From: Bisrat Woldemariam, Water Action, Ethiopia <wact@TELECOM.NET.ET>

Concerning the points you have raised on how the systems are run. Please find the following information.

The beneficiaries of the schemes are the students, teachers, priests and the surrounding communities. The school structures serve 1,100 people and the church structures serves 500 more. The project has built up a water committee which charges 0.15 birr for 2 jerry cans of water ($1=8 Ethiopian Birr and 1jerrycan=20 litre). The money is collected by two committees and deposited with the main committee. The committee consists of seven members and sub-committees are located in the school and monastery.

The water in the school compound is rationed as follows

One 40m3 reservoir for teachers,

One 40m3 reservoir for students and

Two-40m3 reservoirs and one 75m3 reservoir for the surrounding communities. The maximum amount of water a household could get is only 4 jerry cans per day.

From the church schemes they give priority for the church service and then to the priests monks, nuns and the surrounding communities.

Please note that the total effective run-off from the school and the churches roof catchments was found 992m3/annum. Though the criteria were set deliberately considering only the water usage i.e. (only for drinking and cooking purpose), there is still a deficit of 2900m3 of water per annum to satisfy the whole requirement of the beneficiaries. However, it is important to bear in mind that the schemes were not intended to supply the whole requirement but they were intended to supplement the usual water shortage occurring during the dry season from ponds, and hence, improve the health condition of the beneficiaries to a certain level

The impact of the programme is that it has released people, particularly women, from walking long distances to collect water and saved working time. It has also improved people's health. Since base line health data is not available, clear indication of changes are not possible. Before 1995 the area faced severe water shortages. The main source of water was the Zeba River and hand dug wells, which dried out in early summer. To fetch water from the river was a 6 hours round trip. To reach it was a difficult task with the path on a cliff edge.

Moreover, it's believed that the scheme have a great impact and role on community awareness towards the use of other alternative water sources other than the traditional ponds and may encourage the beneficiaries to similar replication of roof water harvesting individually or on group basis. In fact till now there is no a replication of institutions RWH schemes constructed by the community itself.

From Brett Martinson, DTU Warwick University **dbm@eng.warwick.ac.uk**

Bisrat raises some interesting points about the use of institutional roofs for domestic supply.

1. The problems of serving a large number of people (in this case 1,100) from a community roof. Even if the roof is over 500m2, the area per person is less than 1m2, at such a small roof area per capita, demand will soon outstrip supply - particularly if it is envisaged the RWH system will be used for bridging dry seasons. Strict rationing will be required. What conflicts can be expected and how would they be resolved?

2. Replication. Institutional rainwater harvesting is often put in to demystify the technology to surrounding households and encourage replication. What experiences do people have of the effectiveness of this. Does the technology take off or does it simply stay in the schoolyard?

From: Rajindra de S Ariyabandu, Sri Lanka **wrsrds@sltnet.lk**

Let me also contribute my two cents worth to the institutional roofs debate. I think we have to take these in the context of the location. It appears from Bisrat's account of institutional roofs in Ethiopia is a success. The main reason is the other water sources are 6 hours away. Even the limited quantity of water per household appears to be properly managed. We in Sri Lanka do not have large scale institutional roof water harvesting at present. However, we did try in schools and at an Agrarian Service Centre in a rural area. The first one had limited success and the second one failed miserably. Both for the same reason, management! The question with institutional roofs is who owns the institution, or for that matter the roof. When there were champions to manage the RW systems in schools it became a success. Champions are those who take special interest in managing the RWH systems. In one school it was the Agricultural teacher who apparently resided in the school quarters. This incidentally, was the same reason why such institutional systems failed in Thailand schools. Who owns and who manages? The system at the Agrarian Service Centre functioned to a limited extent during the time of a very powerful secretary to the Ministry of Agriculture. After he retired the system was neglected, though there was definite benefits from the system. So the point is there is something more that just technical criteria for the success of external interventions in rural areas.

By the way Bisrat, who manages the school reservoirs you have in Ethiopia? How effective is the management?

From: Bisrat, Water Action, Ethiopia

Glad to hear from you again. The school reservoirs are managed by a committee. The committee consists of seven members and sub-committees are located in the school and monastery. Though some training was given for committee members on technical and financial management, the committee expressed a clear need for additional training to water committee members.

From: Kobusingye Annette, ACORD, Uganda

This is my small contribution on the above matter

Institutional Rain Water Harvesting in Uganda is practiced and mainly supported by NGO's, like UNICEF in primary schools and ACORD in some Secondary schools and hospitals. UNICEF's goal is to improve sanitation and hygiene in schools so the water is not accessible to the rest of the community members. The tanks are fairly large but the water is only for the pupils and the teachers.

ACORD has built ferro-cement tanks in schools too but the water is also for the targeted people not the whole community.

Institutional Rainwater harvested from hospitals is used by the patients and the nurses and to a small extent by the neighbouring community which buys this water. Institutional rainwater is sold in order to generate some income to maintain the structure.

From: **Paito Obote, WaterAid, Uganda** **<paitoobote@wateraid.or.ug>**

To add a word to the debate, WaterAid in Uganda supported a small NGO in Kisoro district, southwestern Uganda to provide 'communal' roof catchment systems in an area where rainwater is the only readily available source of potable water supply. Initially every household harvests rainwater on a small scale during the rainy season and in the dry season they all converge to a pond with the animals. Most of the tanks were constructed in private homes and a few were constructed on the few institutional houses like schools, churches, mosques, and administrative buildings. The unique feature here is that all houses are roofed with iron sheet simply because there is no thatching