figs 3,4,6)Turbines have been well researched and developed yielding high efficiencies, but are still high in cost and complex to manufacture.
- **Waterwheels**- an age old technology where water enters at either the top or middle or it acts along the base. Waterwheels rose in popularity during the industrial revolution, but declined as electrical power took over from mechanical power, and have remained largely ignored ever since.
- **Archimedian Screw**- used for hundreds of years as a motor to raise water from lower fields for irrigation. Recently there has been renewed interest as the screw can be reversed running water from above, through the screw, turning a motor and generating electricity. Sparse experimental evidence exists but efficiencies are estimated at 70-80% (1).

2.5 **Waterwheels**

History of the Waterwheel

2.51 The inventor of the waterwheel is unknown but the undershot wheel is described by Vitruvius in 27BC (8). Initially the waterwheel was used to lift water and irrigate fields but was later used as a means to generate mechanical power for milling. The rapid industrialization of the Middle Ages led to an increase in waterwheel usage- 5000 mill sites are recorded in the Domesday Book of the 11th century .(2)

2.52 Interest in the waterwheel continued from the 12th to the 20th century (2) reaching a peak in the 19th century. In England in 1850 there were 25-30,000 waterwheels in operation, in Ireland at the same time there were 6,400 and in Germany there were 40,000. (5) Many of the wheels constructed were built using rules of thumb passed down rather than specific scientific analysis. Texts such as "Water or Hydraulic Motors" (1894) by Philip R. Bjorling (7) contain rough formulae and tables for estimating the number of buckets, the theoretical velocity and the power output.

2.53 However the waterwheel was an important energy source that began to attract scientific interest. In 1752-54 John Smeaton built scale models of undershot and overshot wheels to test their efficiencies (8). The French government offered large rewards for more efficient designs, leading to the Poncelet design that was later refined and patented by Zuppinger (8). New roles were devised for the wheel such as on steam paddle ships where fuel was burnt to evaporate water, and create steam, turning the paddles, pushing the boat forwards. (9)

2.54 Waterwheels continued to be used well into the last century; in Bavaria in Germany 7,554 wheels were operating in 1927 (1), and in Switzerland nearly 7,000 small scale hydropower stations were being used up to 1924 (4). However the "lack of strong and reliable gearing systems, coupled with the advent of steam power and the introduction of higher speed water turbines rapidly led to the demise of the waterwheel" (3). In the UK waterwheels were left to rust or were removed, weirs were forgotten about or destroyed, populations moved away from the streams to the city and working knowledge of waterwheels was lost.

2.56 **Advantages of Waterwheels**

- Simpler technology than turbines lending themselves to the developing world for local fabrication and maintenance.
- Fish will hopefully be able to pass through waterwheels unharmed (more research is needed on this) and expensive fish screens will not be necessary (23)
- Faster pay back periods than turbines and in some cases Archimedian screws (1)
- Unlike wind turbines there seems to be less public resistance to waterwheels as they are not so out of place in the countryside for example the virtual wheel in Fig. 7. In fact the public seem to be interested in waterwheels judging by the number of visitor centres that proudly posses one.

Fig.7 A typical weir with a virtual wheel installed (1)

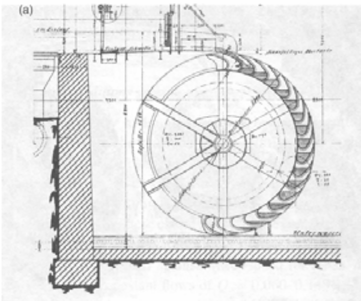
2.57 **Disadvantages of Waterwheels**

- The slow rotation of waterwheels (6-10 rpm) leads to high gearing ratios when trying to generate AC Electricity at 600- 1500 rpm. More research is needed into different gear boxes and configurations.
- Waterwheels do produce a "low *frequency thumping noise*" (25) which is not well understood and could cause complaints. It is thought that altering the blade shape to a "spoon-shape" would lessen the blow on impact whilst maintaining a high drag coefficient. This would be better investigated by experiment.
- A lack of knowledge in the engineering profession. Few model experiments have been carried out on waterwheels and there is still much unknown about the flow, efficiency and physical properties of waterwheel
- If wheels are fixed to the side of the river then changes in flow level will cause fluctuations in power output making them unreliable. If the wheel is fixed to a barge or catamaran then a build up of river bed silt or a reduction in the water level could lead to the blades becoming damaged hitting the river bed. Some sort

of high frequency measuring device would be needed on the barge to check the distance between the wheel and the river base, with regular maintenance checking wear and tear on the blades.

2.58 In this dissertation turbines and the Archimedian screw have not been investigated due to a lack of head at the site. Types of waterwheel include:

- **Overshot wheels**- 2.5m<Head<10m, Flow<0.2 m^3 s^{-1} per m width (1). Water enters above the wheel and falls into buckets turning the wheel with efficiencies of possibly 85% (1)



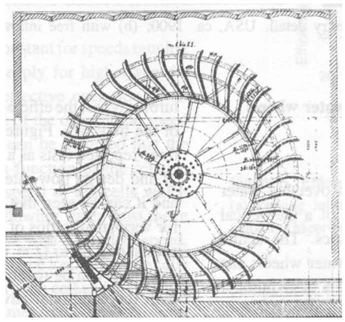


Fig. 8 Overshot wheel (24) Fig. 9 Undershot Zuppinger wheel (24)

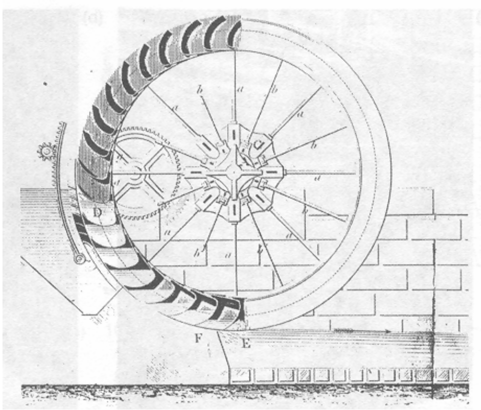
- **Breast shot wheels**- 1.5m<Head<3m, 0.3<Flow<0.65 m^3 s^{-1} per m width (1). Water enters half way up the diameter of the wheel, falling into buckets turning the wheel. Recent experiments at Queens University, Belfast indicate efficiencies of up to 87% (23), making them a viable option for low head sites.



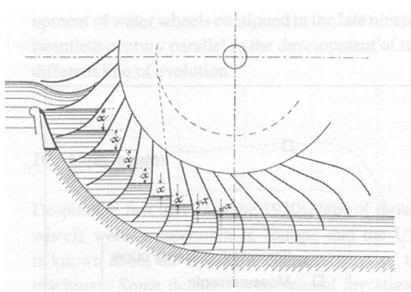


Fig. 10 Breast shot wheel(24) Fig. 11 Working principle for breastshot wheel(24

- **Undershot wheels**- 0.3m<Head<2.0m, 0.45<Flow<1 m^3 s^{-1} per m width (1). Some models use a very small head drop and curved blades to take potential energy from the river (60-77% efficiency (24)), others use the kinetic energy of the river on the blades (only 33% efficiency (8)).

2.6 Types of Undershot Wheels

Although considered inefficient even in the Industrial Revolution the undershot waterwheel continued to be manufactured as they could be sited on small streams in flatter areas, nearer to centres of population (8).There are several types of undershot wheel:

2.61 Zuppinger wheel

Designed by Walter Zuppinger and patented in 1883 this wheel uses only the potential energy of the river making it more efficient. The blades are curved carrying the water down a curved channel from a small weir and releasing it most efficiently, with minimal losses at the entrance or exit.

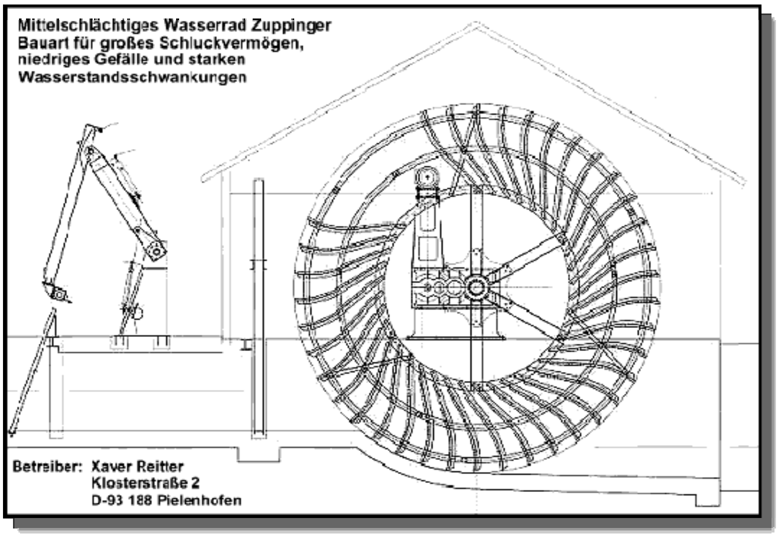

Fig. 12 above Sketch of installed Zuppinger wheel (27)

Fig. 13 right Same installed Zuppinger wheel (26)

Although sparse experimental data exists for all wheels Zuppinger wheels have perhaps been the most investigated. In 1979 students at the Technical University in Stuttgart, Germany tested an existing Zuppinger wheel that had been running since 1886. The test determined the flow rate and power output for a speed of 4.85 rotations per minute (rpm) and two flow rates of 1.48 and 3.1 $m^3 s^{-1}$. For Q/Qmax=0.5 the efficiency reached 77% and for Q/Qmax=1 efficiency reached 71% (24).

Figs 12 and 13 show a recently installed Hydrowatt Zuppinger wheel of diameter of 6.5m, a width of 2.3m, using a head difference of 1m to produce an electrical power output of 20kW at an overall efficiency of 70% (10). German based firm, Hydrowatt have built and installed 15 Zuppinger wheels with heads of 1-2.2m and power outputs of 4-45 kW from 1993 to 2001(10).

2.62 **Impulse or Stream Wheels**

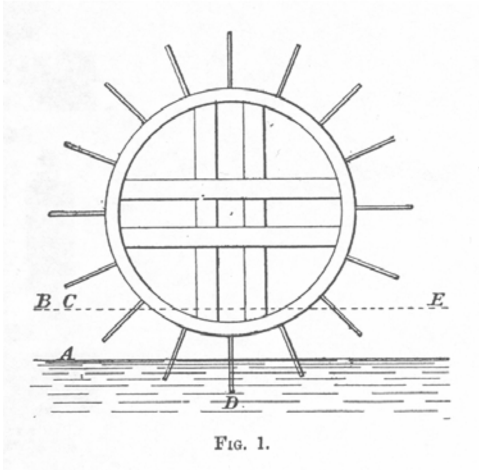

Fig.14 Diagram of midstream wheel ((7) pg 18)

Considered the least economic these large diameter wheels have flat paddles immersed in the flow and use the kinetic energy of the current, requiring zero head.

As this is less than the potential energy the stream wheel is often regarded as being inefficient, however interest has resurged in them as *"their application does not constitute a major change of river"* (25). No civil works are required, the wheel can be moored on a barge or fixed to the side, and the relatively simple dimensions and layout mean that it can be constructed and repaired locally, lending itself more to the developing world than the Zuppinger wheel.

The Universities of Southampton and Berlin TU have joined together to test a 500mm stream wheel shown in Fig. 15 (25) Testing is due to start this month and will investigate the design characteristics such as the power output against speed, the overall efficiency and differences in the upstream and downstream depths, with a view to building an actual stream wheel in Munich. Data on that stream indicates that the flow is supercritical at $5ms^{-1}$ with the depth being only 0.5m (39).

Fig. 15 Stream wheel model at Berlin Technical University, 2005 (53)

2.63 **Stream wheels in rectangular channels**

If an undershot wheel is positioned very near the base of the river bed, and is nearly as wide as the channel then the power output and efficiency will be increased as the flow is forced through a small space at high velocity, becoming critical.

An early investigation into this phenomenon was the Cairo University based paper "Design of momentum water wheels used for mini hydropower" published in 1985 (28). The test set up an undershot waterwheel close to the base of the river bed with a sluice gate beside it. Water is forced through the narrow opening under the gate, increasing the speed as it passes some of its kinetic energy to the wheel, then settling at a lower height and slower speed downstream (See Fig.16 below). The paper estimated that efficiencies of up to 63% were possible with this design.

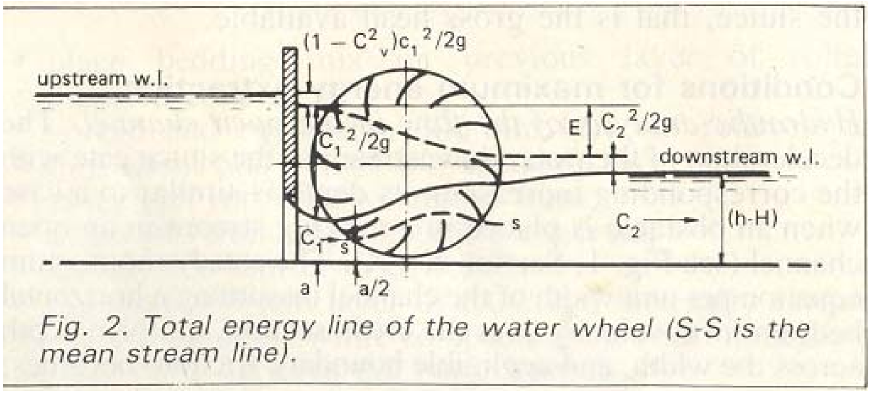

Fig. 16 Cross Section of wheel and sluice gate with water flow and energy lines marked on ((28) page 48)

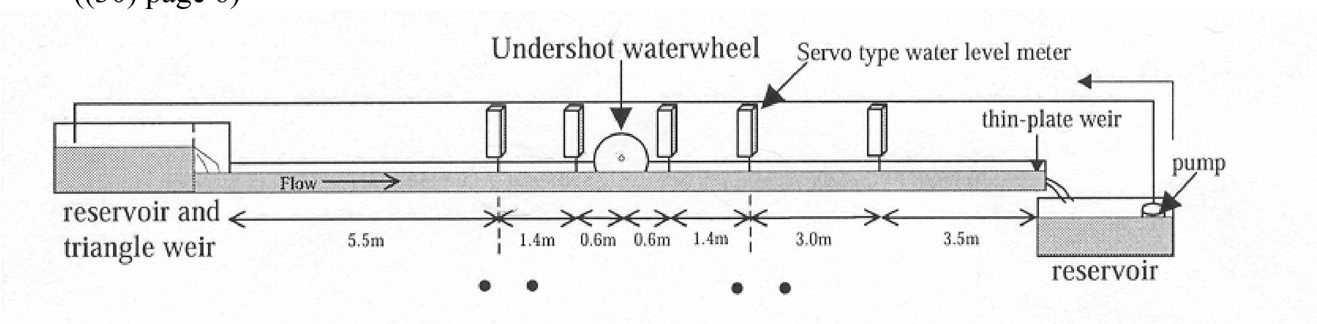
A more conservative outlook was expressed by a Japanese paper (30) in 2001 where an undershot waterwheel was placed 3mm from the test bed and power output was measured by simply attaching weights to the wheel until it no longer turned. The tests were very comprehensive altering the upstream height, Froude number and blade heights finally concluding that 45% efficiency could be obtained provided the dimensions of the channel and flow lay within set parameters.

Fig.17 Cross section of rectangular channel experiment with undershot waterwheel ((30) page 6)

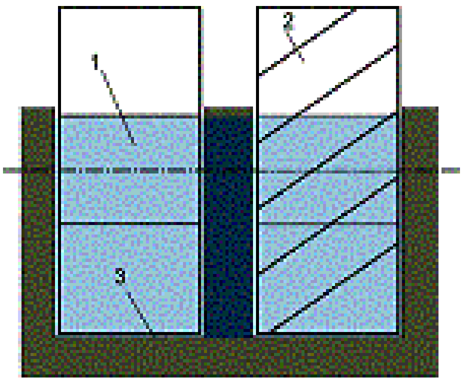


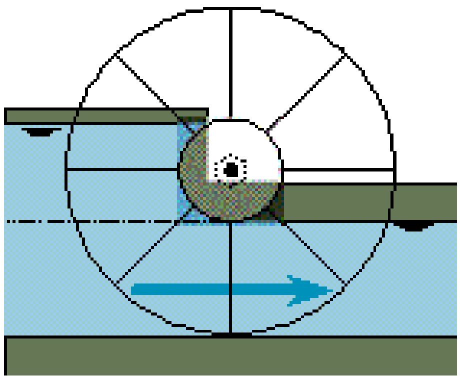
An Austrian engineer has shown interest in this style of wheel developing his own untested "Staudruckmaschine" (45). Roughly translated as "hydropressure machine" the wheel is shown below.

The development of these types of wheels is hampered by their strict requirements of narrow shallow streams with high flows, smooth beds and sides (reference 30 sites irrigation channels as being suitable for these wheels) , that are uniform enough to position a wheel in. The accuracy of construction and installation make them unsuitable for developing countries, and they would need a large trash rack to keep out debris. No study has been undertaken into how fish would navigate the wheel but with high velocities, and faster blade rotation this wheel could have a negative effect on aquatic life.

Fig. 18 (above) Photo of Staudruckmashine installed (45)

Fig. 19 and 20 (below) End view and cross section of wheel showing water (45)





2.7 Choice of waterwheel type

Seeing as the hypothetical site has no head difference a Zuppinger wheel would be unsuitable. The stream wheels fixed in rectangular channels require uniform channels with smooth beds and sides, which are not common in Scotland. So it was felt that a stream wheel would be most relevant to this dissertation requiring no head and being easy to fabricate.

2.8 Case Studies

Whilst researching this dissertation it became clear that waterwheel usage is not only held back by the lack of research and experimental evidence, high gearing ratios, etc. but also a perception amongst engineers and the public that an old technology could have no relevance to the present day. To help change this attitude the following case studies are included to illustrate scenarios where waterwheels have been installed or are used successfully.

2.81 **Heatherslaw Mill, Ford and Etal Estates, Northumberland**

Heatherslaw is a working mill grinding flour on the River Till in Ford and Etal Estate in the north east of England (see Fig…). The site has milled flour using hydropower since 1830 and is currently run by miller Mrs. Julia Nolan. The mill uses an undershot wheel 5m in diameter and 1.52m wide. Through a series of cogs, wheels and stones the rotating force of 20 horsepower (with sluice gate is fully open) transferred into mechanical power grinding grain into flour. The current wheel was constructed in the mid-1970's from wood partly because it is easier to replace and to also prevent sparks in the highly flammable mill.

Although the miller admitted that a Zuppinger-style wheel would be more efficient and produce more power the mill could not risk the loss of revenue in time spent waiting for specialist servicing or replacement part production.

So one and a half wheels were constructed locally (the half being for spare parts), and the wheel is maintained locally.

Fig. 21 right Heatherslaw Mill (Authors own, 2005)

The river Till is well known locally for having a fast flow, aided by its sand gravel river bed. The half dam on the mill side (seen in Fig. 22) was actually installed to hold water in reserve in case of low rainfall. Water is drawn just in front of the dam into a covered channel running under the bank. The channel turns about 90 degrees (causing a drop in velocity), passes the trash rack and then enters the mill.

Fig. 22 River bank and half dam
(Authors own, 2005)

Fig. 23 Entrance to waterwheel. The rectangular inlet channel can be seen, the sluice gate is just under the wooden walkway (Authors own, 2005)

Controlling the power output is important in order to mill different grains to different flour densities and so a sluice gate in front of the wheel controls the area of flow. There is also a sluice gate behind the wheel preventing back flow from storm surges jamming the wheel. At 10 rpm the wheels rotation is relatively slow allowing eels to pass through easily swimming to breeding grounds nearby.

Ford and Etal Estates receive a growing number of visitors each year to the mill and are keen to power the mills' lighting (it has no heating) with renewable energy. A research project with Newcastle University has concluded that using the wheel's outflow, and the considerable head drop there to turn a turbine would prevent altering the complex milling machinery and would raise visitor's awareness of another type of microhydropower. (37)

2.82 **Howsham Mill Project, Renewable Heritage Trust, North Yorkshire**

Sitting on an island in the river Derwent in Howsham this former watermill was been abandoned as a derelict shell (see Fig. 25 next page). The mill was built in about 1770 by the eminent architect John Carr of York in the Gothic Revival style of fussy details that was seldom used on functional buildings. This lead to Howsham mill being described as "a building of maximum historical interest" by an inspector for the Royal Commission of Historical Monuments some 40 years ago (31).

The mill closed in 1947 and despite its Grade II listing and presence on several buildings at risk registers the mill fell into disrepair and dereliction, the roof fell in and parts of the undershot waterwheel were stolen (31).

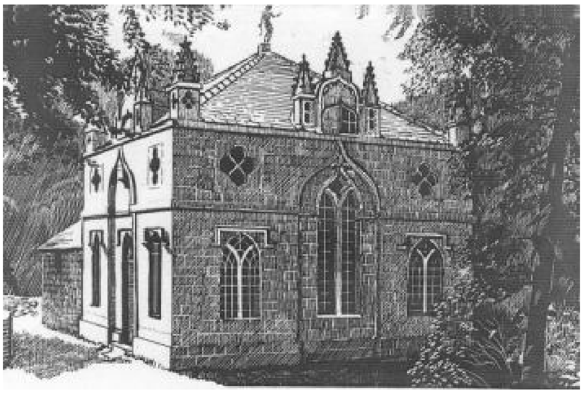


Fig. 24 Howsham Mill c.1945 (32)   Fig. 25 Howsham Mill before renovation (32)

A local charity called the Renewable Heritage Trust have formed to restore the mill, turning it into an educational centre about renewable energy and to reinstate a waterwheel to power the centre, giving the public a chance to see renewable energy close up (32). The Trust relies on grants and donations and the hard work of their volunteers to carry out much of the renovation work giving the project a feel of community involvement (See Fig. 26).

A research project with Gerald Muller at Queens University has been carried out over 2004-2005 to determine a suitable wheel design. From his tests into breast shot wheels and their efficiencies the Trust are hoping to install a breast shot wheel designed by him. The site has plenty of water and the centre only needs a small output (approx 0.5kW) and so feel that a breast shot wheel, being smaller in diameter than an undershot wheel, would rotate faster limiting gearing ratios and being cheaper to construct. There are also plans to install an Archimidian hydraulic screw in the sluice channel which would enable the Trust to sell some power back to the National Grid funding, further rebuilding. (38)

Fig. 26 Community renovation of Howsham Mill (46)

2.83 **Pedley Wheel Charitable Trust, Sri Lanka**

The Pedley Wheel Charitable Trust began in a similar grass-roots renewables vein as the Howsham Project. In 1991 the trust built a demonstration overshot waterwheel in Pedley Wood in Cheshire to interest young people in renewable energy.

After many attempts at solving the high gearing ratios the trust replaced the original tractor gearing systems they had with a chain configuration and an industrial gearbox (33). The trust also run their wheels as quickly as possible to minimise the torques and gearing ratios using about 65% of the power theoretically possible (34).

Fig. 27 An example of a Pedley Wheel (34)

In 1998 the trust visited Lower Amanawela in the high up Southern Uplands of Sri Lanka. Although situated at approximately 460 m above sea level (35) the village did have two discarded irrigation channels, one 5m below the other, providing an ideal low head site.

The trust then designed the 3.5m dia wheel in the UK, and had it built in Colombo whilst villagers built the powerhouse and civil works. To many critics surprise the wheel has worked well since installation producing 2.75 kW to light and heat 25 homes. There is also a stand alone gearbox allowing mechanical power for milling, woodwork, rice hulling etc. The electricity is administered by the Village Electricity Consumer's Society who maintain the system and issue each house with a time slot when they can exceed their allocated 100W usage (35).

Since this project the trust has completed four waterwheel projects in Sri Lanka and are planning four more (36) providing power to a diverse range of properties including houses, community centres and computer training facilities.

3 Technical Background

3.11 Waterwheel Design

Unlike overshot and breast shot wheels a stream wheel does not rely on a difference in head (See Fig. 28) but instead uses the potential energy of the water to generate power.

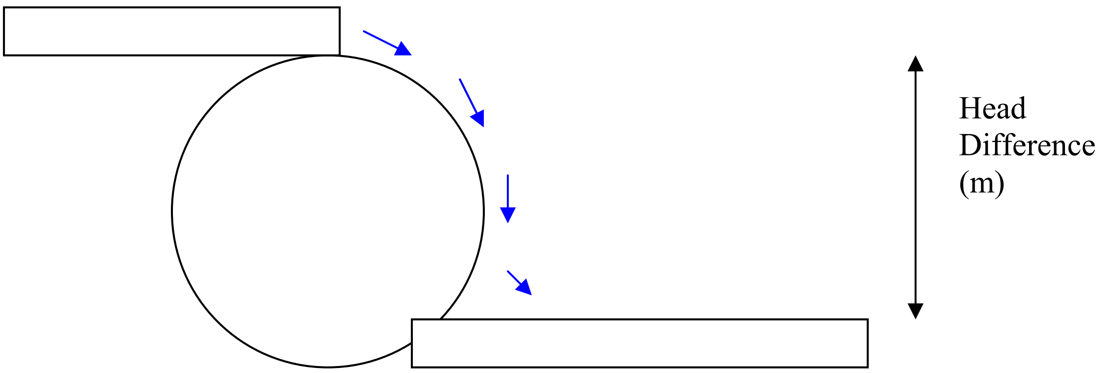

Fig. 28 Overshot wheel using potential energy and head difference to generate electricity

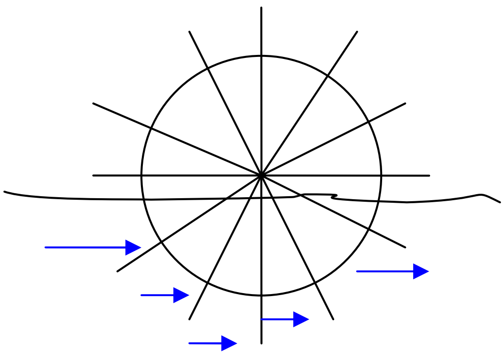

Fig. 29 Stream wheel using the kinetic energy of the flow to generate electricity

3.12 The Force on one paddle of a stream wheel is given by rearranging the drag equation to get : $F = 0.5 \times \rho \times Cd \times A \times V_r^2$ where ρ = Density of Water, Cd = Drag Coefficient, A = Area of blade in the water and Vr = velocity of the blade relative to the velocity of the water. MathCAD sheet can be viewed on enclosed CD

3.13 Determination of Cd

The drag coefficient for any object is influenced by its dimensions and journey through a fluid. From experimental data a variety of standard drag coefficients are known for set shapes. No experimental data exists on the drag coefficient of a waterwheel blade so here 1.5 has been used as an estimate, as this is the Cd value for a rectangular plate.

3.14 Determination of A

The area of the blade in the water obviously changes as the blade rotates about the central axis. To model this change mathematically the movement from a vertical position in the water to 90 degrees to the vertical is modelled. So if x = the angle at the wheels centre the blade's movement is modelled from x = 0 through x=x1 (when the blade begins to leave the water) to x = xL, (when the blade fully leaves the water). DraftT is the distance between the wheels centre and the top of the water, y is the distance from the wheels centre to the top of the blade and a(x) is the vertical distance from the wheel centre to the waterline.

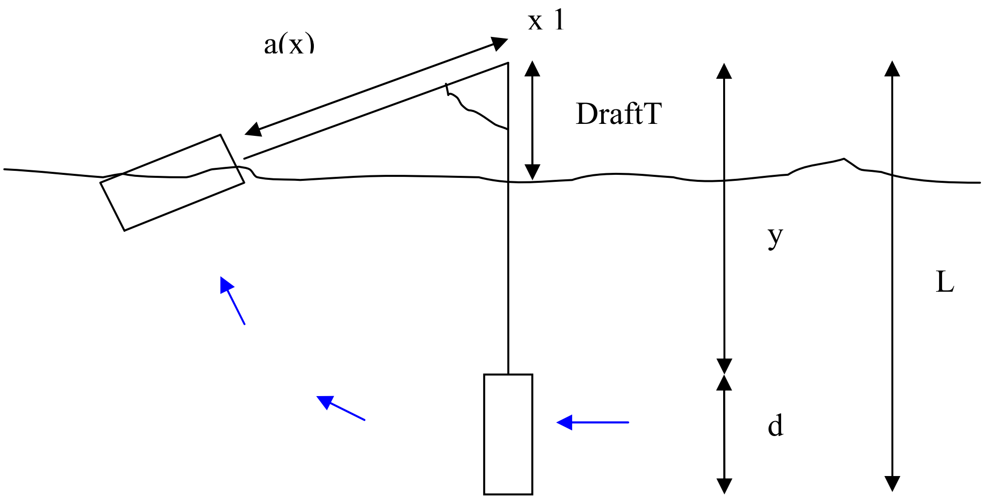

Fig. 30 Diagram showing the passage of one blade through the water

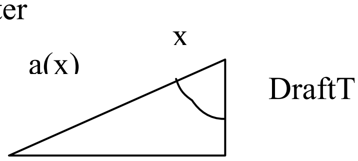
Using basic trigonometry a(x) can be expressed:



$$Cos\theta = adj \div hyp$$

$$Cosx = DraftT \div a(x)$$

Re-arranged to get: $a(x) = DraftT \div \cos x$

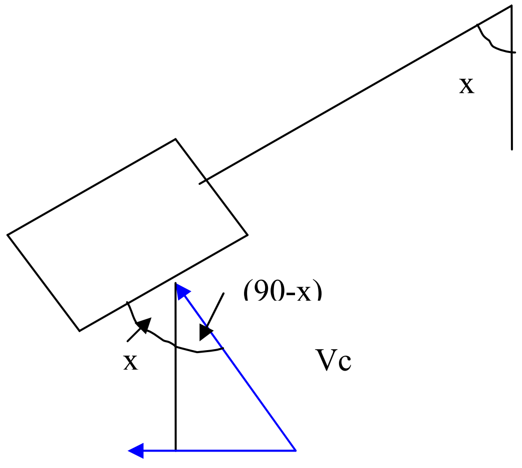
If a(x) is $\leq L - d$ then the paddle is still fully submerged and this area is given by: $A(x) = d \times f$ where f = width of the blade

However as the angle x increases towards x1 (when the blade begins to leave the water) a(x) increases and the submerged area decreases: $A(x) = (L - (a(x)) \times f$

3.14 Determination of Vr(x)

In order to express the relative velocity, Vr it is necessary to know the velocity of the blade, Vb and the velocity of the current in the direction of the blade, Vc. Vc is found by using trigonometry:

$$\sin\theta = opp \div hyp$$
$$\sin(90 - x) = Current \div V_c$$
$$V_c = Current \times \sin(90 - x)$$
$$V_c = Current \times \cos(x)$$



Fig… Diagram showing the current component in the blade's direction, Vc

The velocity of the blade, Vb is equal to the Current speed multiplied by a constant, p that represents the proportion of the Current the blade should absorb for maximum power output.

A way to think of p is to imagine the amount of work the water needs to do to turn a blade. If the wheel is allowed to rotate freely with the speed of the current then the water will easily push the blades around transferring no energy from water to blade- "freewheeling". If the wheels speed is less than the current then the water will have to push harder to turn the blades the same distance transferring energy to the blade.

If, however the wheels resistance increases too high then the water will find it too difficult to move the blades, instead flowing around and underneath them, leaving the wheel stationary.

This phenomenon was first described by Antoine Parent in 1704 who correctly identified that the optimum value for p was 1/3 (40).
This has been since proved by M.Denny in "The efficiency of overshot and undershot waterwheels" (8). In that paper the constant p is renamed c and the Power Output and Power Input are calculated. Efficiency = Power Ouput/Power Input and through cancelling out common terms, p is found to be 1/3 and the maximum efficiency, 33% (8).
Further evidence is provided in J. Wolfram's derivation in Appendix B and testing using the MathCAD worksheet on page…
In order to maintain this blade speed the generator would be calibrated to provide a set amount of resistance. Some waterwheel owners prefer to run the wheel faster than 1/3 of the current speed, in order to limit the gearing ratios involved, even at the expense of some efficiency (34)
So in conclusion,

$$V_c = V_c - V_b$$
$$V_c = (Current \times \cos x) - (p \times Current)$$

3.15 **Moment at the Waterwheel Centre**

The moment at the waterwheel centre is given by:
M (x) = F * LeverArm
Where LeverArm = distance from the centre of the wheel to the centre of the submerged areas of the blade
The work done between x = 0 and x = xL is equal to the integral of moment at the wheel centre. The work done by one blade from entering the water to leaving is given by:
WorkDone = 2 * ∫ M(x) dx
As the work done is measured in terms of radians not degrees a conversion factor of π/180 is used and the work done by the entire wheel is found using:
Total Work Done = N * Work Done * (π/180)

3.2 **Basic Barge Design**

In order for any object to float the downwards force that its weight supplies must equal the upward force supplied by the water. Archimedes found this upward force to be equal to ρgV where ρ is the density of the fluid displaced (usually water), g is the gravitational constant and V is the volume of the object underwater. This seems logical when considering cruise liners with hundreds of rooms, swimming pools, restaurants etc. that balance their large weight with many storeys being below the waterline.

However in order for a barge to float it also has to be stable. Too much swaying from side to side may lead to water entering and the barge sinking or capsizing.

The Centre of Gravity (CG), that the ships weight acts through must be in the same vertical line as the Centre of Buoyancy (CB), which is in the centre of the underwater volume. Swaying from side to side is can be caused by the CG moving if one side is heavier than another, this in turn will cause the CB to move to line up vertically with the new CG position. Both centres can be defined using 3 co-ordinates but for stability the Vertical Centre of Gravity (VCG) and Vertical Centre of Buoyancy (VCB) are used.

VCG represents the height that the entire weight of the ship acts through, normally measured from the base.

$VCG = \sum(MassesOfComponents \times IndividualCentreofGravity) \times \sum MassesOfComponents$

VCB is simply given by $DraftT \div 2$, and in this case the draft is decided by the waterwheel's requirements. In most barge design standard codes will be set as to the appropriate draft depth.

If a barge sways to one side due to wave action the Centre of Gravity will remain in the same place and the Centre of Buoyancy will move as the volume of barge underwater changes. If a vertical line is drawn from the original CB through CG upwards, intersecting a line from the new CB point they will meet at a theoretical point above the barge called the Metacentre, M. The distance BM is calculated using $Ixx \div V$, where Ixx is the second moment of area of the waterplane from the centre line axis (for a rectangular shape $= bd^3 \div 12$).

The Metacentric height, GM is given by $= VCB + BM - VCG$ and is the standard value used to determine a vessel's stability. An iterative process is used firstly inputting dimensions similar to previous designs, balancing the applied forces and then insuring GM is within acceptable limits.

4 MathCAD Model

The following flow chart describes the design process for the waterwheel model. Design is very much an iterative process of refining and feeding in new ideas as they come to light

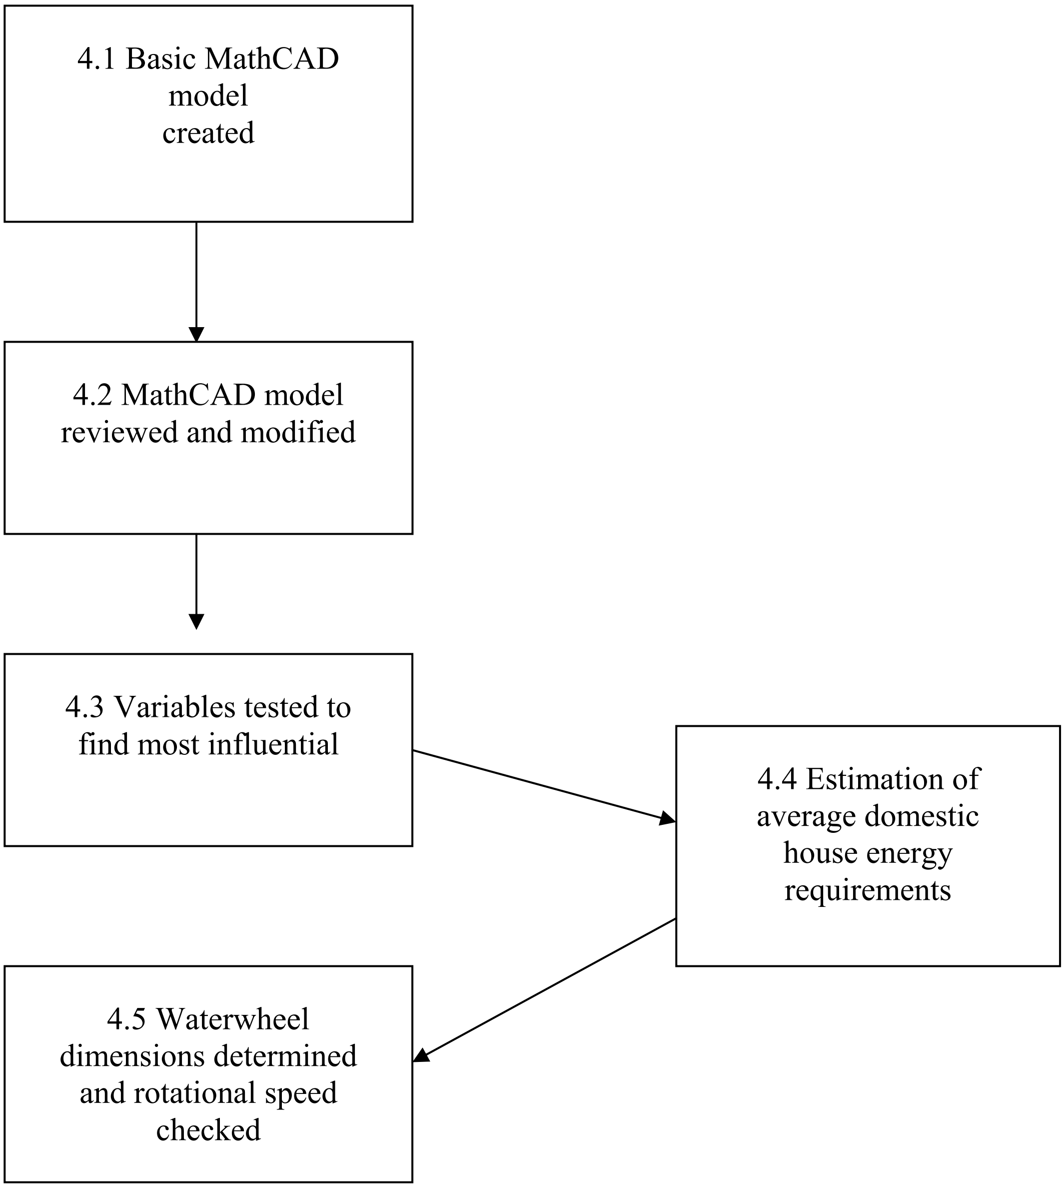


Fig. 32 Design process for waterwheel

4.1 Basic MathCAD Model

Using the theory explained in the Technical Background a basic MathCAD model was created describing the movement of a blade from the vertical position to the point when it leaves the water (see enclosed CD for copy). A copy of this early model appears on the next five pages with user inputs highlighted in red and observations highlighted in blue.

Initial assumptions included:

- The angle at which the blade leaves the water, xL is determined by the designer as 45 degrees.
- The area of the blade submerged decreases proportionally as the angle, x increases.
- The constant, p will be kept at the optimum 1/3 by later generator selection and design.
- The top of the blade sits at the waterline so once x is larger than zero the blade begins leaving the water (see fig. 33 below)
- The rate of rotation of the blade is constant; there is no acceleration or deceleration.
- The drag coefficient, Cd equals 1.5.
- The velocity of the Current is constant across the blades surface

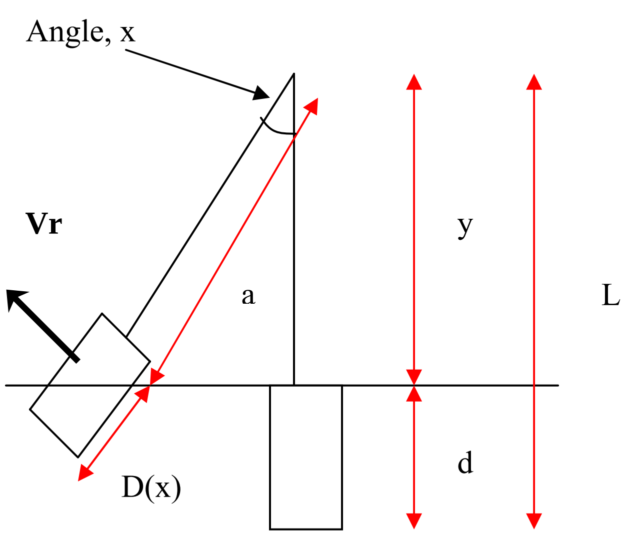

Fig. 33 Rotation of one blade through water

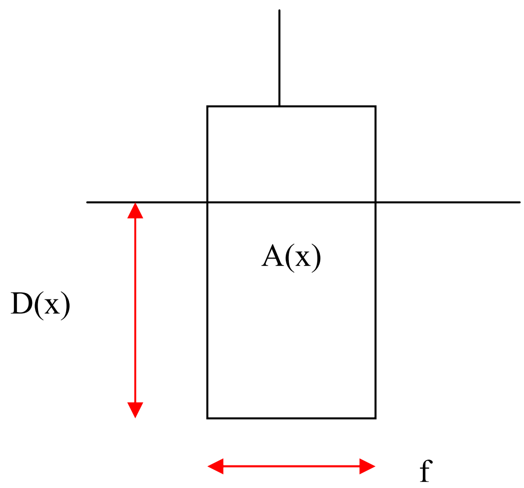

Fig. 34 Cross section of a blade

Fig. 35. Initial MathCAD design

Expressing Vb and Vc

$t := 1($ t= time taken for one blade to rotate 360 degrees

$Current := 2$ Current= velocity of the river

$x := 0..45$ x= angle at the centre of water wheel

$xL := 45$ xL= angle at the centre of the waterwheel as the blade leaves the water

$Cd := 1.2$ Cd= Drag Coefficient

$\rho := 100($ ρ=Density of Water

In this early design model it was decided that the user would specify the time for one blade to rotate 360 degrees. This was later changed to be derived from the blades velocity.
The angle that the blade would leave the water was also specified by the user regardless of the wheels dimensions. There is no DraftT value incorporated so the top of the blade is in line with the waterline, meaning the area decreases as x increases and so the power output was low.

Expressing Area, A

The dimensions of the wheel are decided by the user based on aesthetics, site conditions and minimising cost

$x := 0..45$

$f := 0.30$ f= width of the blade

$d := 0.5$ d= depth of blade

$L := 1.3$ L= distance from centre of waterwheel to bottom of blade

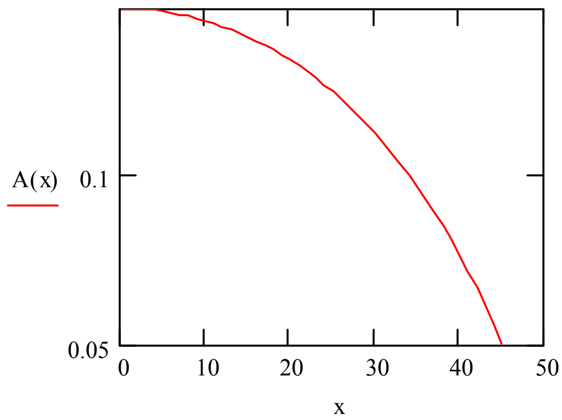
$y := L - d$ y= distance from centre of waterwheel to top of blade

$y = 0.8$

$a(x) := \dfrac{y}{\cos(x \cdot deg)}$ a=diagonal distance from the centre of the waterwheel to the water line

$D(x) := L - a(x)$ D(x)= depth of blade in water

$A(x) := D(x) \cdot f$ A(x)= surface area of blade in water



As the Force output is based on the Area this graph will give a low output as the area is decreasing with x. A more optimum design would have a constant area for as long as possible and then a quick drop in submerged area

Expressing Vr

The lever arm changes as the blade leaves the water and the submerged area decreases

$$\mathrm{Larm}(x) := L - \left(\frac{D(x)}{2}\right)$$

Larm is the lever arm from the centre of the waterwheel

$$p := \frac{1}{3}$$

p = the optimum proportion of velocity the blade absorbs from the current. Constant.

$$\mathrm{Vb}(x) := \mathrm{Current}\cdot p$$

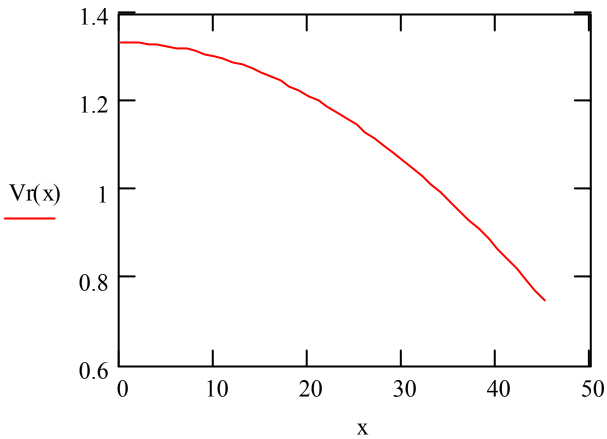
Vb(x)=rotational velocity of the blade

$$\mathrm{Vc}(x) := \mathrm{Current}\cdot\cos(x\cdot\deg)$$

Vc(x)= component of the current in the blade's direction

$$\mathrm{Vr}(x) := \mathrm{Vc}(x) - \mathrm{Vb}(x)$$

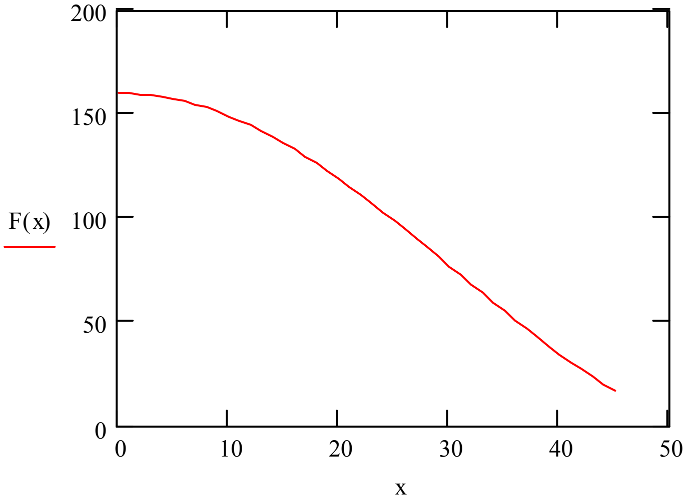
Vr= relative velocity



As expected the relative velocity drops as the blade begins to leave the water

Finding the force on the blade

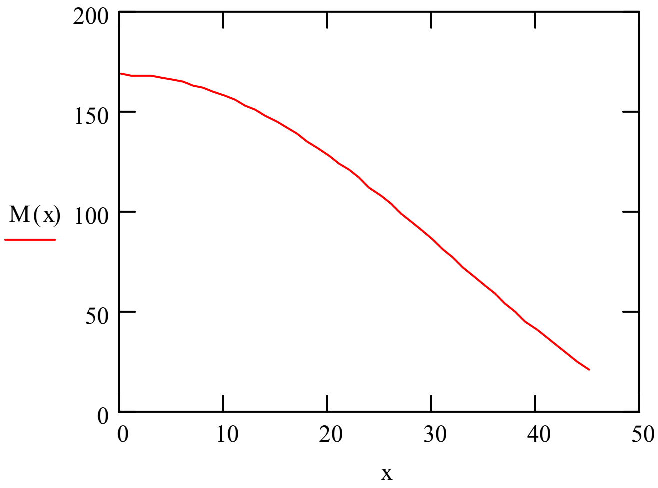
$F(x) := 0.5 \cdot \rho \cdot Cd \cdot (Vr(x))^2 \cdot A(x)$ F(x)= Force on the blade



Finding the Moment at the waterwheel centre

$M(x) := F(x) \cdot Larm(x)$ M(x)= Moment at the waterwheel centre

Both graphs seem consistent with less Force and Moment being produced as the blade leaves the water



Expressing the Work Done and Power Absorbed

Workdone in the 2nd half of travel = Work done in the first half of travel, so the Total Work Done on one paddle moving through the water= 2* the integral of the Moment at the centre of the wheel

$$\text{WorkDone} := 2\cdot\int_0^{xL} M(x)\,dx$$

WorkDone1= work done on 1 blade whilst moving through the water

$$N := 7$$

N= number of blades

$$\text{TotalWorkDone} := N\cdot\text{WorkDone}\cdot\left(\frac{\pi}{180}\right)$$

TotalWorkDone = total work done for the whole wheel. A conversion is needed to change degrees into radians

$$\text{PowerAbsorbed1} := \frac{\text{TotalWorkDone}}{t}$$

$$\text{PowerAbsorbed1} = 120.584$$

$$\text{PowerAbsorbed} := \frac{\text{PowerAbsorbed1}}{1000}$$

PowerAbsorbed (kW) = total amount of power absorbed by the wheel during one movement through the water.

$$\text{PowerAbsorbed} = 0.121$$

4.20 Reviewing and Modification of MathCAD Model

The basic model had a number of inaccurate features that could be improved; a copy of the improved worksheet can be seen over the next four pages. Improvements included:

- Introduction of a waterline and a DraftT value which then allows the designer to alter how low in the water the wheel is sitting.
- The exit angle, xL is now defined in terms of the draft and the diameter, L allowing a more integrated design.
- The change in submerged area is also linked to the draft and the model has been updated so the area is constant until the blade begins to leave the water.
- By rearranging time = distance/speed in terms of rotational distance/blade velocity a more accurate value for t is produced.

Fig. 36 Modified MathCAD design

Expressing Vb and Vc

$Current1 := 2$

$DraftT := 0.4$ DraftT= Distance between the axis of the waterwheel and the top of the water

$L := 4.5$ L= distance from centre of waterwheel to bottom of blade in metres

$$xL := \left(\operatorname{acos}\left(\frac{DraftT}{L}\right)\right)\cdot\left(\frac{360}{2\pi}\right)$$

$xL = 84.9$ xL= angle at the centre of the waterwheel as the blade leaves the water

$x := 0 .. xL$ x= angle at the centre of water wheel in degrees

$Cd := 1.5$ Cd= Drag Coefficient

$\rho := 1000$ ρ=Density of Water in kgm^-3

A more realistic design is created by inputting the waterline and noting the Force created from x = 0 to x = xL.

$f := 4$ f= width of the blade in metres

$d := 3.5$ d= length of blade in metres

$L := 4.5$ L= distance from centre of waterwheel to bottom of blade in metres

$y := L - d$

$y = 1$ y= distance from centre of waterwheel to top of blade in metres

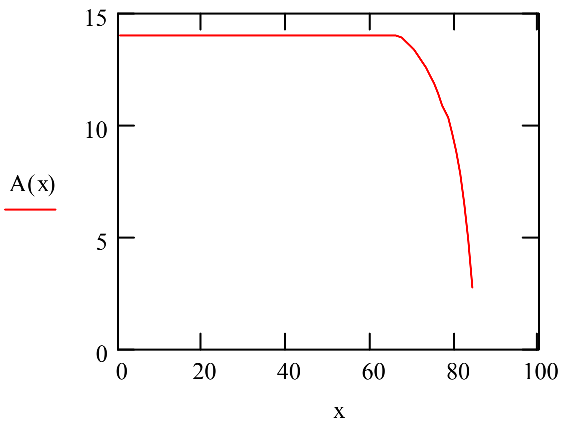
DraftT= Distance from centre of waterwheel to the water line when x=0

$a(x) := \frac{(\mathrm{DraftT})}{\cos(x \cdot \deg)}$ a(x) =diagonal distance from the centre of the waterwheel to the water line in metres

$$D(x) := \begin{vmatrix} d & \text{if } L - a(x) > d \\ (L - a(x)) & \text{otherwise} \end{vmatrix}$$

D(x)= depth of blade in water in metres

$A(x) := D(x) \cdot f$ A(x)= surface area of blade in water in m^2



The inclusion of a DraftT term allows the Area to be accurately calculated. The graph above shows the blade area being constant, as it moves through the water and then suddenly dropping as it leaves the water

Expressing Vr

p=proportion of speed blade takes up from river

$p := 0.33$

$$t := \frac{2 \cdot \pi \cdot L}{p \cdot Current1}$$

t= time taken for one blade to do one revolution (seconds)

Calculation of t is now linked to values of L and the Current speed

$t = 42.84$

$Vb := p \cdot Current1$

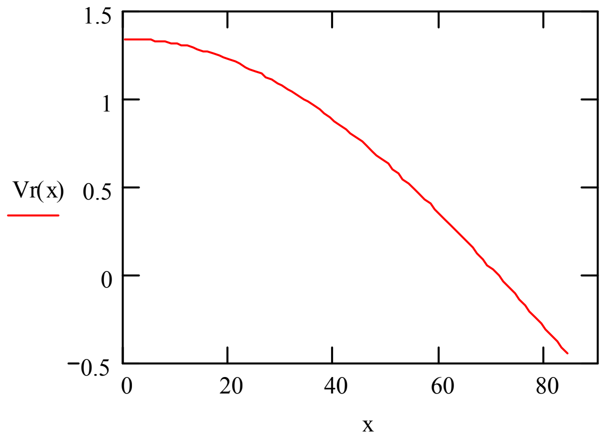
Vb(x)=rotational velocity of the blade in ms^-1

$Vc(x) := Current1 \cdot \cos(x \cdot deg)$

Vc(x)= component of the Current in the blade's direction in ms^-1

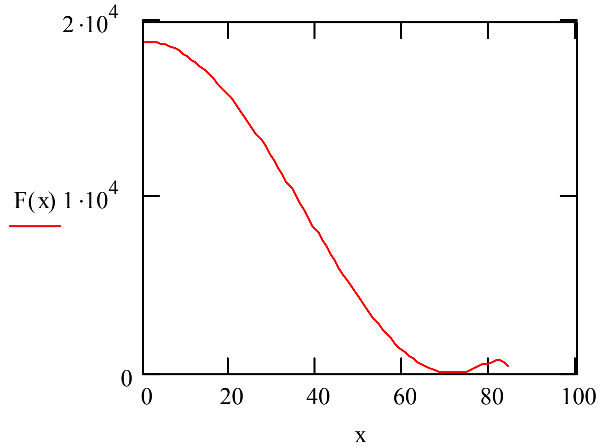
$Vr(x) := Vc(x) - Vb$

Vr= velocity of the blade relative to the speed of the Current in ms^-1



Finding the force on the blade

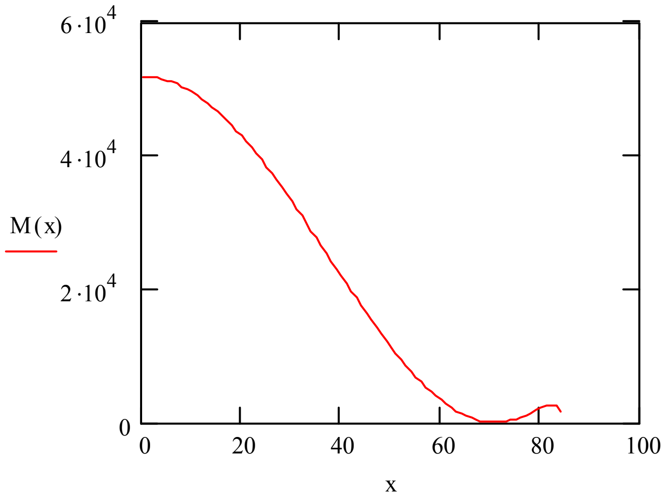
$F(x) := 0.5 \cdot \rho \cdot Cd \cdot (Vr(x))^2 \cdot A(x)$ F(x)= Force on the blade in kgms^-2 or Newtons



Finding the Moment at the waterwheel centre

$Larm(x) := (L) - \left(\frac{D(x)}{2}\right)$ Larm is the lever arm from the centre of the waterwheel in metres

$M(x) := F(x) \cdot Larm(x)$ M(x)= Moment at the waterwheel centre in kgm^2s^-2 or Nm



Expressing the Work Done and Power Absorbed

Workdone in the 2nd half of travel = Work done in the first half of travel, so the Total Work Done on one paddle moving through the water= 2* the integral of the Moment at the centre of the wheel

$$WorkDone := 2 \cdot \int_0^{xL} M(x)\,dx$$

WorkDone= work done on 1 blade whilst moving through the water in Nm

$$N := 16$$

N= number of blades

$$TotalWorkDone := N \cdot WorkDone \cdot \left(\frac{\pi}{180}\right)$$

TotalWorkDone = total work done for the whole wheel in Nm

$$PowerAbsorbed1 := \frac{TotalWorkDone}{t}$$

$$PowerAbsorbed1 = 2.477 \times 10^4$$

PowerAbsorbed1 = total amount of power absorbed by the wheel during one movement through the water in Nms^-1or Watts

$$PowerAbsorbed := \frac{PowerAbsorbed1}{1000}$$

PowerAbsorbed= total amount of power absorbed by the wheel during one movement through the water in kNms^-1 or kWatts

$$PowerAbsorbed = 24.771 \text{ kW}$$

4.21 **Further Modification**

It can be seen from the graph of Vr(x) against x that there comes a point when the velocity appears to be negative causing an upturn in the Force against x graph (below).

Considering Vr = Vc – Vb

= (Current * cos x) – (Current * p)

= (cos x) – p

So in that case when cos x = 1/3 then Vr will equal zero. This will occur regardless of the current at approximately 70.5 degrees (see graph below).

Fig. 37 Further Modification of MathCAD sheet

$p := 0.33$ p=proportion of speed blade takes up from river, proved in Appendix

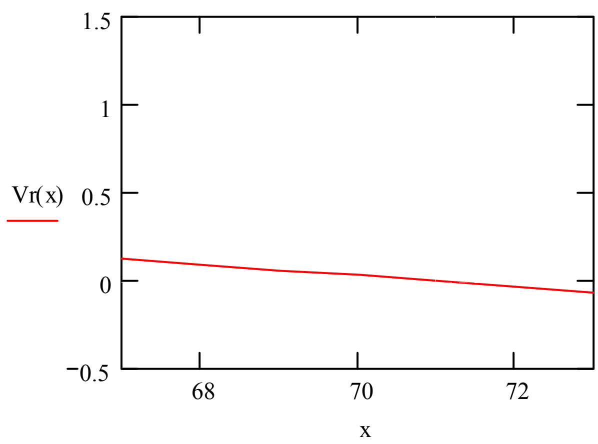
$Vb := p \cdot Current1$ Vb(x)=rotational velocity of the blade in ms^-1

$Vc(x) := Current1 \cdot \cos(x \cdot deg)$

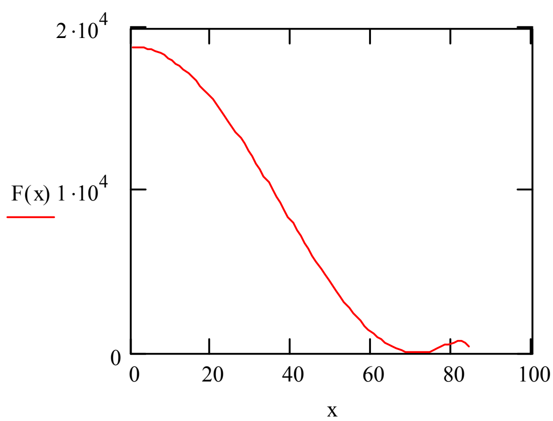
Vc(x)= component of the current in the blade's direction in ms^-1

$Vr(x) := Vc(x) - Vb$

Vr= velocity of the blade relative to the speed of the Current in ms^-1



$F(x) := 0.5 \cdot \rho \cdot Cd \cdot (Vr(x))^2 \cdot A(x)$



This can be physically reconciled by considering the blade's path through the water (See Fig. 38). When the blade is vertical in the water the Current velocity acts at right angles to the blade, generating the most force. As the blade rises the angle changes enabling more water to flow under the blade not passing on energy. At 70.5 degrees the current passes on no more energy to the blade managing to escape around the base and sides. Above 70.5 degrees its is suggested that the system may begin to lose energy as the blade push aside water above it to reach the surface.

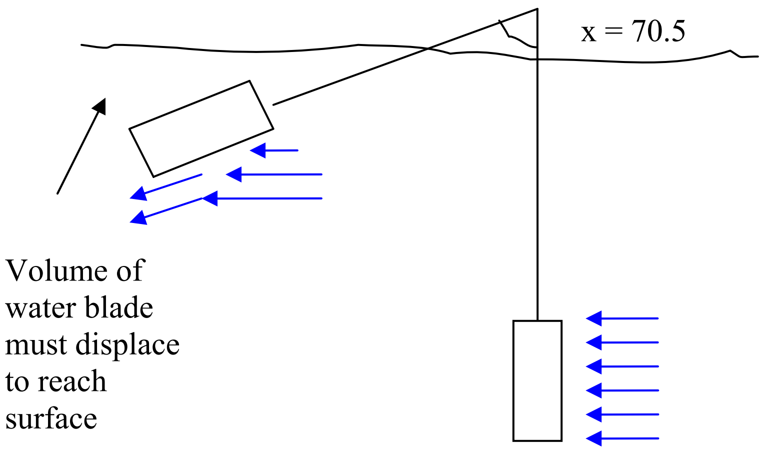


Fig. 38 Diagram showing blades at 0 degrees and 70.5 degrees.

This implies that the blade need not be in the water past 70.5 degrees, which in turn decides the optimum Draft for the system;

$L := 5.5$ L= distance from centre of waterwheel to bottom of blade in metres

$x1 := 70.5$ x1= the optimum angle for the blade to begin to leave the water

$y := 2$ y= the lever arm distance from the waterwheel centre to the top of the blade

$$DraftT := \cos(x1 \cdot deg) \cdot y$$

$DraftT = 0.668$ DraftT= Distance between the axis of the waterwheel and the top of the water

$$xL := \left(\operatorname{acos}\left(\frac{DraftT}{L}\right)\right) \cdot \left(\frac{360}{2\pi}\right)$$

$xL = 83.028$ xL= angle at the centre of the waterwheel as the blade leaves the water

$x := 0 .. xL$ x= angle at the centre of water wheel in degrees

By adjusting the Vr equation all negative values of Vr are ignored, removing the upturn in the Force graph;

$Vb := p \cdot Current1$

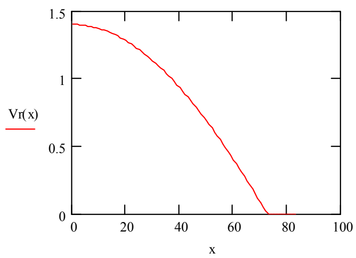
Vb(x)=rotational velocity of the blade in ms^-1

$Vc(x) := Current1 \cdot \cos(x \cdot deg)$

Vc(x)= component of the current in the blade's direction in ms^-1

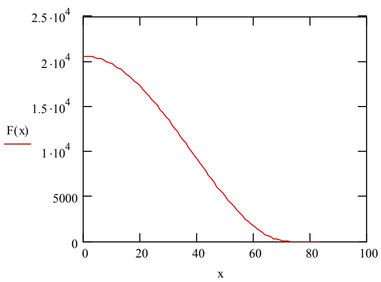
$Vc(30) = 1.732$

$$Vr(x) := \begin{cases} (Vc(x) - Vb) & \text{if } (Vc(x) - Vb) > 0 \\ 0 & \text{otherwise} \end{cases}$$



$$F(x) := 0.5 \cdot \rho \cdot Cd \cdot (Vr(x))^2 \cdot A(x)$$

F(x)= Force on the blade in kgms^-2 or Newtons



The only assumptions still in the final worksheet were:

- The drag coefficient, Cd equals 1.5.
- The rate of rotation stays constant, there is no acceleration or deceleration of the blades
- The velocity of the Current acts constantly across the blades surface
- The forces experienced by the blade are simplified not considering the effects of turbulence, currents or loss of energy through splashing.
- Blades are flat, rectangular blocks
- Constant p is kept at 1/3 by later generator selection and design

4.2 Variables Testing

By altering the input variables individually by 50% and noting the corresponding Power Absorbed the most influential variables can be found, leading to a more complete understanding of how they influence power output.

4.31 Initial Values- number of paddles, N =7

Current= 2 ms^-1

DraftT= 0.8m

Width of blade, f= 0.3m

Depth of blade, d= 0.5m

Length from axis to base of blade, L= 1.3m

Lever arm, y= 0.8m

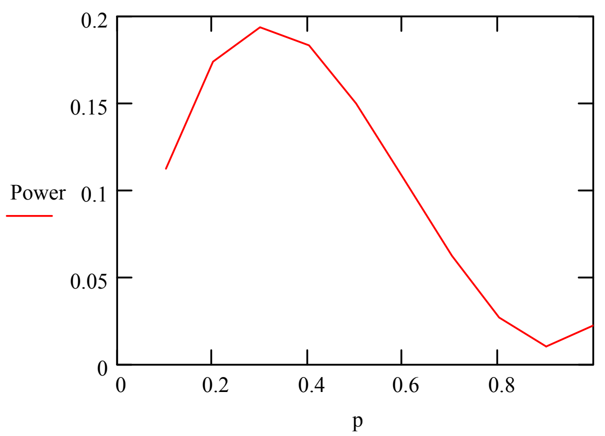
Constant, p= 0.33

Angle blade leaves the water, xL= 52.02 deg

This gives an initial Power Output of 0.12 kW

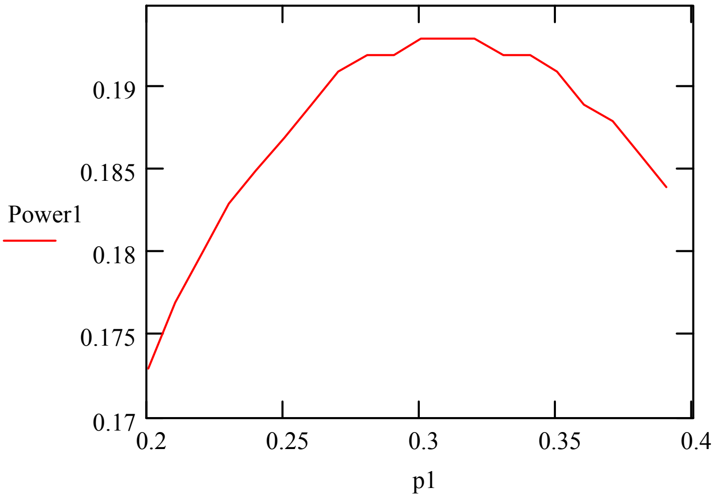
4.32 **Test 1.0- Confirmation of p=0.33 value**:

i) Values of p from 0-1.0 were plotted against power output and the maximum was found to lie between 0.2 and 0.4



$$p := \begin{pmatrix} 0.1 \\ 0.2 \\ 0.3 \\ 0.4 \\ 0.5 \\ 0.6 \\ 0.7 \\ 0.8 \\ 0.9 \\ 1.0 \end{pmatrix} \qquad Power := \begin{pmatrix} 0.112 \\ 0.173 \\ 0.193 \\ 0.183 \\ 0.15 \\ 0.107 \\ 0.062 \\ 0.027 \\ 9.896 \cdot 10^{-3} \\ 0.022 \end{pmatrix}$$

ii) Values of p from 0.20-0.39 were plotted against Power Output values (kW) with the maximum occurring at 0.3 confirming the proof work in the Technical Background chapter



$$p1 := \begin{pmatrix} 0.20 \\ 0.21 \\ 0.22 \\ 0.23 \\ 0.24 \\ 0.25 \\ 0.26 \\ 0.27 \\ 0.28 \\ 0.29 \\ 0.30 \\ 0.31 \\ 0.32 \\ 0.33 \\ 0.34 \\ 0.35 \\ 0.36 \\ 0.37 \\ 0.38 \\ 0.39 \end{pmatrix} \qquad Power1 := \begin{pmatrix} 0.173 \\ 0.177 \\ 0.18 \\ 0.183 \\ 0.185 \\ 0.187 \\ 0.189 \\ 0.191 \\ 0.192 \\ 0.192 \\ 0.193 \\ 0.193 \\ 0.193 \\ 0.192 \\ 0.192 \\ 0.191 \\ 0.189 \\ 0.188 \\ 0.186 \\ 0.184 \end{pmatrix}$$

Test 1.1- Change of blade area:

i) Increase in blade width, f by 50%. Power Output noted

ii) Increase in blade depth, d by 50% which led to increases in length, L and leaving angle of blade, xL. Power Output noted

Test 1.2- Change in number of blades:

i) Increase in number of blades by 57%. Power Output noted.

Test 1.3- Change in lever arm:

i) Increase in lever arm, y by 50% leading to an increase in length, L and leaving angle of blade, xL. Power Output noted.

Test 1.4- Change in current speed:

i) Current speed increased by 50%. Power Output noted

Test 1.5- Change in DraftT

i) Increase in DraftT, causing a decrease in leaving angle of blade, xL. Power Output noted.

ii) Decrease in DraftT, causing an increase in leaving angle of blade, xL. Power Output noted.

Fig. 39 Results from Tests 1.1-1.5. Blue variables have been changed; yellow shows other variables reacting to that change

Test	N	Current (ms^-1)	Draft T (m)	f (m)	d (m)	L (m)	y (m)	p	xL	Power Output (kW)
Initial Values	7	2	0.8	0.3	0.5	1.3	0.8	0.3	52.02	0.12
T1.1 i)	7	2	0.8	0.45 +50%	0.5	1.3	0.8	0.3	52.02	0.187 +156%
ii)	7	2	0.8	0.3	0.75 +50%	1.55 +117%	0.8	0.3	58.9 +113%	0.19 +158%
T1.2	11 +57%	2	0.8	0.3	0.5	1.3	0.8	0.3	52.02	0.196 +193%
T1.3	7	2	0.8	0.3	0.5	1.7 +31%	1.2 +50%	0.3	61.9 +119%	0.158 +132%
T1.4	7	3 +50%	0.8	0.3	0.5	1.3	0.8	0.3	52.02	0.421 +350%
T1.5 i)	7	2	0.12 +50%	0.3	0.5	1.3	0.8	0.3	22.62 -56.5%	0.015 -87.5%
ii)	7	2	0.4 -50%	0.3	0.5	1.3	0.8	0.3	72.08 +38.6%	0.152 +26.7%

From the table above can be seen the increases in the variables and the corresponding increases in Power Output. The most influential variable for a stream wheel is the Current velocity shown by Test 1.4 as with a 50% increase it produces a 350% increase in Power Output. This is consistent with the relative velocity, Vr value being to the power of 2 in the Force equation.

The second most influential variable, which can be controlled by the designer is the number of blades. However the MathCAD model does not take into account that too many blades will lead to the water not being able to flow freely around the blade and so less force being generated on each blade. It was felt between 12 and 16 blades was optimum.

The tests show that an increase in the lever arm, y is more influential than either an increase in the depth or width of the blade (which produce very similar Power Output increases) and any change in draft is surprisingly uninfluential.

4.4 Estimation of Typical Domestic Energy Requirements

There are no published figures for a typical 3-bedroom house's energy requirements so in order to estimate them a list of household appliances was drawn up, their power ratings and duration of usage estimated. Obviously not all of these appliances will be running all day every day, so the duration of usage (in a month) is estimated and multiplied by the rating to get the power usage in kWhr. This is then divided by the number of hours in a month to get an overall power requirement in kW.

Standard appliances have been used throughout as have some of the findings of the Energy Consumption in the UK Report (41) which shows statistically appliances that are widely owned. From the graph below the household appliances considered "typical" included- VCR, washing machine, microwave, fridge freezer, refrigerator.

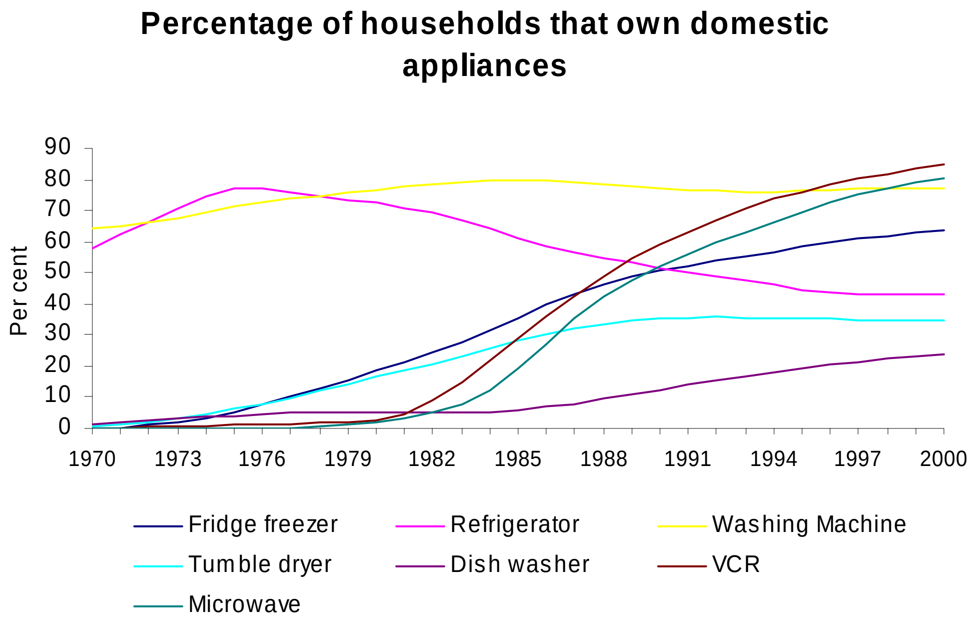


Fig. 40 Graph showing the percentage of household appliances owned in the UK, 1970-2000 (41)

From page 25 of the report it was noted that 59% of UK households have two or more colour televisions, 45% of UK houses own a home computer and that energy consumption for lighting had risen over the last decade due to multiple lights and table lamps (41). According to more recent DTI (42) data electric heating is the second most common form of heating, far behind gas so it is fairly realistic for the house in this dissertation to be heated using electricity.

Fig. 41 Table calculating the typical energy requirements of a three bedroom, four person family based on figures from (43).

Appliance	Quantity	Power rating in W	Average hours per month	Energy used (kWhr) per month
Blender	1	350	3	1
Coffee Maker	1	900	12	11
Electric Kettle	1	1500	15	10
Refrigerator freezer	1	500	300	150
Microwave Oven (0.5 ft)	1	900	10	9
Range and oven	1	3500	25	90
Toaster	1	1200	4	5
Washing machine (33 loads/month)	1	500	26	13
Electric water heaters Family of four	1	3800	140	532
Iron	1	1000	12	12
Water pump (1.2 hp)	1	1000	44	44
Electric Heating	1	1000	250	250
Hair Dryer	1	1000	5	5
60 W bulbs	15	900	120	108
Portable electric heater	1	1000	350	350
Telephone	1	6	720	4

Vacuum	1	800	10	8
Appliance	Quantity	Power Rating in Watts	Average hours per month	Energy used (kWhr)per month
Home computer	1	250	240	60
Radio	1	5	120	1
Stereo	1	120	120	14
Colour Television	1	100	125	13
Video Cassette Recorder	1	40	100	4
Total Energy Usage				1694 kWhr
Number of hours per month				720 hrs
Total Power Rating Required				**2.35 kW**

The average power rating is 2.35 kW but obviously there will be periods where there is a higher consumption e.g. morning breakfast and evenings, winter time.

For their electrical system the Pedley Wheel Trust estimates efficiencies in the region of generator- 81% and gearbox- 97% (49). Using these figures the overall power output will be 7.857 kW. By choosing 10 kW as the design output for the wheel enough energy can be insured and excess power may be stored in a battery or sold back to the national grid

4.3 Final Waterwheel Specification

The final waterwheel output is 10.5kW of power with specifications of:

L = 3.5m

y = 1m

d = 2.5m

f = 3m

DraftT = 0.42m

N = 12

4.41 Rotational speed check

One of the *"main disadvantages of water wheels for electricity generation is the slow shaft speed"* (24) as AC generation requires a high rotational speed. Ideally at the most a 1:100 gear ratio will be used needing a rotational speed of at least 6 rpm from the wheel. Using $Rotationalspeedofthewheel = (9 \times Current) \div Diameter$ (6) the rotational speed of the final waterwheel was calculated as being 2.75 rpm. Chapters 5 and 6 detail a barge and catamaran design to support the wheel and also increase this rotational speed.

5 Barge Design using Excel

Following the calculation of a low rotational speed of waterwheel one possible solution was suggested- a barge with two waterwheels either side. A breakdown of the tasks involved in the barge design is shown below:

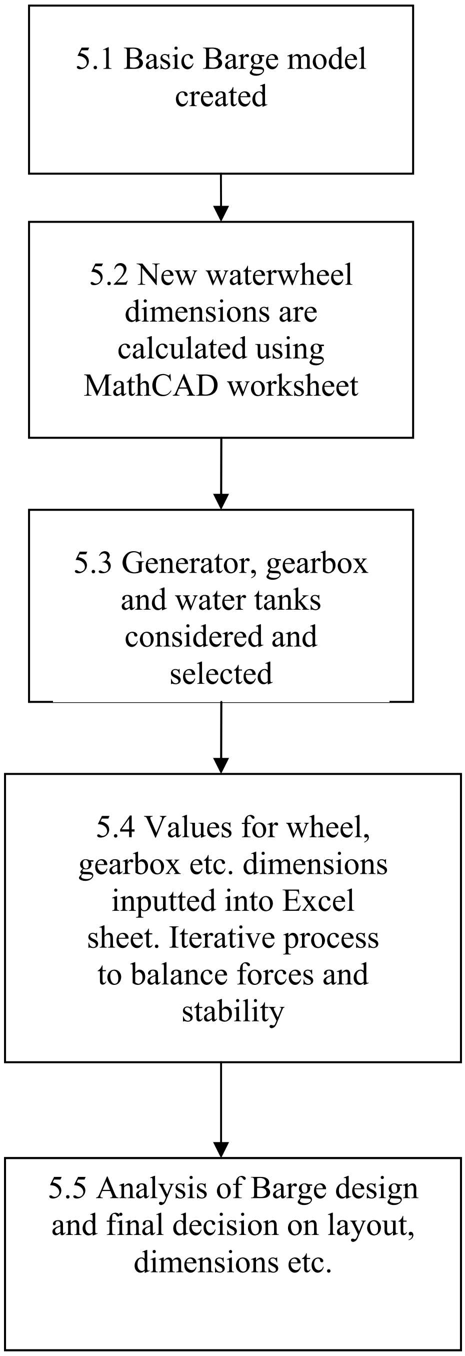

Fig. 42 Design process for barge

5.1 Basic Excel Model

Using the basic naval architecture given in the Technical Background section the basic barge design spreadsheet over pages 62-64 was generated (see enclosed CD for spreadsheet).The triangular barge ends pictured below prevent waves and turbulence at the barge ends. For this small scale design it was felt that the metacentric height, GM should be at least 30cm. Although drawn here the trash rack is not included in the spreadsheet.

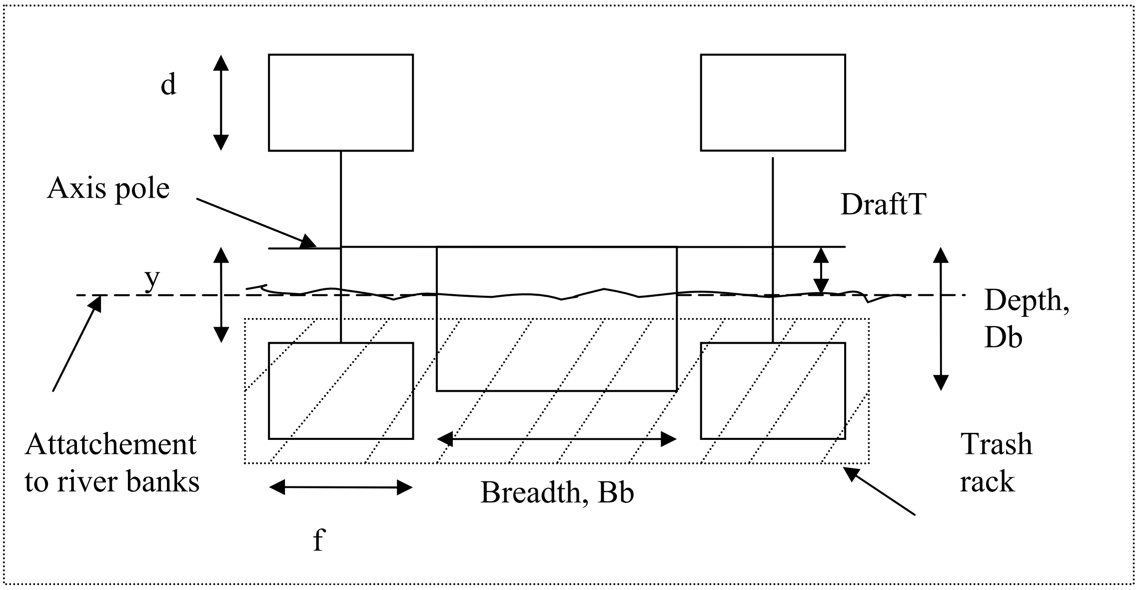

Fig. 43 Cross section showing barge with two waterwheels attached at either side

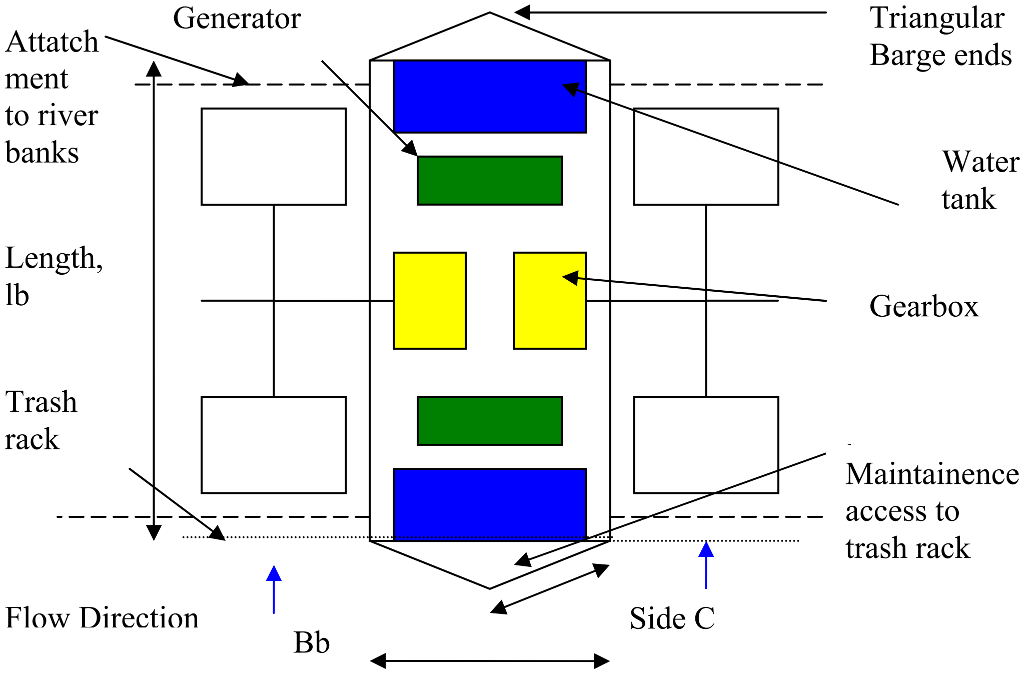

Fig. 44 Plan of barge showing approximate layout of generator, gearbox and watertanks

5.2 Waterwheel Re-design

The decision to have two 5.32 kW waterwheels producing the same 10.64 kW total power output as one wheel would have, leads to a lesser diameter for each wheel, increasing the rotational speed of the wheels, lessening the gear ratio.

Working in reverse from the optimisation of 4.32 now it becomes a matter of which dimensions can be lessened, whilst still keeping power output as high as possible. In changing the diameter, L the depth of the blades, d and the lever arm, y will lessen. Tests 1.1 and 1.3 showed that the depth of the blade is more influential in power output terms, so is kept as high as possible.

The final dimensions for each wheel are:

L = 1.5m

y = 0.4m

d = 1.1m

f = 3.5m

DraftT = 0.169m

N = 12

The rotational speed for each wheel is now 6rpm allowing a gear ratio of 1:100.

It is assumed that both wheels will experience the same velocity of current and so rotate at the same speed.

5.3 Generator, Gearbox and Watertank selection

5.31 Gearbox selection

A disadvantage often sited about waterwheels is their slow rotational speed. In the industrial revolution when they were often used to mill or lift water this posed no problem but to generate AC electricity a large gearing ratio is needed.

Waterwheel installers have sought to overcome this in a number of ways- using tractor gearboxes (6), modified car alternators (47), or even washing machine motors (48). Some groups advocate using integral geared motors, describing them as being available world wide and relatively cheap (49) whereas others claim using them as a generator is expensive (6).

The system shown below uses a specially designed Hydro-alternator that is ideal for low rotational speeds and is self-adjusting, and so useful for variable flows. The Canadian manufacturer supplies remote fishing cabins that generate their own electricity for domestic use and fishing boat battery recharging (50). Notice by building a sloped off-shoot stream to the main river the velocity can be increased.

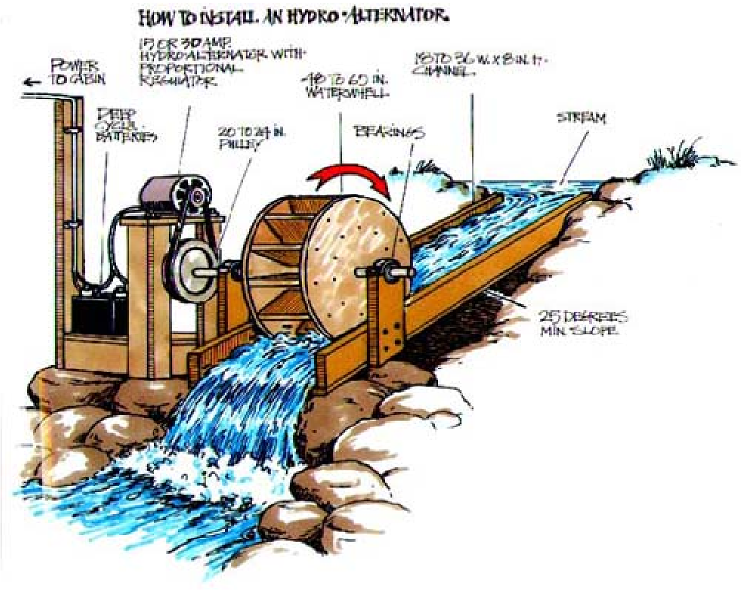

Fig. 45 Diagram showing Hydro-alternator wired to a waterwheel, Canada (50)

For the purposes of this dissertation a gearbox has been chosen to give a fairly accurate idea of the typical weight and dimensions involved, to more accurately calculate the downwards force on the barge and the space required. For a real-life design a trained mechanical engineer would be consulted.

Following advice from Dr. Davies of Heriot Watt University a type of reduction gearbox was chosen from suppliers, Boston Gear's (www.bostongear.com) non-flanged reducer 600 series range. Gearbox 623A-100 has been chosen with a ratio of 1:100 and weight of 36 lbs (≈16.3 kg) (51) with the overall dimensions in Fig…

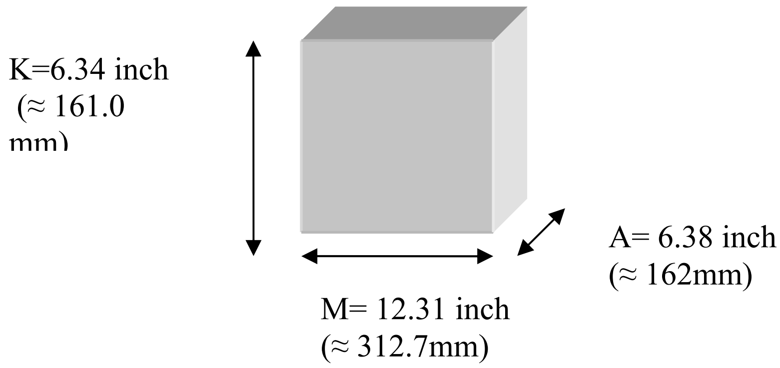

Fig. 46 Overall dimensions of gearbox from (51)

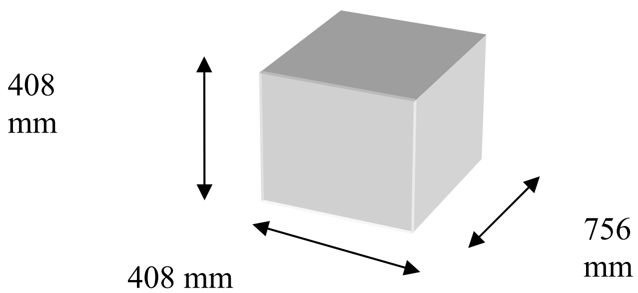
5.32 Generator Selection

As most houses require AC electricity it was decided to pick a Permanent Magnet Alternator that produces AC current. Other generation and storage systems could be selected but this is just a preliminary selection to give some indication of the weight and dimensions. After much searching a 2.5 kW Alternator was selected and its weight and overall dimensions multiplied by 1.5 to roughly equal a 5 kW Alternator, giving weight ≈ 60 kg (52)

Fig. 47 Overall dimensions of generator (52)



5.33 Watertank Design

In barge or catamaran design it is necessary to exactly balance the downwards force of the barge and its contents, with the upwards thrust of the volume of water displaced. To allow for future design changes that lead to an increase or decrease in weight (such as new, heavier gearbox or more blades on waterwheels, lighter generator etc.) two water tanks are included in this design. If further load is added later the equivalent weight of water can be removed from the tanks, keeping the vessel at the same draft depth.

5.34 Iterative barge design

There are two main components to designing a barge; on one hand the force downwards has to equal the force upwards and the stability criteria have to be met. The downwards force of the barge and its contents is balanced by the volume of water the barge is displacing. In that case it follows that a greater underwater volume will lead to a greater load supported.

However the metacentric height, GM is calculated using $GM = VCB + BM - VCG$ where VCB is the Vertical Centre of Buoyancy, BM is the distance between the centre of buoyancy and the metacentre and VCG is the Vertical Centre of Gravity. This can be rewritten:

$$GM = (Draft \div 2) + (2ndMomentofArea, Ixx \div Underwatervolume)$$
$$- ((\sum Mass \times DistToCentreofGravity) \div \sum Mass)$$

The draft value is given from the MathCAD sheet and ideally is not altered. So to maximise the GM value BM has to be at a maximum and VCG at a minimum.

$$BM = (bd^3/12) \div (l \times b \times (d - Draft))$$

It is difficult to maximise BM as increasing the top line containing breadth and depth will lead to a proportional increase in the bottom line, as it also contains breadth and depth.

Working with the Excel spreadsheet it seems as though maximising the length and minimising the depth and breadth slowly increases the metacentric height, however despite several design changes, such as lighter material for the wheel (wood instead of steel), a low 4 kN of watertank weight and the inclusion of triangular barge ends, contributing to the underwater volume the metacentric height still failed to rise above zero. Over the following three pages a copy of the Excel file can be seen with the two forces balancing but the metacentric height still being too low.

It was felt that this indicated the unsuitability of a barge to support two waterwheels, especially two wheels that had to be set low into the flow to generate high enough outputs. It was therefore decided to modify the Excel file to investigate a catamaran layout (Chapter 6). This would not need to be as rigorously analysed for stability as catamarans are inherently more stable, having two hulls rather than one.

6. Catamaran Design

Following the unsuccessful barge design a catamaran design was suggested. The original problem of a slow turning wheel was now solved by using the sides of the catamaran to restrict flow towards the wheel, increasing the speed. Test 1.4 earlier showed that an increase in Current of 50% could lead to an increase in power output of 350% allowing the wheel diameter to be lessened, increasing the rotational speed of the wheel.

Taking the modified MathCAD output the Excel model was altered to design a catamaran (see enclosed CD for catamaran file) and an iterative process was begun to balance forces in both directions.

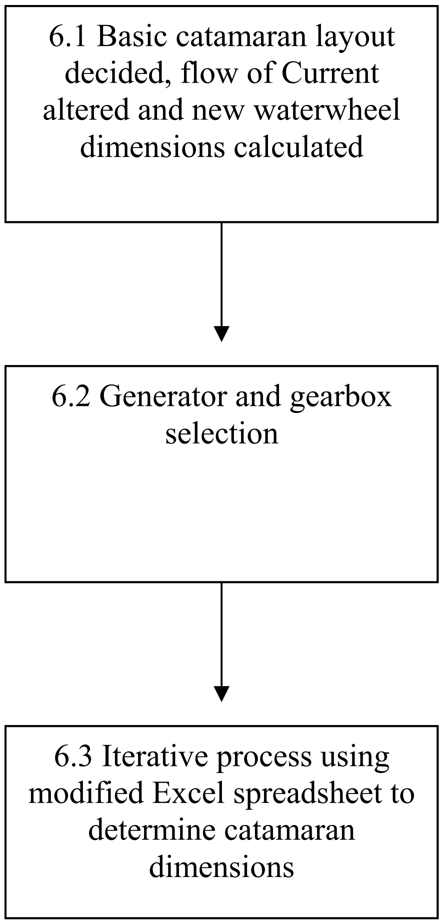

Fig. 49 Diagram showing design process followed for catamaran

6.1 Catamaran layout and Re-design of Waterwheel

6.11 Catamaran Layout

The catamaran design involves a wheel in between two hulls containing the gearbox, generator and water tanks as symmetrically as possible (See Figs 50 and 51 below). Although shown here neither the trash rack nor stability bars are considered in the Excel file, being fairly lightweight.

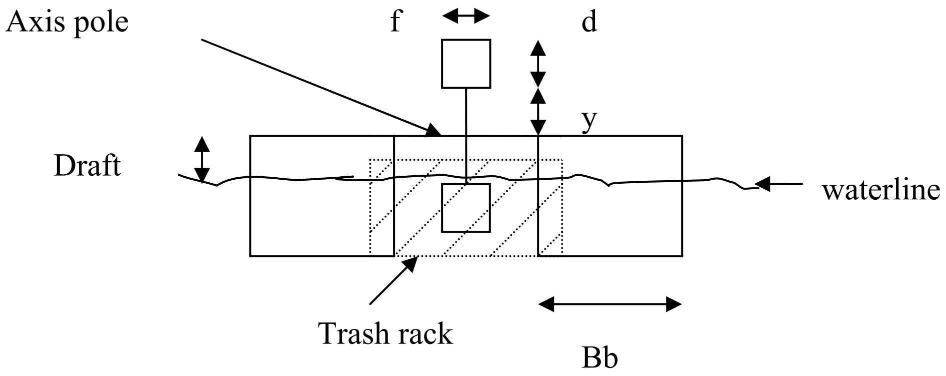

Fig. 50 Cross section of catamaran in direction of flow

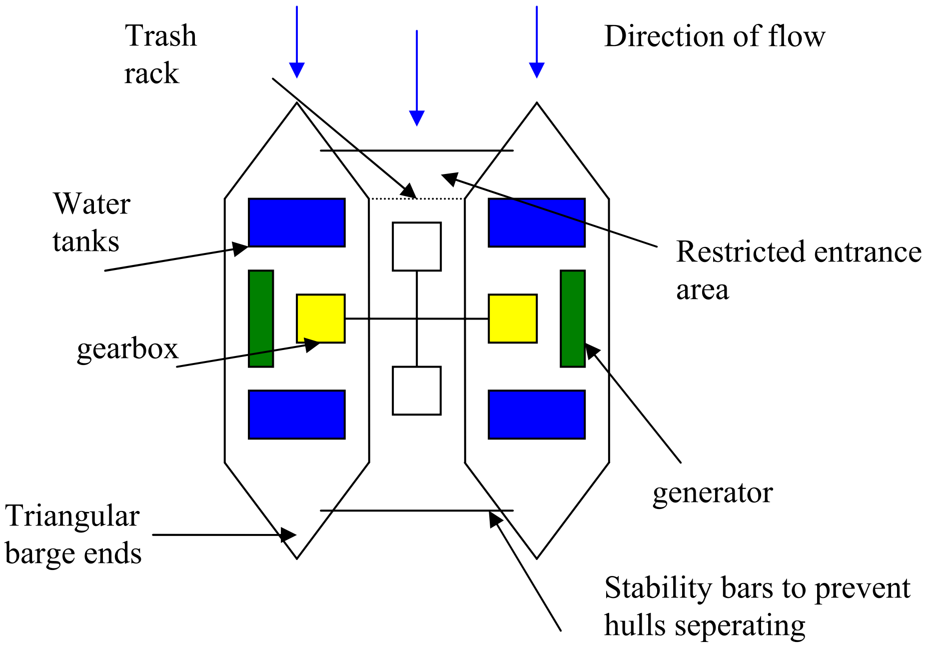

Fig. 51 Plan of catamaran

6.12 New waterwheel design

To evaluate the increase in Current caused by a restricted opening area to the wheel firstly the flow in the river has be inputted. As actual data is not available it is estimated that the channel is 4m wide and the distance from the waterline to the river bed is 3m. If site investigations showed otherwise these figures can be changed manually in the MathCAD program (see attached CD for program).

From this a flow rate of 24 m^3s^{-3} was calculated. The restricted area of the flow before the wheel is equal to the multiplication of the catamaran depth (kept fairly deep to ensure high velocities and water flowing into wheel rather than underneath catamaran) and the distance between the two hulls, set at 0.5m more than the width of the blades. In this example using this arrangement increases the Current from 2 ms^{-1} to 3.5 ms^{-1}

This increased speed allows for smaller wheel dimensions leading to an increase in the rotational speed of the wheel. The final wheel dimensions are:

L = 1.25m

y = 0.5m

d = 0.75m

f = 1.75m

DraftT = 0.211m

N = 12

This gives an output of 10.76kW turning at a speed of 12.6 rpm.

6.2 Generator and Gearbox Selection

Although in a real life application a different gearbox and generator would be selected the same pair are being kept here. The selection in this dissertation would probably not be actually used in reality; here it is an indicator of size and weight.

Instead of a 1:100 gear ratio 1:50 could be used here, and again two 5kW generators would be incorporated.

6.3 Catamaran Design

The Excel sheet for the barge was altered to include the two hulls of the catamaran (see enclosed CD for program). The new dimensions of the wheel were then added and the barge dimensions and water level in the tank were altered to balance the downwards and upwards forces. As catamarans are more stable than barges it was considered unnecessary to calculate the metacentric height of the system. The following 72-73 pages show the Catamaran Excel sheet.

The significant drop in the waterwheel weight means that the wheel can now be manufactured out of steel (coated against corrosion) with a density of 7700 kgm^{-3} rather than the wood used for the barge design with a density of 500 kgm^{-3}. The catamaran is still made from wood, however.

The increased displacement volume of two hulls allows for 34 kN of water to be stored on the catamaran allowing large weight changes to be made in the future. This could help with future maintenance e.g several people standing on the catamaran to clear the trash rack or bringing on heavy tools to repair or replace parts. The dimensions of the catamaran and water tanks have been kept uniform to ease construction, although a scale would be needed on the water tank for 1.78m of water to be measured out easily.

Fig. 52 Copy of Catamaran Spreadsheet

Catamaran Design Spreadsheet

Total Upwards Force (kN)	286.1523413

7 Conclusion

7.10 The waterwheel has played an important part in energy production over the last 2000 years, reaching its peak in usage in the early 19th century, but in the end losing out to steam and motor power. The waterwheel is today experiencing renewed interest as engineers, scientists and now energy suppliers (due to the Renewables Obligation) look for new renewable energies to combat climate change.

7.11 However progress is hampered by a lack of government support, high gearing ratios, little recent research and a perception amongst engineers, scientists and the public that waterwheels are old fashioned and irrelevant.

7.12 Waterwheel progress is most apparent on the internet with many sites written by home enthusiasts and small charities. This dissertation includes three case studies as a homage to this group and an example of how interested and keen the public are on interactive renewable energy.

7.13 Scotland has been chosen for this dissertation because of it plentiful supply of small rivers and streams, the high yearly rainfall and a rural population who could benefit from decentralised power. After briefly evaluating different types of wheel an undershot wheel was chosen, as it utilised the lowest heads. From this group the stream wheel was picked for this project as the site had zero head, and a fairly fast flow. Additionally stream wheels are simple to manufacture and considered “fish friendly”. Experiments currently running at Berlin Technical University will be able to shed new light onto their flow and power output capabilities.

7.14 A mathematical model of the flow of a stream wheel and its corresponding power output was created. The program was then used to estimate the dimensions for a typical domestic house’s energy requirements. The slow rotational speed of this design and the consequent large gearing ratio led to an investigation in fixing the wheel to a barge, and later a catamaran.

7.15 A basic barge layout complete with water tanks, generators and gearboxes was modelled in Excel and from the output it was concluded that the stability of a barge with two waterwheels either side was not satisfactory. So the spreadsheet was altered to describe a catamaran design with two hulls either side of a waterwheel. The benefit of this was that the entrance area of the water between the hulls was restricted, leading to a higher Current and so a smaller wheel for the same power output. Further advantages to this system included a high rotational speed, low gearing ratios, and a large amount of on board stored water, which allows later design alterations.

7.16 In conclusion it can be said that a waterwheel is a viable, aesthetically pleasing option for domestic energy generation that would benefit from further investigation.

8 Suggestions for future work

8.10 Being so previously unresearched waterwheels now present a large variety of potential projects. Fundamentally there has been little work into the characteristics of the flow of waterwheels. Understanding exactly how energy is transferred, how the blade interacts with the water and how these characteristics can be optimised is crucial to the advancement of all wheels especially the stream wheel, and the stream wheel in a rectangular channel

8.11 From this predominately experimental and case study based work designs can be generated for the blade shape and size (with the drag coefficient being researched experimentally), optimum number of blades, and external works. An evaluation into the relative merits of fixed waterwheels perhaps sited in their own diversion channel or moored waterwheels on barges and catamarans is needed. Ecological studies are needed into the effects of waterwheels as is the simulation and minimisation of the impact noise so as to prevent wheels becoming unpopular with their neighbours.

8.12 In the wider context an evaluation is needed of the low head (‹ 25 kW) sites in the UK with more accurate estimates of the potential of microhydropower. A lack of knowledge of previous waterwheel installations also hampers progress so an in-depth investigation into case studies worldwide would enable a type of guide to be drawn up detailing successful practice. When combined with experimental and scientific theory this guide could slowly replace the wealth of intuitive knowledge lost at the end of the industrial revolution. Further afield the application of waterwheels to developing world sites is virtually unknown.

8.13 Any form of renewable energy will rely on generators, gearboxes, alternators or batteries to gain and store power and waterwheels are no exception. Further research is needed into gearing methods that are both efficient and easy to construct, and relatively inexpensive.

Appendix B

Proof of "p" by J. Wolfram

$$Power = Force \times Bladevelocity$$
$$Power = (0.5 \times \rho \times Cd \times A \times V_r^2) \times V_b$$

$$V_r = V_c - V_b$$

$$Power = (0.5 \times \rho \times Cd \times A \times (V_c - V_b)^2) \times V_b$$
$$Power = (0.5 \times \rho \times Cd \times A \times (V_c^2 V_b - 2V_b^2 V_c + V_b^3))$$

To find the maximum Power this expression is differentiated and set equal to zero

$$dPower / dV_b = (0.5 \times \rho \times Cd \times A) \times (V_c^2 - 4V_c V_c + 3V_b^2)$$

$$0.5 \times \rho \times Cd \times A \neq 0$$
$$V_c^2 - 4V_b V_c + 3V_b^2 = 0$$
$$V_b = 1 \times V_c$$
$$V_b = 1/3 \times V_c$$

By solving the quadratic two values of Vb are found- one when Vb = Vc (the wheel is freewheeling at this point) and one when Vb=1/3 Vc, which has been used in these calculations.

Domestic Roofwater Harvesting
Research Programme

NEW TECHNOLOGY FOR VERY-LOW-COST DOMESTIC ROOFWATER HARVESTING

DFID KaR Contract R7833

April 2002

Development Technology Unit
School of Engineering, University of Warwick

CONTENTS

1 INTRODUCTION

This report is an output from a 27 month research contract (R7833) for the UK Department for International Development and describes work done during the 4 month prototyping phase of that project. The prototyping phase has developed out of the practice descried in the report to the DFID “R1, Very-Low-Cost Domestic Roofwater Harvesting in the Humid Tropics: Existing Practice” and the constraints identified in “R2, Very-Low-Cost Domestic Roofwater Harvesting in the Humid Tropics: Constraints and Problems”. The work itself was carried out by the DTU along with members of the Lanka Rainwater Harvesting Forum in Sri Lanka, Water Action in Ethiopia and ACORD in Uganda.

The Sri Lankan portion of this work would not have been possible without the facilities and kind assistance of the Nation Builders Association. In particular we would like to thank Mr Adikarum, Mr Amarasinge, Mr Widasecara and Mr Siripala for their help, insight and patience during our time there.

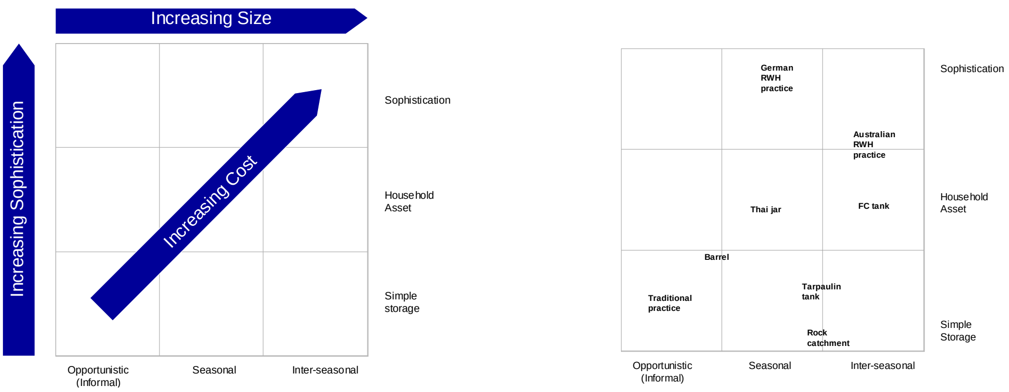
1.1 The need

Surveys carried out in the initial phase of the project have pointed to cost as the number one constraint facing users adopting roofwater harvesting so if it is to become an affordable option for poor people in developing countries, the cost of systems must be reduced.

In R2 a methodology for cost reduction of roofwater harvesting systems was discussed. The method revolved around the building of a rainwater harvesting service framework as shown in Figure 1.1 focusing on the quality of structure as well as the quantity of water delivered. By reducing the structural quality to a level closer to the quality of housing found in poor areas, large savings can result.

Figure 1.1: Service framework for rainwater harvesting systems

a. Framework b. How current systems map onto the framework



In reducing the quality, however, there are a number of critical functional constraints that should be regarded as a minimum specification:

- Gutters should deliver a good fraction of the water falling on the roof – dependent on the local rainfall, roof size storage size and demand pattern
- The tank should not have excessive loss through seepage or evaporation – <5% of the water drawn from it

- The tank should not present an excessive danger to its users, either by their falling in or by the tank failing violently
- The water must be of a quality consummate with its intended use – water that is used for drinking requires a certain care in transport and storage:
  - The catchment area should be smooth and free from accumulated debris
  - The water should be filtered to remove gross impurities or the first flush removed
  - The tank should be covered to prevent entry of light, and sealed against intrusion by vermin
  - The tank should be ventilated to prevent anaerobic decomposition of any washed-in matter

1.2 Methods of cost reduction

The methods used to reduce the cost of rainwater harvesting systems are covered in report R2, the methods described are:

- Material reduction (Improved formwork, Shape optimisation, Function separation)
- Material substitution (Using cheaper materials, use of "free" materials)
- Mass production
- Use of existing containers

1.3 Basis for cost comparison

Costing "rainwater harvesting systems for the poor" is more complex than simply adding up component costs on a bill of materials. Some materials are only available at a cost through purchasing channels, while others are available at no cost if one is willing to gather them. This report will group materials and labour into the following categories:

a. *Economic materials*; materials relying on industrial processes – in their purchase cash will be removed from the area

b. *Local economic materials*; materials which must be bought but where production is from local sources – the cash will remain in the community

c. *Skilled labour*; labour that must be paid for

d. *Local materials*; materials that can be gathered from the land – they may or may not have an economic value but tend to be freely available

e. *Householder labour*; labour that can be provided by the household – it may be skilled, but in locally used techniques (such as wattle and daub construction).

For the poor the latter two costs may be heavily discounted when compared to any cash outgoings, and consequently they will be are separated from the first three 3 in costings presented in this report.

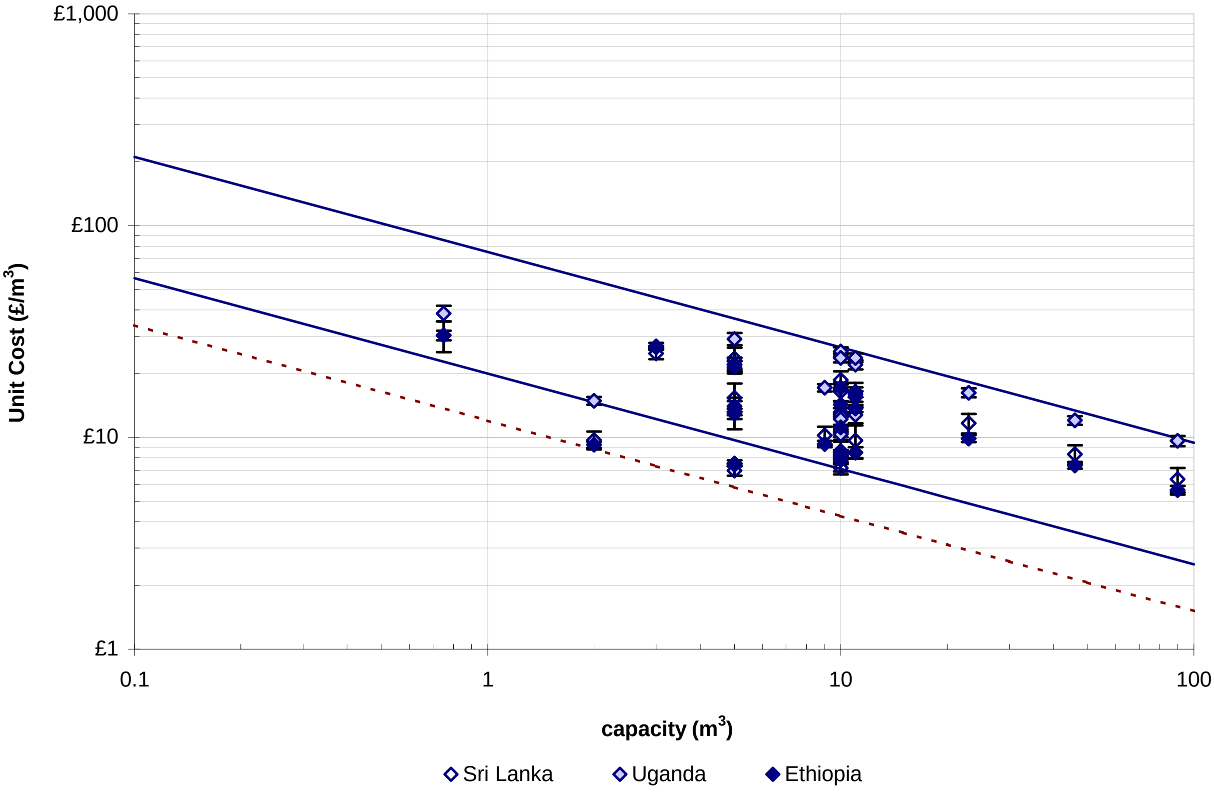
Household labour is often ignored in costing programmes aimed at the poor, however this may become unrealistic if the household labour contribution becomes burdensome. Another approach is to allocate an opportunity cost of 50% of the unskilled labour rate to such a contribution to reflect the loss of time to the household. The real value of their time to a householder should lie between these two figures, so both will be quoted in this report They are referred to as "HH labour discounted" cost and "HH labour ignored" cost. A total cost with no discounting is also included for reference.

2 TANKS

2.1 Current state-of-the-art

Current practice is comprehensively described in report R1 so only a brief summary of current best practice will be given here as a baseline from which to judge new developments. Water storage forms the largest single cost component of a RWH system and so is the most likely candidate for cost reduction. Current state-of-the-art for storage tanks in developing countries is ferrocement construction, either based on a fixed solid mould or on an open framework. Generally, a solid mould results in a cheaper tank, as the wall thickness of the tank can be more tightly controlled and work is done against an inflexible surface. Open frameworks have the advantage of allowing greater flexibility in tank size but at the cost of plastering work taking place against an elastic backing which lets some mortar through resulting in greater and more variable wall thickness and a higher cost per tank. Tanks are also made from bricks which can reduce costs by material substitution but the savings are often not great although more of the money remains in the community. A graph of current costs of various techniques in the three study countries is given in Figure 2.1.

Figure 2.1: Tank costs



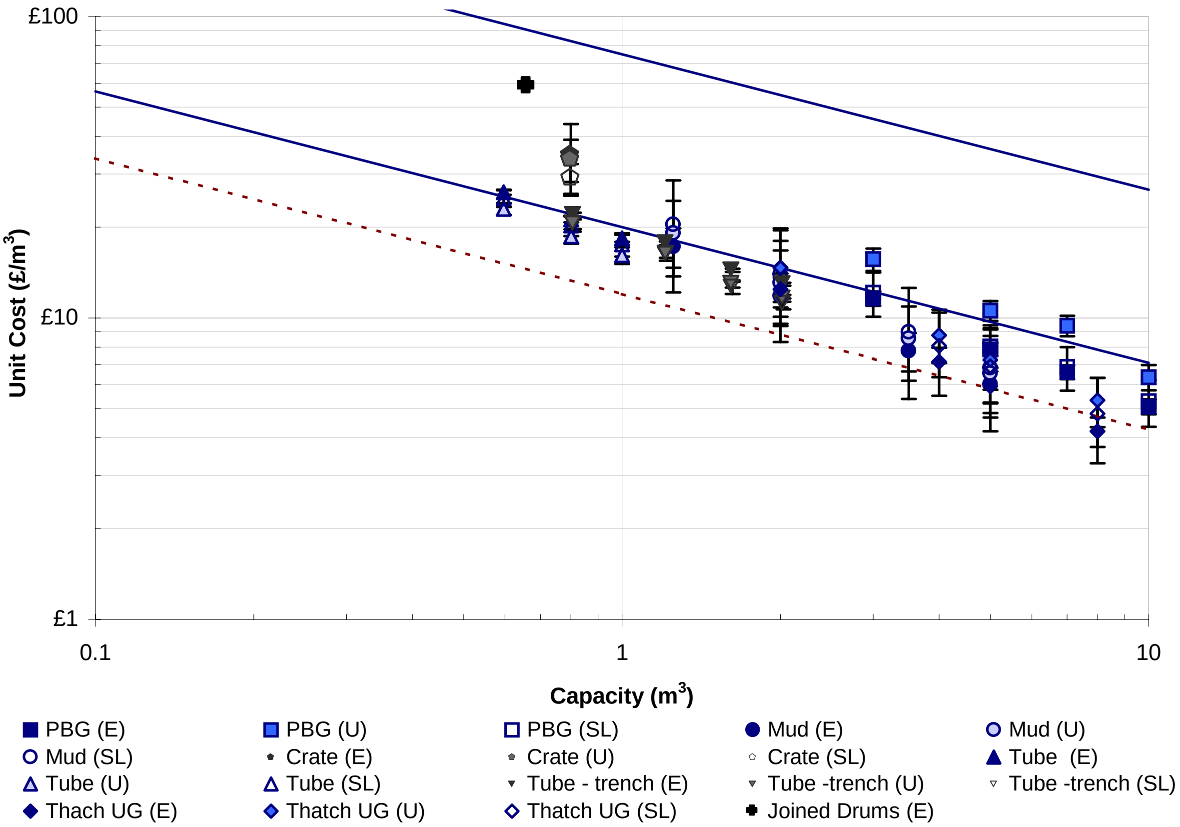
Notes: Points represent costs with household labour discounted, error bars represent the extremities when household labour is included in full or ignored altogether

Lines slopes correspond to a cost:capacity sensitivity of 0.6

A cost sensitivity to volume of 0.6 – 0.7 is the norm, so designs can be usefully compared over a wide range of capacities. The Solid blue lines represent the bounds of normal state-of-the-art. the dotted red line represents the lower limit of a region populated by “exceptional” designs such as the Thai jar and the Ugandan tarpaulin tank. It is this region that forms the target cost range. Tanks developed during the prototyping phase of the programme fall mainly into the benchmark range as shown in Figure 2.2.

Most of the designs also have a greater reliance on household labour and local materials so compulsory cash costs are kept lower still (as indicated by the bottom extent of the error bars).

Figure 2.2: cost comparison of tanks developed during the prototyping phase



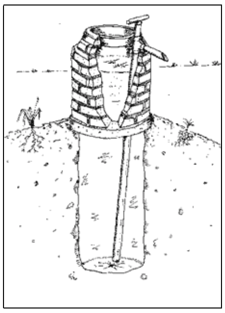
2.2 Below-ground designs

Below ground designs are the mainstay of low cost tank design. If built in stable soil, the ground itself will act as a stiff spring taking much of the load, reducing the role of the lining material to waterproofing. In these circumstances, tank wall thicknesses can be very small and materials that have good waterproofing properties but suffer from a low structural strength (such as polyethylene sheet) can be used.

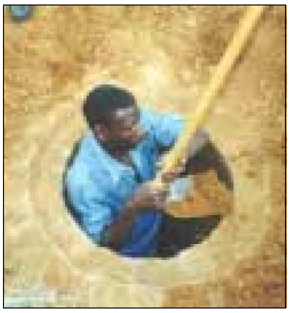
Tube tank

The tube tank was originally developed by the DTU in July 2000 (Rees & Whitehead, 2000), as part of a technology development project funded in part by the Morris Laing Foundation. The design was based around a widely available plastic tube of about 500 microns thickness sold by the metre on a roll of 3ft width. The cost of this tube is £0.38 in Sri Lanka, £0.54 in Ethiopia and £0.40 in Uganda. When opened, the tube forms a cylinder of Ø54cm resulting in a volume of 0.23m^3 per metre length. The cost of storage, is therefore only £1.66, £2.33, £1.75 (SL, Et, Ug) per m^3 of storage for the tube itself. The original design (see Figure 2.3) was based on the partially below ground principle where most of the tank was below ground, but about 1m protruded as a brick parapet, avoiding stormwater ingress and providing a visual presence for the tank. A hole was dug to accommodate the tube and a bag was formed by folding and tying off the end. The bag itself was fixed between two courses of bricks and an overflow pipe was fitted in a hole in the bag and sealed with a small amount of cement.

Figure 2.3: Original tube tank design. (all pictures from (Rees & Whitehead, 2000))



General arrangement of tube tank Mk 1



Digging the hole

Bag tying

Overflow arrangement and fixing of the bag between brick courses

The design was fairly successful and several of the tanks are in service however it has some problems, most which have become apparent after a year of use:

- The cost of the parapet wall dominates the overall tank cost and forces the design to compete directly with more robust and desirable designs such as the ferrocement jar
- The hole is difficult to dig
- The tied joint at the bottom can leak
- The liner is extremely difficult to remove if it is punctured – those that do leak have not been repaired
- The overflow can leak resulting in accumulation of water between the bag and the excavation walls

The new design (see Figure 2.4)addresses these problems by including the following changes:

- A more classic underground design using a precast concrete cover reduces the cost. The cover itself is similar to the arrangements found on some handpumps and so should be familiar to use. It is made using similar casting techniques to pit latrine covers (sanplats).
- The tube has been folded in two, eliminating the tied joint, making the hole 40% larger and consequently, easier to dig
- The tube itself is easily replaceable by using a retaining ring and binding wire to hold the tube in place.
- A variant folds the tank into a “L” shape reducing the depth of the excavation and replacing the vertical hole with a trench

Figure 2.4: Modified tube tank design.

General arrangement of tube tank Mk 2 | **Retaining ring** | **Overflow** | **Horizontal folded tube tank being filled**

With these modifications, the design is extremely inexpensive at less than £18 for a 700l tank and £26 for a 2m^3 folded tank. Although the prototypes were made using in-situ casting in the ground, the slab has designed with pre-casting in mind and so is well suited to factory production where savings of up to 50% can be made by drastically reducing labour content.

The tank design is also ideally suited to rapid implementation projects such as refugee camps; if the excavation is done by the householders, an agency can simply transport a number of prefabricated parts and each tank can be assembled within an hour.

Tank size is determined by hole depth so the deeper a household digs, the larger the store, extra storage is relatively cheap as the cost of the tank is dominated by the concrete slab. The alternative horizontal folded design is more suited to less stable soils as the excavation itself is about 60cm deep and can be tapered if necessary, however the cost is higher due to the need to cover the trench over. Costs of several capacities of each type of tube tank are shown against benchmarks in Table 2.1.

Table 2.1: costs of tube tanks

a. vertical

Capacity (m^3)	0.6	0.8	1.0
Total	£16 – 17	£16 – 17	£17 – 19
Total (HH labour discounted)	£14 – 16	£15 – 17	£16 – 18

Thin shell cement slurry lining

Neat cement is about 40% stronger and twice as flexible as mortar. It is also almost completely impermeable, making the material ideal for the construction of very thin shells to line pits. Initial experiments on a 1m depth pit of Ø1.5m revealed leakage of less than 10 litres/day and the surface showed no cracks. A larger pit of 3m depth was also tried, however the cement was applied without due care and cracks developed. The leakage from this pit is 80 litres/day, however no additional cracking has been observed as a result of the significant head of water acting on the shell.

The thin shell cement lining technique can result in material economies of up to 50% when compared to conventional mortaring, however the care with which it must be applied to the soil may make it unsuitable to unsupervised (free market) construction at a local level.

Direct application of mortar

It is common practice to put mesh in an underground tank when lining with mortar. Typically this takes the form of a layer or two of chicken wire. The given reasons are that it:

- adds strength
- provides a surface upon which to plaster (lath)
- Reduces cracking

Looking at the first of these reasons, a single layer of chicken mesh will have an in-line volume fraction less than 0.2% when compared to the mortar (assuming a 1cm mortar layer), so its contribution to the strength of the composite is fairly minimal (about 20% using the law of mixtures). Of course, the strength of an underground tank is mostly from the reaction of the soil itself.

The second may be true, but the initial layer of mortar is usually applied to the hole *adding* the mesh (indeed placing mesh directly on the soil is risky as it will certainly corrode from contact with moist soil). Further layers can be built up by scoring the original thus providing keys in the mortar itself. Such scoring is also simple to add to a hard soil and should provide a good keying for mortaring.

Crack reduction can be a useful property, particularly in tanks with large surface areas, however in smaller, domestic tanks cracking is not big problem as witness the popularity of mortar tanks in Thailand.

Thus the supposed advantages of using mesh may be insubstantial in this application and are certainly small compared to the advantages of using the strength of the soil wall.

Conversely, the mesh itself will cause problems when added to a concave surface such as the inside of a hole. The problem is basically one of overconstraint. If one considers, for the sake of argument a flexible sheet placed inside a cylinder. It can be either just the right size, too small or too big. If it is too big, the loose mesh forms bubbles, losing the benefit of the earth wall's support, if it is too tight it will stretch tight across the wall rather than following the curve, resulting in voids. Adding fixing points is the usual solution to these difficulties but this often simply turns one large problem into several small ones. The more fixings, the better the fit but also the greater likelihood of human error – the result can even be areas of too tight mesh next to bubbles of too loose mesh.

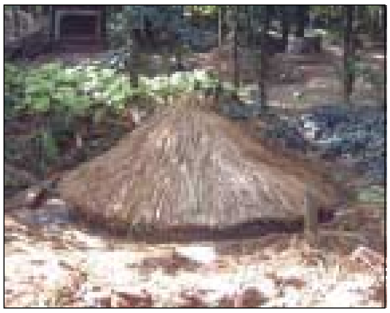
Directly applying mortar to the walls has proven to be a simple technique to apply in the field. A thin layer of 1cm can be applied with ease and with good quality control. The mortar itself has no need for high strength so can be as lean as 1:8 (cement:sand) in a good soil. Waterproofing is provided by a thin cement slurry applied while the mortar is wet. Several tanks have been built using this method to depths of up to 2.5 meters with no visible cracking and lower leakage than evaporation. The direct application of lean mortar with a slurry coat is the basis for two interrelated designs of tank, the below-ground cement tank with a cheap roof based on organic material and the partially below ground tank with a ferrocement dome.

Below-ground cement tank with organic roof

Ring beam with trench

Shuttering for pump and overflow mounting

low-cost tank cover under construction



Finished tank with cover in place

As the cost of the below-ground waterproof tank is reduced, the cover of the tank becomes the dominant cost. Organic roofs are used on many buildings in poor households and so the skills to build them are common. The materials themselves also tend to fall into the "gatherable" class. To put an organic roof onto a water tank, however, a number of precautions must be taken.

- The organic material must not fall into the tank and contaminate the water
- Runoff from the organic roof will be of low quality and so must not be allowed to enter the tank
- The roof must provide a good barrier to vermin entry, especially as some creatures make their homes in thatch.
- The wooden supports must not be exposed to the humid atmosphere inside the tank which will make them liable to rot
- To aid bacteriological die off, the roof must provide a good barrier against sunlight entering the tank

A polyethylene barrier fulfils the need to protect the organic matter from moisture and also to protect the water from falling debris. If the joining is handled well, it can also act as an excellent seal – completed by the use of inner tubes around the rim. Prevention of water entry can be afforded by the use of a sloped ring beam which will divert the water away from the tank and into a drainage channel.

Below-ground tanks also need care with avoiding floodwater ingress and also with overflow arrangements. The new design uses a syphonic overflow by employing an upwardly facing elbow connected to an outflow pipe which leads either to a nearby slope or to an infiltration pit. Stormwater ingress is handled by digging a channel around the ring beam to a width and depth determined from the runoff.

The overall combination of direct mortar application and low cost roof yields a tank that uses very little material but is quite householder labour intensive. The costs for the tank are shown in Table 2.2.

Table 2.2: Cost of underground mortar tank with organic roof

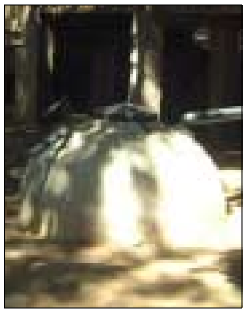
Capacity (m^3)	2	4	5	8
Total	£28 – 40	£32 – 43	£33 – 46	£37 – 51
Total (HH labour discounted)	£25 – 29	£29 – 35	£30 – 36	£34 – 43
Total (HH labour ignored)	£19 – 23	£22 – 29	£23 – 29	£26 – 3`5
Target range	£18 – 29	£26 – 43	£26 – 48	£38 – 63

Partially below-ground tank with ferrocement dome

Lining the pit

Fixing the frame for the dome

first layer of mortar for the dome



Finished tank

A solution to the overflow and floodwater problems of an underground tank is a partially below ground design where most of the tank is underground takes advantage of the economies to be found from soil support but with some of the tank protruding. Partially below-ground tanks form a bridge between underground tanks and above-ground tanks. They are somewhat more expensive than purely underground tanks, as the above-ground section can cost 3-4 time more per unit volume than the underground section. The Below-ground cement tank can be upgraded to form partially below-ground tank by simply adding a ferrocement domed cover. The dome uses a removable frame that leaves behind only wire mesh as reinforcement. The mortar can either be applied without any other formwork by using one person outside to apply the mortar and one person inside to provide a backing (the addition of a small amount of sacking fibres to the mortar was found to help this process) or by making a temporary formwork from cardboard. The dome can be built when the tank is first commissioned or added later when more funds are available. The finished tank is slightly more expensive per litre than the organically roofed over tank but will require less maintenance. Costs for the tank are shown in Table 2.3.

Table 2.3: Cost of partially below-ground tank

Capacity (m^3)	3	5	7	10
Total	£37 – 43	£41 – 51	£49 – 62	£54 – 71
Total (HH labour discounted)	£35 – 39	£39 – 47	£46 – 57	£51 – 65
Total (HH labour ignored)	£30 – 35	£34 – 43	£40 – 52	£43 – 59
Target range	£22 – 37	£29 – 48	£35 – 58	£43 – 71

2.3 Above-ground designs

Above ground designs are generally more popular than below ground solutions, however the cost is often also higher as the tank must now cope with the full force of the water pressure acting on it. The principle of functional separation allows some scope for cost reduction. Waterproofing can be done by either mortar or a liner.

Fabric tank

end of fabric tank with bracket

top sheet showing rubber seal

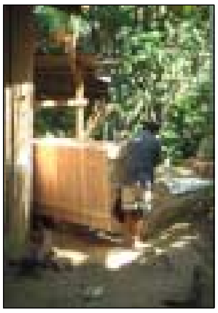
completed fabric tank

An above-ground tank is almost essential in poor crowded urban areas as the ground can be very contaminated. Ideally, a tank should also be fairly portable as tenure in such communities can often be insecure and many squatter communities live under constant threat of being moved on. The fabric tank goes some way to fulfilling these needs by providing a tank with a small footprint, protruding only 45cm from the dwelling. The tank can also be collapsed down into a long, thin package for transport. A polyethylene tube is placed within a fabric sleeve which is hung on a framework. The fabric takes the pressure load while the polyethylene provides waterproofing.

Unfortunately, the tank has proved problematic as the fabric itself stretches and puts high loads on its fixings which then fail. The fixings could be made stronger and more expensive fabrics should stretch less, however they will make the tank unaffordable.

Crate tank

lid with hole for inlet



delivering the crate to the household

Internal configuration

Finished tank in use

A similar design to the fabric tank has a wooden crate forming the load-bearing structure. The design has the same small footprint as the fabric tank but is not as portable as it can only easily be knocked down into its component walls. It is, however, much better protected from accidental damage than the fabric tank. The design is similar in concept to the tube tank with a retaining ring holding the top of the tube to the top of the tank providing an inlet. The tube than folds around and the other end is attached to the overflow. A tap is attached at the bottom of the “U” and sealed with bitumen. The outlet and overflow can be on any of three sides of the tank to help it fit in with its location. The total cost of the tank is slightly higher than the target range, however the need for a slender profile and portability may make the tank usable in areas where cheaper alternatives will be inappropriate. The manufacture of the tank employs only skilled labour but is very portable (deliverable) so it lends itself to mass production at a central location which could reduce the cost.

Table 2.4: Cost of crate tank

Capacity (m^3)	0.8
Total	£23 – 28
Target range	£11 – 18

Wattle and daub tank

Bamboo frame

Detail of manhole

Mud blocks used for testing

Finished tank

A simple way of producing an above-ground tank with the economy of a below ground tank is to bring the ground up. Several earth technologies have been used in building for millennia and such techniques are often the mainstay of housing for the poor. Wattle and daub is a widespread practice for building from earth, particularly when householders their own homes. The technique uses unmodified mud to fill a frame structure made from roundwood. The materials necessary for this type of constructions are all in the "gatherable" class so cash costs are extremely low, being limited to the liner and plumbing.

A small sample of mud blocks from different sources were tested for tensile strength and it was found that they lay in the fairly narrow range of 730kPa to 900kPa with ant-hill mud generally at the higher end. This compares poorly with 2 – 5MPa for Portland cement mortar so walls have to me made quite thick – typically 15 to 20cm. Initial tests used cement as a liner, however the mud structure expands slightly under load and the lining cracked resulting in leakage and damage to the mud walls. The use of a plastic liner has proved much more satisfactory.

Table 2.5: Cost of wattle and daub tank

Capacity (m^3)	1.25	2	3.5	5
Total	£25 – 37	£27 – 40	£31 – 45	£34 – 48
Total (HH labour discounted)	£22 – 26	£24 – 29	£27 – 32	£30 – 35
Total (HH labour ignored)	£16 – 18	£17 – 20	£20 – 23	£22 – 26
Target range	£14 – 23	£18 – 29	£24 – 40	£29 – 48

Rammed earth

The use of rammed earth provides a stiffer structure than wattle and daub and can be rendered internally with mortar. The earth can also be stabilised with Portland cement to provide a better wet strength than with mud construction. The DTU has done some previous work with this technique to build cylindrical tanks (Rees, 2000) however they proved difficult to construct due to movement of the round mould during manufacture. To combat this, trials have taken place to develop a rectangular tank using traditional corner jointing methods and reinforcing. The trials are thus far incomplete but show some promise for a controllable product that can be used in sandier soils where mud construction is impossible.

Connected drums

Drums form an easily accessible form of storage and many households already have at least one drum performing various duties, among them water storage and even opportunistic rainwater collection. Very few households employ more than one such drum however despite the extra water this could provide. Drums also have a small footprint and are light enough to be portable. They do suffer from problems such as the possibility of residual toxicity and solar heating of the water through the metal.

Several configurations of 2 or 3 drums have been tried, including two forms of vertical connection and one horizontal one. The pros and cons of these are detailed in Table 2.6. Initial Cleaning of the drums is usually done by using a locally produced caustic soda, however there is still some uncertainty about its effectiveness.

Table 2.6: pros and cons of different drum configurations

Type	Pros	Cons
1. Vertically stacked drums connected by means of pipefitting.	• Doesn't require welding or electricity. • The piped outlet allows incorporation of a slow-sand filter • Small footprint	• There is some leakage in the lower drum between the lid and circular clamp.
2. Vertically stacked drums connected by means of welding.	• The number of fittings is reduced • There is no leakage in the system • Small footprint	• Depends on the availability of a welder.
3. Horizontally placed drums connected by means of pipefitting	• An unlimited number of drums can be connected without leakage from the top • Repeated filtering provides different grades of water. • Doesn't require welding or electricity	• The required space is relatively higher compared to others and thus the material for the plinth is greater

The final design uses two vertically stacked drums with welded seams to prevent leakage and an internal slow sand filter. As the slow flow through the filter could reduce the storage, particularly in heavy storms, an optional separate tank has been added to catch this overflow. The overall cost is quite high by very-low-cost standards but still within state-of-the-art boundaries especially considering the design incorporates quite sophisticated filtering.

Table 2.7: Cost of drum configurations[1]

Type	1	2	3	final
Number of drums	2	2	3	3
Capacity (litres)	340	420	620	540
Total	£30	£31	£36	£38
Target range	£7 – 11	£7 – 12	£9 – 15	£9 – 14
Upper limit of state-of-the-art	£41	$47	£58	£53

Note: Costs are based on Ethiopian experience

Several connected jerry cans

Many households already have a fair storage in the form of several jerrycans. The cans themselves are inherently portable and can be distributed throughout the dwelling to save space and so are a good solution for crowded urban areas. The requirement is for a system of plumbing to connect these cans together to form a continuous storage. The cans then fill up in turn with the water quality improving in each successive can. A system of siphons empty the plumbing into the last can or to an overflow so there will be no leakage when a can is removed for use, however the problem of accidentally leaving a can out of the chain (with disastrous consequences when it rains) is still unsolved. The cost of the cans themselves is also a problem and could make the system uneconomic unless the household already has a reasonable number available.

Cascade of water jars

Many households use water jars for water collection. These jars are well suited to stacking in an array. The water runs down the outsides of one jar into the mouth of another with quality improving as it moves down the cascade. The rounded jars do allow the water to progress unhindered to the next, however the overall storage is quite low at 75 litres. The framework necessary is also quite expensive and puts the entire array into the higher end of the state of the art at about £16. the jars themselves are fairly low in price, however and so a cheaper frame (e.g. a suspended chain) could make the system more economic but it will never be a very-low-cost option.

3 ROOFS

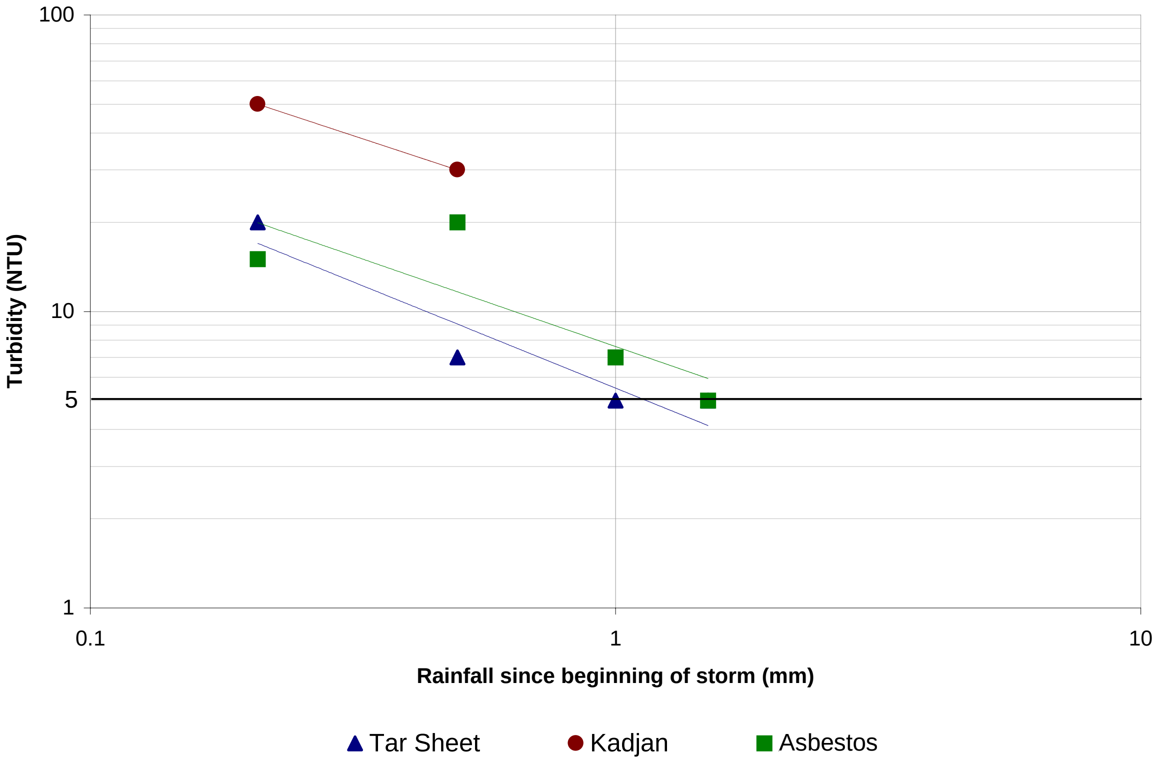
Another difficulty with roofwater harvesting is its reliance on an impermeable roof. Penetration of corrugated iron sheet roofs is growing rapidly and the costs are becoming competitive with professionally thatched roofs, however many poor houses in developing countries still have organic roofs. The reasons for this include cost, particularly where the roof is made by the householder, insulation and ventilation of the smoke from cooking fires.

There are five strategies for utilising organic roofs for rainwater harvesting;

1. Use the water for secondary processes
2. Treat the water
3. Cover the roof with an impermeable cover
4. Build a separate roof structure in the household compound
5. Use a nearby public building

Covering the roof and roof structures are the most obvious technical solutions, however, it was found that covering an organic roof with an impermeable barrier can cause problems to the roof itself, as water cannot evaporate presenting ideal conditions for mould growth, and the ultimate rotting of the structure. The runoff water quality from a number of materials for that might be employed to either to cover a roof or on a separate structure was measured. The materials tried were corrugated iron sheet, corrugated asbestos sheet, polypropylene sacking, tar sheet and palm-leaf organic roofing (*cadjan*).. A typical set of runoff quality results is shown in Figure 3.1. The characteristic runoff quality follows a power law decay with different materials having different starting points. Organic roofs predictably having the worst water quality while tar sheet, which is readily available and inexpensive has a good runoff characteristic, in line with asbestos but the water does contain petro-chemicals whose levels and rate of decay has not yet been quantified. Turbidity for the GI sheet is below the minimum level that can be discerned with the Del Agua turbidity meter used for this measurement and is therefore below the 5NTU level for turbidity set by the WHO (WHO, 1997)

Figure 3.1: Runoff quality of different roof types



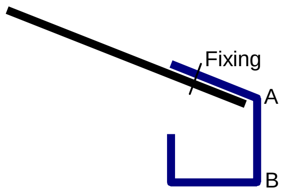
4 GUTTERS

Guttering on a very-low-cost roofwater harvesting system can take up a substantial amount of the cost so its optimisation is important here. Typical state-of-the-art gutters in developing countries tend to be quite expensive with a typical 10m length costing from £10 to £25. Some work has been done in East Africa with vee shaped gutters which have a typical cost of £8 for a similar length. Research at Warwick on optimising gutter size based on carrying capacity suggests that a vee shaped gutter of only 7.5 cm width is sufficient to carry water from all but the most severe downpours and will deliver more than 90% of the water it catches. Such a small gutter should cost less than £3 for a 10m run.

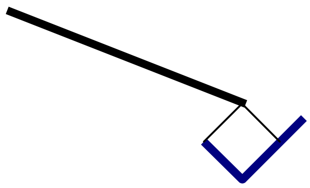
Water interception is a slightly more difficult issue. Water often has to fall some distance from the roof to the gutter and is thrown from the roof different distances depending on the intensity of the downpour. It can also be blown by wind in unexpected directions. Two solutions for this have been tried.

Figure 4.1: Gutters configurations

a. G-shaped gutter



b. extended vee



The first (Figure 4.1a) is a complete solution that captures the water at the end of the roof and directs it into the gutter below. The gutters are also very quick to install as the slope is determined by a variable manufactured length of vertical support (between A and B) so no adjustment is necessary. Cleaning is also simple as the inside edge is open for a brush all the way along its length. Problems with the gutter appear when the length to be guttered is longer than 5m or when thick roofs need to be accommodated. Under these circumstances the vertical support becomes very long and can flex causing the gutter to spill. This can be alleviated by using support wires with the loss of some ease of cleaning, however as the vertical support can use a substantial amount of material, the gutter starts to become expensive at over £9 for 10m.

The second uses the concept of a “upstand”, where one side of the gutter stands proud of the other, effectively raising the catchment height of the gutter. In the design the usual square gutter has been simplified to a vee and the upstand is merely an extension of one arm of the vee. This extends the catchment of the gutter upwards and moves the centre of the catchment out from the roof edge better matching the profile of water flowing from a roof. The gutter is extremely cheap (less than £3.50 for a 10m run) and can be applied to any sized roof without the need for a facia board. Like all suspended gutters, the design does need adjustment to maintain the slope and the suffers from guy wires obstructing cleaning.

5 CONCLUSION

The cost of rainwater harvesting systems can be reduced by a number of methods several of which have been presented here. The most promising are:

- The use of thin shell cement lining as found in the underground cement tank with an organic roof and the partially below-ground tank with a ferrocement dome
- The use of free materials and local techniques such as wattle and daub construction and organic roofs
- Earth technologies such as wattle and daub and rammed earth
- Mass production methods and the use of plastic linings as used in the tube tank and crate tank
- Incorporation of existing structures such as drums
- Smaller profile, sheet-metal gutters which can incorporate features such as water guides or extended catchment surfaces

Less successful were such techniques as:

- Distributed storage in jerrycans and multiple pots
- Very portable, yet fragile tanks such as the fabric tank

- Over-thin plastering techniques that rely on excessive quality control such as Thin shell cement slurry lining

Special circumstances can also be incorporated at little cost

- Tall thin structures such as the crate tank and vertically stacked drums can be built for crowded urban areas
- Auxiliary roofs can be constructed at little cost as an alternative to poor quality organic roof catchments

But

- Very portable, yet fragile tanks such as the fabric tank
- Roof covering treatments that are built onto an existing roof

Are problematic and cannot be recommended.

RN – RWH04

RWH Performance Predictor for Use with Coarse (i.e. Monthly) Rainfall Data

by

Terry Thomas

This document is an output from a project funded by the UK Department for International Development (DFID) for the benefit of developing countries. The views expressed are not necessarily those of the DFID.

CONTENTS

1. THE NEED TO MODEL RWH SYSTEM PERFORMANCE

In every roofwater harvesting system there is a trade-off obtainable between increasing system performance and increasing system cost. The medium of this trade-off is normally tank size and hence at the centre of RWH design is the optimisation of that size. Many methodologies for tank sizing have been published, several are reviewed by (Gould & Nissen-Petersen, 1999). Fortunately, as with all optimisation, the plot of performance (e.g. cost:benefit) against tank size is 'flat-topped' in the area of interest, so that a ±10% variation in size there has little influence on economic performance. The cost of a tank of given size can usually be readily assessed, but the performance of the system containing that tank cannot. We therefore seek a methodology for predicting performance over a system's expected life: one that suits both the surrounding constraints (e.g. of data availability and access to computing facilities) and the RWH system use envisaged.

It is only possible to *roughly* predict the performance of a RWH system. Performance depends upon many factors, so its prediction can only be as good as knowledge of those driving factors. Some of these like tank size and roof size, once selected, remain conveniently constant. By contrast future user-demand behaviour and climate are uncertain. Water demand may vary widely with house occupancy, social calendar and season. Rainfall is hard to forecast more than two days ahead. To model system performance we therefore essentially average such variables in some way, assuming for example uniform water demand or a climatically 'typical' year. Normally we use the past as a template for the future. Since the critical factors can be estimated but crudely, we will do well to predict performance measures within 5% accuracy.

There are many such measures, including *reliability* (fraction of days that demand is met), *satisfaction* (fraction of demand volume that is met), *efficiency* (fraction of run-off water that is used) and *water value*. These measures can be applied to a typical year, to a typical wet or dry season or to an exceptional year/season, such as the driest in the last decade. They can be expressed for a representative location or for a particular one – for which meteorological data must then be available.

Suitable meteorological information is actually, at least in developing countries, rarely available and affordable in the right form and for the exact location of interest. This note addresses the specific problem of inadequately rainfall data.

RWH performance models are generally based on 'mass' balances. At each time-step, the roof run-off belonging to that step is added to the volume (mass) in the tank and the user's draw-off is subtracted. Tests and corrections are applied to cover the three cases 'tank overflows', 'tank runs dry' and 'demand exceeds the water available'. The time-step may be 1 day or 1 month: which of these is appropriate is discussed below. There are further fine modelling details to be decided, for example whether inflow is assumed to *precede* draw-off within any one time-step or to follow it.

A distinction needs to be made between RWH systems with respectively *no* storage, *some* storage and *very large* storage, since modelling them has quite different data needs. Three flows are to be modelled - input, usage and overflow - normal interest is in usage and occasionally in overflow. Modelling a 'no storage' system is simple: all daily inputs in excess of daily demand are spilled. Both *volumetric demand satisfaction* and *reliability* can be simply calculated directly from the rainfall record. Modelling a 'very-large-storage' system is even simpler. If annual roof run-off R_a exceeds annual water demand D_a then *satisfaction* and *reliability* will be 100% and *efficiency* will equal D_a/R_a. Conversely if R_a is less than D_a then *satisfaction* and *reliability* will fall to R_a/D_a , while *efficiency* will rise to 100%.

The situation however becomes more complex when the storage volume can be approximated neither to zero nor to infinity. This situation is addressed by the rest of this Note.

2. DATA NEEDS OF RWH PERFORMANCE MODELS

The list of data required to run a performance-prediction model comprises

- roof area and a roofwater run-off coefficient (for the latter, a constant such as 0.85 is often used to approximate the very variable behaviour found in practice)
- nominal ('standard') daily water demand *D*
- the management strategy the user proposes to use for selecting demand on a particular day as a multiple, greater or less than 1, of nominal demand
- a past rainfall record long enough to act as a reliable guide to future precipitation patterns
- proposed tank size *V*

We may express the tank size via an associated water residence time *T*, defined as tank volume divided by nominal daily demand ($=V/D$). Generally the rainfall data to accurately drive any model of that tank needs to be expressed in time steps shorter than *T*. Low-cost (and thus low-security) RWH systems having tanks of under say 15 day's capacity (T<15) need daily data sets, whereas high-security RWH systems with '3-month' tanks may be modelled with monthly data.

The length of the requisite rainfall record depends mainly on the level of supply reliability sought. Large RWH systems that constitute a supply of last resort in arid areas must be modelled (Vyas V., 1999)with long data sequences (say 25 years) in order to pick up extreme climatic events. Low-cost systems can usefully be modelled with 5 or 10-year sequences or with incomplete records where corresponding portions of previous years' data may have to be pasted into gaps.

The desirability of using *daily* rainfall data in RWH modelling has been noted (Heggen, 1993). Table 1 explores the error introduced by employing monthly instead of daily data to drive a RWH performance model. For four climate types the model was driven firstly with daily rainfall and then with rainfall produced by uniformly spreading each month's rainfall uniformly across the days of that month. In both cases the average *reliability* over 10 years was computed. The 'error' tabulated is the difference between the two reliability estimates.

For the large tank, both with a low demand (D = 0.6 x mean daily roof run-off) and an unmeetably high demand (D = 1.2 x mean runoff), the use of monthly data introduces negligible error. An even larger tank would raise the *reliability* with the high demand towards its theoretical maximum of 83% and get an even close agreement between forecasts using actual and 'uniform' daily data. For the medium and small tank sizes however, there is a significant error introduced by using synthetic uniform ('monthly') data instead of actual daily rainfall.

Table 1. Computed *reliability* of RWH supply as a function of rainfall data used in model

Mean run-off = constant 100 l/day.
Demand = constant.
Measures are averaged over 10 years.
Forecasts using *actual* daily data compared with those using *uniform* daily rainfall = monthly / 30

Location, annual rainfall and climate type	Rainfall data used for model	Small tank, 700 l		Medium tank, 3000 l		Large tank, 12000 l	
		Nominal daily demand as percentage of mean daily roof run-off					
		60%	120%	60%	120%	60%	120%
Saiya, W Kenya	actual daily	0.79	0.51	0.97	0.69	1.00	0.76
1507 mm/year	uniform	0.83	0.39	0.99	0.51	1.00	0.76
Double rains	*error %*	*4%*	*-12%*	*2%*	*-18%*	*0%*	*0%*
Bangkok	actual daily	0.58	0.42	0.73	0.57	1.00	0.76
1500 mm/year	uniform	0.58	0.45	0.71	0.56	1.00	0.76
Monsoon climate	*error %*	*0%*	*3%*	*-1%*	*-2%*	*0%*	*0%*
Panama	actual daily	0.71	0.50	0.83	0.66	1.00	0.76
1500 mm/year	uniform	0.71	0.47	0.83	0.59	1.00	0.76
Long single rains	*error %*	*0%*	*-3%*	*0%*	*-7%*	*0%*	*0%*
Petrolina, Brazil	actual daily	0.45	0.27	0.65	0.47	0.96	0.76
mm/year	uniform	0.55	0.38	0.71	0.48	0.98	0.76
Semi-arid	*error %*	*11%*	*11%*	*6%*	*0%*	*2%*	*0%*

Notes: *(a) Reliability is the fraction of days in 10 years that demand was met.*

(b) The error measures the bias in the estimates of supply reliability introduced by using coarse (monthly) rainfall data instead of fine (actual daily) data.

(c) Shaded cells indicate reliability less than 50% and therefore not very suitable for RWH

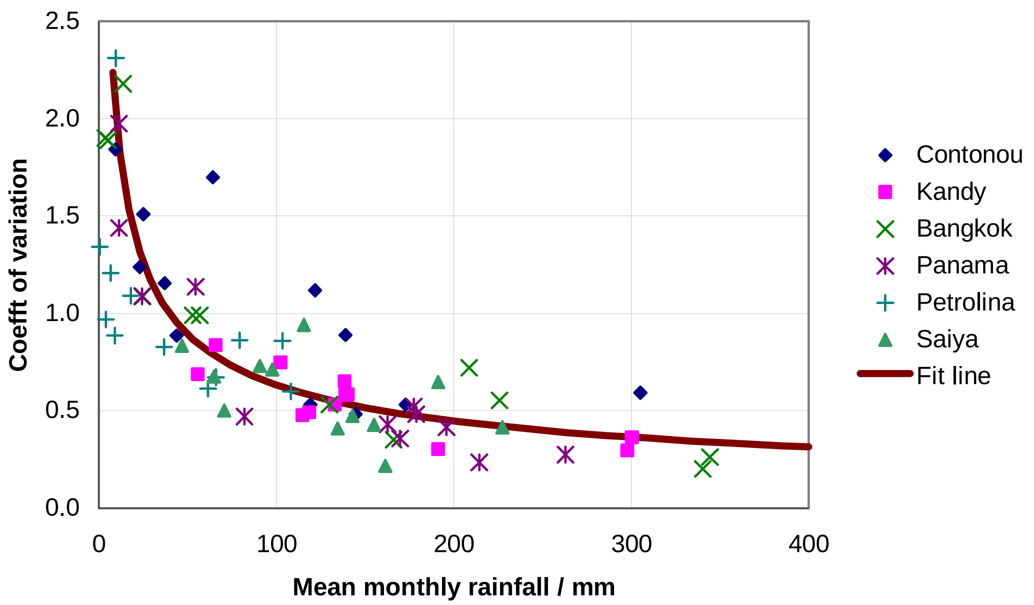
Tables similar to Table1 have also been produced to show not *reliability* but *satisfaction*. The values in such tables are of the order of 10% bigger than in Table 1 but the error introduced by employing only monthly data is similar. Other management strategies, such as rationing when the tank content is low, have also been modelled and show similar levels of error.

3. AVAILABILITY OF SUITABLE DATA

Meteorological data is rarely detailed, reliable and free. In many countries a 10-year daily rainfall record costs more than a small RWH system to buy. Rainfall varies with location, season and year. Its spatial variability is strongly influenced by topology and factors like distance from a coast. Its temporal variability becomes proportionally greater the lower the mean rainfall. The rough 'Fit line' in Figure 1 below shows that the variability, as measured by a coefficient of variation, may be expressed by $CoV = (R_m/40)^{-0.5}$ where R_m is the mean rainfall for that month in that location. The data is for two tropical sites from each of the Asian, African and American Continents.

In terms of geographical location, it may be possible to interpolate between neighbouring meteorological stations, or to use annual records to obtain a rainfall multiplication factor to apply to data from one place to make it better suit another.

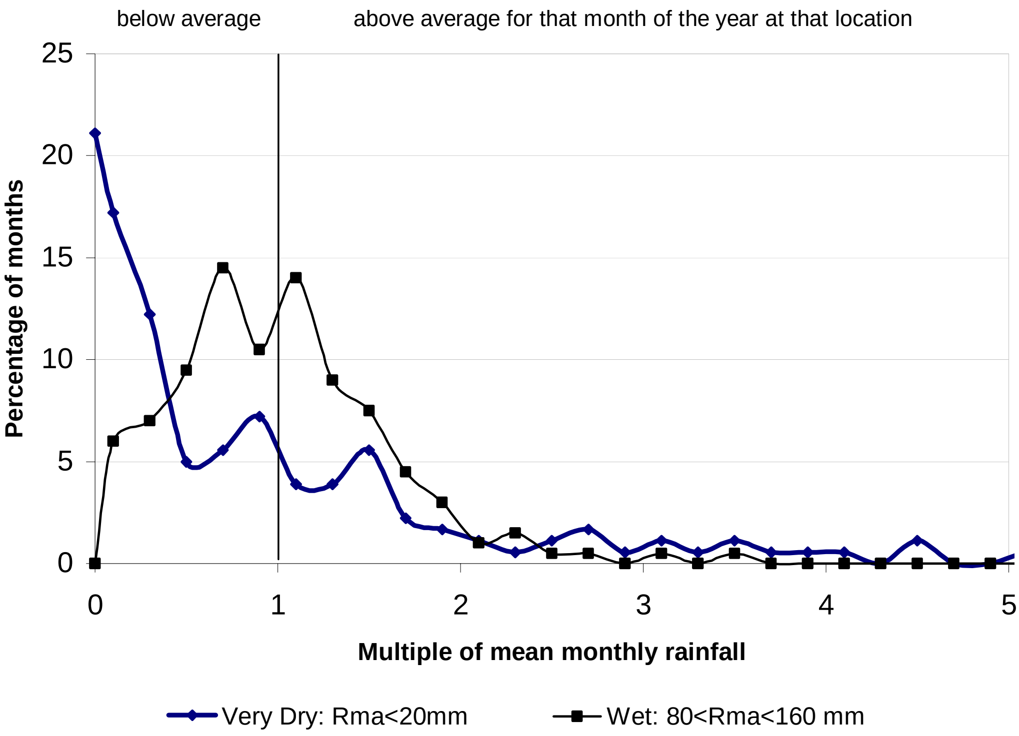
Figure 1. Variation in monthly rainfall (over 10 years & 6 sites)



In terms of time resolution, rainfall data is most readily available in ‘mean annual’ form, then as ‘mean monthly’, then as ‘actual monthly’ and least readily as ‘daily’. Even half-hourly data is available in richer countries with automatic recording equipment. Unfortunately ‘mean annual’ rainfall is little use for RWH modelling unless the modeller also possesses a library of representative seasonal distributions for the relevant region. ‘Mean monthly’ data is both too coarse and too time-averaged, but it is of some use and it is quite widely available (Pearce E & Smith C G, 1998). (Figure 2 shows amplitude distributions for 180 ‘dry-month’ tropical rainfalls and 200 ‘wet-month’ rainfalls normalised to the mean rainfall for the relevant calendar month and location. It confirms the greater variability and much higher chance of zero rain in months with a low average rainfall.) ‘Actual monthly’ data may be sufficient for quite accurate modelling as will be discussed below. Daily rainfall records may be regarded as effectively unavailable or unaffordable for most tropical sites.

Figure 2. Amplitude probability distributions

Monthly rainfalls placed in bands of width 20% mean monthly, or as zero rain



4. GENERATING PSEUDO DAILY RAINFALL DATA FROM ACTUAL MONTHLY RAINFALL DATA

In using monthly data directly we are effectively assuming constant daily conditions throughout that month – this is a very poor approximation and we could do better. From daily records for a climatic zone we could statistically characterise the rainfall distribution (in amplitude and sequence). We can then use these statistics to generate random rainfall data with the correct distribution and monthly totals.

In the normal collection and generation of rainfall data, daily records are condensed into monthly or annual records by the process below ($\rightarrow^{S}$ denotes summation and $\rightarrow^{A}$ denotes averaging).

$$\textit{Actual daily rainfall } (r) \rightarrow^{S} \textit{Actual monthly } (R_m) \rightarrow^{S} \textit{Actual annual}(R_a) \rightarrow^{A} \textit{Mean annual } (R_{aa})$$

$$\downarrow^{A}$$

$$\textit{Mean monthly } (R_{ma})$$

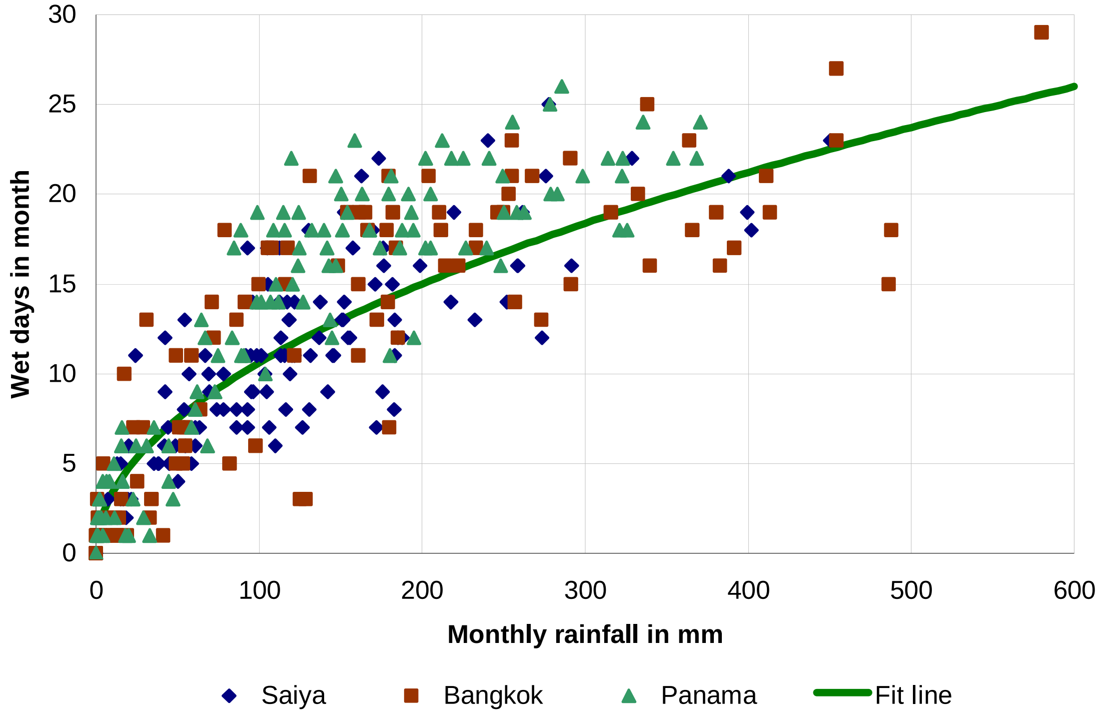
In generating pseudo data we reverse the process ($\rightarrow^{R}$ denotes randomisation)

$$\textit{Mean monthly } (R_{ma}) \rightarrow^{R} \textit{Pseudo monthly } (R'_m)$$

$$\textit{Actual } (R_m) \textit{ or pseudo } (R'_m) \textit{ monthly} \rightarrow \textit{Probability of wet day } (P) \rightarrow^{R} \textit{Pseudo daily } (r')$$

The amplitude distribution for daily rainfall we can treat as having two parts, an impulse at the origin corresponding to no-rain days and a generally falling curve away from the origin (reflecting that the lighter the rainfall the higher its probability of occurring). It is practical to replace these parts by a probability P (of a day being wet) and an amplitude distribution applicable only if the day is wet. The latter should give the correct wet day average R_w which in the humid tropics varies surprisingly little with variation in monthly rainfall (i.e. in wetter months there are primarily more wet days rather than wetter wet days).

Figure 3. Wet days per month (i.e. 30 P) versus monthly rainfall



The number of wet days in a standard month will be $n_w = 30\ x\ P$. Figure 3 shows a relationship between wet days and monthly rainfall and a crude fit line suggesting the number of them (and hence P) is proportional to square root R_m. In subsequent modelling we have therefore used $P = \mathrm{SQRT}(R_m/A)$ where $A = 800$ mm generally gives a good fit in the tropics. To maintain the correct monthly totals we have a mean wet-day rainfall $R_w = R_m / n_w$ and this ranges from around 6mm in a dry month to around 16mm in a very wet one.

The distribution of these wet days is open to debate. Table 2 (column 4) compares the actual probability of getting rain on successive days with that derived from a random (Poisson) rain-event sequence having the same mean wet-day probability P. ‘Rain yesterday’ clearly raises the probability of ‘rain today’ above its long-term value, indicating some bunching of rainy days. The table suggests that there is a higher than expectedly high chance of rain on successive days and a lower than expected chance of rain on alternate days. The auto-correlation of a long record of daily rainfall (with a 1-day shift) is also typically positive and of size 0.1 to 0.2. Seasonality explains some, but not all, of this apparent bunching

Table 2. Spacing between rainy days, actual *v* random (same average spacing)

Location	**Basis of prob-abilities**	**Probability of rain today**			
		In General $P = 1/ d_a$	**yesterday was wet**	**last rained 2 days ago**	**last rained >14 days ago**
Saiya, W Kenya	Actual	0.353	0.509	0.338	0.145
	Poisson	*0.353*	*0.353*	*0.353*	*0.353*
Bangkok	Actual	0.338	0.566	0.414	0.043
	Poisson	*0.338*	*0.338*	*0.338*	*0.338*
Petrolina NE Brazil	Actual	0.157	0.407	0.178	0.054
	Poisson	*0.157*	*0.157*	*0.157*	*0.157*

In computational terms, producing a suitable Markov process, whereby yesterday's turn-out affects today's probability, is complex and therefore to be avoided unless proven really beneficial. Initially, therefore, all modelling will be done assuming no such preceding-day influence – i.e. each day will be considered independent and only influenced by monthly rainfall. Thus wet days are taken to be randomly spaced and can be assigned using a random number generator ("wet if $X<P$" where X is a random number that is uniformly distributed between 0 and 1).

We next meet the task of assigning pseudo rainfall to each wet day. Examination of graphs suggest a roughly falling exponential amplitude distribution for wet day rainfall: $p_r = e^{-r/R}/R$ where p_r is the probability density in units of mm^{-1}. However it can be shown that the probability of very low and of very high rainfall is higher than this distribution would suggest. The modeller has therefore the options of using a straight exponential amplitude distribution – which is fairly easy to implement, or of 'tweaking' such a model with an additional tuning adjustment or of using some other distribution difficult to mimic. The second option was employed in this study. It can be shown that transforming a uniformly distributed random variable X (range 0 to 1) by the equation $r' = -R \ln(X)$ gives the generated rainfall r' the desired distribution, provided that the constant R is the mean wet-day rainfall R_w for the current month. The probability of low and high rainfall can be increased by processing X before taking its logarithm: a suitable algorithm is:

$$r' = -R \ln(\mathrm{Z}) \qquad \text{and} \qquad Z = \mathrm{a}X + \mathrm{b}X^2 + \mathrm{c}X^3 \qquad \text{where} \quad \mathrm{b} = 3(1\text{-a});\ \mathrm{c} = -2(1\text{-a})$$

Table 3. Procedure for generating pseudo-daily rainfall *r"* from monthly rainfall R_m

Step	**Procedure**
(i)	Estimate the wet-day probability *P* from the monthly rainfall R_m and hence also obtain mean wet-day rainfall R_w for that month,
(ii)	Use a random number generator in conjunction with the threshold *P* to decide if today is a wet day,
(iii)	If it is a wet day, generate a random rainfall *r'* for today which has a suitable amplitude distribution (assuming no influence from the previous day's rainfall)
(iv)	Re-scale all the daily *r'* values for the month to generate new values *r"* that add correctly to the given monthly total R_m

Using this procedure, pseudo rainfall sequences were generated for three tropical locations with respectively double rains, Monsoon rains and low erratic rains. The agreement between actual and pseudo daily rainfall – in terms of totals, rainy days and distributions as shown in

Table 4 – is quite good, and of course much superior to the agreement between actual and *uniform* simulated rainfall as shown italicised.

Table 4. Comparison of characteristics of actual, pseudo and 'uniform' daily rainfall

Location	Data type	Annual rainfall	Wet days per year	Wet days/year >30mm rain	Wet days/yr <10mm rain	Auto-correlation
Saiya W Kenya	Actual	1482	131	11	84	0.144
	Pseudo	1486	133	11	82	0.025
	Uniform	*1486*	*354*	*0*	*339*	
Bangkok	Actual	1546	121	15	75	0.250
	Pseudo	1551	113	16	65	0.149
	Uniform	*1551*	*318*	*0*	*270*	
Panama	Actual	1528	154	13	108	0.107
	Pseudo	1530	127	13	76	0.083
	Uniform	*1531*	*345*	*0*	*318*	
Petrolina NE Brazil	Actual	507	56	3	41	0.221
	Pseudo	506	65	3	46	0.094
	Uniform	*507*	*312*	*0*	*312*	

On the strength of this comparison we may now test the accuracy of employing synthetic daily rainfall data where we have no actual such data.

5. PERFORMANCE OF MODELS USING PSEUDO DAILY DATA

Table 5 mimics Table 1 except that now we are using more carefully generated pseudo daily rainfall. As before we compare predicted *reliability* for a range of RWH scenarios using respectively actual and pseudo rainfall data. The comparison is fairly good but not excellent. In the range of practical interest (*reliability* > 50%) the error does not exceed 5% and averages about 2%. As the error is always positive (pseudo data over-estimates performance) it might be prudent to subtract 2% from all *reliability* forecasts.

The source of what error there is may lie in the randomisation process itself – the fluctuations it produces may need longer than 10 years modelling to cancel out. More likely the practical decision to treat successive days as statistically independent, ignoring the small influence of one day's rain on the next day's likelihood of rain, has made the pseudo data slightly too favourable. Extensive natural clumping of rainy days is likely to increase the probability of tank overflow and hence degrade performance: such clumping is absent in the pseudo data.

The comparison was deemed sufficiently close to justify offering an open-access RWH system modelling service on the web at www.eng.warwick.ac.uk/dtu/rwh/model which is driven by user's monthly rainfall data and proposed system details and which yields *reliability, satisfaction* and *efficiency* estimates.

Table 5. Computed reliability of RWH supply as a function of rainfall data used in model

(Constant demand, actual daily data compared with pseudo daily rainfall)

Location, annual rainfall and climate type	**Rainfall data used for model**	**Small tank, 700 l**		**Medium tank, 3000 l**		**Large tank, 12000 l**	
		Nominal daily demand as percentage of mean daily roof run-off					
		60%	**120%**	**60%**	**120%**	**60%**	**120%**
Saiya, W Kenya	actual daily	0.79	0.51	0.97	0.69	1.00	0.76
1507 mm/year	pseudo daily	0.84	0.53	0.99	0.70	1.00	0.76
Double rains	*error %*	5%	2%	2%	1%	0%	0%
Bangkok, Thai	actual daily	0.58	0.42	0.73	0.57	1.00	0.76
1500 mm/year	pseudo daily	0.62	0.44	0.76	0.59	1.00	0.76

Semi-arid	*error %*	8%	7%	4%	5%	2%	0%

6. CONCLUSIONS

In the humid tropics, where economy rather than extreme water reliability is the normal design objective, RWH tank volumes may be as small as 7 days' mean roof run-off. Under these circumstances direct use of monthly rainfall data in RWH system modelling will lead to considerable bias in performance predictions.

The conflict, between wanting to use *daily* rainfall data to achieve unbiased predictions and having to make do with coarser available data like actual monthly or even mean monthly rainfall data, can be resolved by generating pseudo daily data. A RWH model that employs suitably generated pseudo daily data as its input gives performance predictions quite similar to one using actual daily rainfall. A procedure for generating such pseudo data, valid for tropical sites, has been identified and employed in a web-based modelling service.

The procedure assumes that 10 years *actual monthly* rainfall data is available for the proposed RWH system site. This condition can often not be met. Since *mean monthly* data is more often available, the user of the performance forecasts can use that instead and hope that an average year is a typical year. This hope is slightly optimistic but acceptable in most circumstances.

Meanwhile studies continue into whether *pseudo monthly* rainfall data, generated by randomising *mean monthly* data can reliably be used for RWH performance forecasting. Other modelling refinements, including using conditional probabilities in lieu of a fixed local value of wet-day probability P, may reduce prediction errors further.

CONTENTS

PREFACE

This Research Note is based in part upon a 'mini-conference' on the topic held in June-July 2002 on the discussion forum RWH@JISCMAIL.AC.UK. RWH is used throughout this Note as an abbreviation for 'roofwater harvesting'. The Note incorporates the (DTU) paper used to initiate the discussion and the observations from some 16 contributions covering international experience and specific experiences in Brazil, Ethiopia, India, Sri Lanka and Uganda. These contributions are included in an appendix. Note that the topic is *not* institutional RWH in general, but only the supply of *domestic* water employing *institutional* roofs, for which the abbreviation 'IRWHDS' has been applied.

1. BACKGROUND

In their classic forms, 'institutional RWH' uses run-off from institutional roofs to meet the water needs of that institution and 'domestic RWH' uses runoff from the roof of a house to meet the needs of its inhabitants. However there is a hybrid form of RWH that bridges these two forms by using the 'spare' or 'unused' capacity of some institutional roofs to collect water for domestic use by households outside that institution.

Not all households possess of roofs of sufficient size or quality to practice their own roofwater harvesting. However community buildings such as schools and places of worship, or commercial buildings, may be present that possess large and potentially clean collection surfaces suitable for rainwater harvesting. Such roofs are already sometimes used for institutional water supply – for example school roofs supply water to school pupils. The abbreviation IRWHDS stands for 'Institutional Roof Water-Harvesting System for Domestic Supply'. An IRWHDS system bears some operational similarities to public water supplies using rock catchments (e.g. as in Gibraltar), to the sale of roofwater to neighbours by householders with large roofs and to the sale of ground-runoff water stored in private ponds and tanks.

Roof run-off is almost always of higher quality than ground run-off, the latter usually requiring treatment if it is to achieve potable quality. This note addresses specifically rainwater harvesting from roofs rather than other catchment surfaces.

2. THEORY OF IRWHDS AND DISCUSSION OF ITS VARIOUS FORMS

2.1. Arguments or circumstances favouring IRWHDS

1. Roofs of communal buildings are often hard (e.g. made of tile, iron or asbestos) even in districts where many private households still only possess soft (e.g. grass) roofs. Access to a hard roof is normally a pre-requisite for successful RWH.
2. There are economies of scale to be had from harvesting from large roofs. The sensitivity of tank costs to tank volume is about 0.6. So that a 5-fold increase in tank

size will halve its unit cost (cost per litre capacity), and a 15-fold increase will bring unit costs down below one third. There are likely to be similar economies in guttering and water treatment.

3. Institutional roofs are generally cleaner than domestic ones, being higher and thus less accessible to humans or vermin. Moreover all roofwater is chemically cleaner than water from most other sources and is often biologically cleaner as well.
4. Certain funding agencies would prefer supporting a ‘communal’ water supply scheme than subsidising supplies to individual households.
5. The presence of a large ‘communal’ tank greatly facilitates the supply of water by bowser to that community if and when all of its other water sources have failed during a drought.

2.2. Arguments or circumstances discouraging IRWHDS

1. Unless the institutional building is close to those households drawing water from it, significant extra collection time is incurred above that needed to collect from house roofs.
2. The management (e.g. rationing) of the water in a large tank shared by many households is difficult – it may require the staffing of a ‘water kiosk’.
3. The total area of institutional roof is rarely sufficient to capture adequate water for more than a small fraction of households in the institution’s catchment area.
4. There are few incentives for an institution to invest, in or to energetically maintain, a communal water supply. In almost all cases the operation of an IRWHDS system will not be the main purpose or interest of the institution, its neglect is therefore quite likely. For success a formal operational arrangement is likely to be required, probably commercial.

2.3. Styles of operation

Any style of operation of a IRWHDS has to address the issues of water management, cost recovery and selection of beneficiaries. It is likely that the (institutional) owner of the roof will require some reward. The maintenance of high water quality is likely to be more demanded of a IRWHDS than of a domestic RWH system.

Some likely modes of operation are

OP1. roof is primarily for institutional water supply with any surplus being gifted to associates of the institution, to ‘deserving’ or to influential households;

OP2. all water from the institutional roof is charitably supplied to deserving households;

OP3. the institutional roof is operated like a business asset, benefiting the institution by the sale of water by the litre, (a variant of this mode is to combine IRWHDS with mobile water-vending, so that the water is delivered by the business to the user households);

OP4. water from the institutional roof is harvested by the community with recovery of capital, maintenance and perhaps end-of-life replacement costs covered via access charges (per litre or per day);

OP5. individual households are allowed to each attach their own tank to part of a communal roof (like a 'sow with piglets') - a rent may be payable to the institution for 'use' of a portion of its roof. Note this mode loses the economy of scale of employing a very large tank.

The amount of water 'surplus to internal needs' will depend upon the sort of institution. Assume a location in the humid tropics with 1200 mm annual rainfall (60% of which reaches a user) and the provision from roofwater of 700 litres per 'institutional member' per year. This gives a rough requirement of $1m^2$ of roofing per such member just to meet their water needs. Only if this threshold is exceeded will there be excess water available for consumption by outside households via any of the operational modes above. If the 'institutional members' are resident on site (i.e. overnight as well as by day) their water requirements will be higher – perhaps 4000 litres per year each – and the threshold of availability of any surplus may rise to $6\ m^2$ per member.

Thus in a single-storey boarding school, hospital or prison there is unlikely to be an exportable surplus, since overall roof area per resident is generally under such a $6m^2$ threshold. (In a multi-storied institution of such a type, an exportable surplus is even less likely.) A day school providing only say 1000 litres per pupil per year (including teachers' families' consumption), may be able to export some of its roofwater. IRWHDS is most likely to be viable if the institution is an office or a place of worship, where almost all the roof run-off is available for export.

2.4. Water management options

As with all other forms of RWH, supply from an IRWHDS is more generous or 'easier' in the wet season than in the dry. Indeed it is so expensive or difficult to guarantee a plentiful supply towards the end of a long dry spell that it is rarely economical to rely solely on RWH at such times. Thus users of an IRWHDS are likely to have to both reduce their consumption and seek water from other sources at certain times of year. As the *unit* value of water to a household declines with increase in daily consumption, and as the effective cost of water from other sources rises in the dry season, there is an economic case for rationing water from any tank. Not only should some wet season run-off be retained for dry season use, but also the 'ration' (i.e. consumption) in the dry season should be lower than in the wet. Whatever precise strategy is decided in the long or short term, it needs to be implemented by controls on the quantities drawn by each user.

WM1 One style of water management is to allocate a declared amount to each household – an amount that varies with household size, with recent rainfall or with current tank contents.

WM2 Another is to permit purchase of any quantity of water, setting a per-unit price that varies by season in order to either achieve a social optimum or to maximise annual income.

In either of these control modes a regulator or bailiff is likely to be needed, directed by the 'owner' of the IRWHDS. By contrast, operation mode OP5 above (sow and piglets) leaves the management of water abstraction entirely to the individual households.

2.5. Cost recovery options

Any RWH system is characterised by the dominance of capital over running costs. Therefore construction has to be authorised by the owner of the necessary capital, whether accumulated before construction by potential beneficiaries, loaned by a financial institution or donated by a charity or government. (Physically the owner of the roof also has powers of embargo and there is a complex interaction between the justification of the roof as a building component and its justification as a water source.) The longevity of the hardware is likely to be at least 10 years, but the asset is hard to 'recover' (move or dismantle into saleable parts) by any owner in the case of users' failure to pay. Uncertainties in payback would be introduced by changes in the quality or accessibility of other water sources in the neighbourhood – including any increase in hard roofing in households.

Running costs increase substantially where staffing is required to issue or to deliver water and the latter will almost certainly have to be reflected in some sort of additional 'delivery charge'.

Thus we arrive at four main modes of cost-recovery

CR1 saving by beneficiaries prior to construction

CR2 loan followed by user subscription

CR3 loan followed by sale by the litre

CR4 gift with no expectation of recovery

2.6. Selection of beneficiaries

The discussion above of operating modes includes some mention of selecting beneficiaries. We can now formalise selection by grouping as follows, with selection of beneficiaries according to respectively:

SE1 their personal closeness to, or social leverage over, the institution

SE2 their geographical closeness to the institutional roof

SE3 their welfare status (e.g. water only to widows)

SE4 their participation in a savings and building group

SE5 their ability to pay for the water service

2.7. Health issues

The quality of water from a shared source needs to be higher, and more thoroughly monitored, than that of any single-household source. We may expect the chemical and physical quality of institutional roofwater to be better than that of other sources, although perhaps rather lacking in taste. The bacterial quality may be somewhat inferior to good groundwater sources. Several design options for obtaining cleaner or clearer water are more viable (in terms of cost and ease of operation) for large roof schemes such as IRWHDS than for small domestic schemes. These options include first-flush diversion, sedimentation buffering of inflows, chlorination and filtering at the outlet. Periodic testing should be applied in accordance with local practice for comparable sources such as protected shallow wells.

3. PRACTICAL EXPERIENCE WITH IRWHDS

IRWHDS is poorly documented in the RWH literature. Gould & Nissen Petersen[1], who devote a chapter of their book to describing numerous examples of domestic RWH around the world, make no specific reference to IRWHDS. The practice has not been described in papers at any of the last three IRCSA conferences (Iran 1997, Brazil 1999 and Germany 2001). Communal and commercial RWH systems are quite numerous, but the water harvested seems to be used only by members of the organisation owning the roof, or for aquifer replenishment, and almost never by neighbouring households.

Participants in the mini-conference did identify a few applications. This in no way could be described as a controlled survey, so the number of systems described has no significance. However the reports give some insight into choices between the many options listed in sections 2.3 to 2.6 above.

In section 2.3 it was argued that 'institutional roofs' capable of yielding surplus water (over institutional needs) were likely to be on places of worship or day schools, rather than on residential establishments. In the examples reported, all were indeed either temples/churches or day schools. Participants also observed that establishing any management/maintenance organisation for buildings such as markets, sports centres and government offices is more difficult than doing so for a church or school. Moreover of the five modes of possible operation (OP1 to OP5), no examples of OP3 (roof managed as an income generating asset) or OP5 ('sow and piglets' attachment of individual tanks) were mentioned. Most reported IRWHDS systems were operated on a basis of partial cost-recovery and with priority given to the (small) water needs of the roof-owning institution.

Cost recovery and tank management is clearly no casual matter and generally requires some sort of water bailiff, whether paid or working voluntarily, with powers to control water issue. (Padlocks are mentioned). Indeed the development of a strong water management structure is asserted to be the key to success in IRWHDS.

Even so, the schemes described were generally sized too small to meet all the water needs of the assigned beneficiaries (or put another way, the choice of beneficiaries was inappropriate, their number well exceeding the system's capacity). One underlying constraint is the relatively small ratio between institutional and domestic roof areas. Often an institutional roof has only say 10 times the area of a typical house's roof, and the latter represents a just-adequate RWH collection area. It hardly justifies the complexity of establishing an IRWHDS management to supply under 20 households.

No survey of overall institutional roof area per inhabitant has been undertaken. A crude calculation (for single storey schools in a country where schoolchildren comprise 25% of the

---

[1] Gould J & Nissen-Petersen E, 1999, *Rainwater Catchment Systems*, Intermediate Technology Pubs, Chap 9

population and where there is 0.4 m^2 of school roof per schoolchild) shows only some 0.1 m^2 of school roof per inhabitant. On this basis, such roofs could meet the water needs of only a tiny fraction – e.g. under 2% - of the population. This raises big problems of water allocation that the institution would normally wish to avoid.

No examples of wholly 'commercial' operation were reported and the capital for construction seems always to have come from government or NGOs, sometimes supplemented by 'revolving fund' savings. This may reflect the legal or social difficulties of any 'public' institution exploiting its assets via a commercial intermediary. However the ideology of aid and development is currently shifting towards the creation of 'livelihoods' within a market economy, so the practice of an institution franchising its roof to a local small business may become more attractive. It seems clear that without an unusual local 'champion' any activity as marginal to an institutions main purpose as utilising its roof for water supply will receive poor institutional support. So devolving any RWH activity to a separate body from the institution itself seems necessary for IRWHDS success. In the reported examples, that devolved body was some sort of committee. Committees function well if their remit is of high priority or community-wide. IRWHDS justifies the description of high priority only under conditions of serious water scarcity; it can rarely be community-wide.

Institutional RWH is sometimes seen as a good demonstrator for domestic RWH and some of the reports hinted at that being the main justification for engaging with IRWHDS.

4. SCOPE FOR IRWHDS

4.1. Scenarios

The scope for employing IRWHDS is strongly limited by the lack of adequate institutional roof area to serve the bulk of the population. It is further limited by the absence of well-established models of management and dependence on rather unsustainable stop-gap modes of operation. IRWHDS is likely to be viable when RWH itself is viable (suitable rainfall, problems with other sources) yet most households cannot for some reason practise it. In a 'charity' mode it may be a useful way of alleviating water scarcity of very poor people living in grass-roofed houses. In a more commercial mode it may offer poor institutions a means of earning some extra money. However both field observations and logical analysis suggest IRWHDS will never have a large role.

4.2. Technology for IRWHDS

IRWHDS requires the same technology as other forms of institutional RWH. The tanks and gutters are larger (and cheaper per capita supplied) than in domestic RWH systems. Water treatment by sedimentation or chlorination is both more necessary and easier to organise than in domestic RWH systems. Instrumentation or equipment to support tight water management seems essential.

4.3. Economics of IRWHDS

As with all other forms of RWH, the economic return from an IRWHDS system is improved by using comparatively small tanks and designing for only modest levels of demand satisfaction. A well-managed IRWHDS system should be able to provide water at 40 to 60% the cost from a single-house RWH system. Each IRWHDS system offers some 14 hours per week of paid employment , and if well-managed can offer water at 50% to 60% the cost of water from domestic RWH of similar reliability and condition of say 5-year amortisation of construction cost.. This tariff includes the employee cost.

4.4. Socio-gender impact

IRWHDS is likely to have the same socio-gender impact as other forms of RWH. It will save time spent in water-fetching (frequently a predominantly female activity). It can be operated under subsidy with a poverty focus or fully-commercially with a richer-household bias. The decision to install a IRWHDS system is likely to be taken outside the user household. In most cases this will also mean less control by female beneficiaries, but in a few cases women may have proportionally more power in the institution (e.g. a church) than in their own homes. Dependency of poor households upon an institution for an essential resource like water may give unhealthy scope for their greater subordination to that institution.

5. CONCLUSIONS AND RECOMMENDATIONS

For lack of much field evidence, these conclusions are over-dominated by theoretical analysis.

1. There is apparently little interest in IRWHDS except as an informal adjunct to conventional institution RWH (via sale of water surplus to institutional requirements). The fraction of a population it could serve is low and economies of scale in construction are offset by complexity of operation.

2. The per-beneficiary capital cost of IRWHDS will generally be less than 1/2 that of domestic RWH giving the same service. However a 'sow and piglets' configuration of IRWHDS (each user has her own cistern) which removes inter-user conflicts, does so with the loss of this strong economy of scale.

3. The management of a seasonally varying water store requires a formal structure, such as a water steward working to rules accepted by the beneficiaries or the issue of water against payment.

4. Achieving high water quality is more important with IRWHDS than with domestic RWH; however it is also easier due to the cleaner roofs used, the lower unit cost of quality assurance measures, the more professional operation and the larger size of cisterns.

5. Only institutions with more than about 6 m^2 of roofing per *institutional resident* will have enough 'surplus' water to justify organising its distribution to outside households. In non-residential institutions the threshold above which exportable water becomes available may fall to 1 m^2 of roofing per institutional member.

6. The sort of operational/commercial body best suited to managing an IRWHDS is often incompatible with the institution whose roofing is to be used. Therefore IRWHDS design must specifically address the institution's interests if it is to succeed.

7. IRWHDS awaits convincing experimentation and demonstration, not so much with respect to technology but with respect to water and financial management.
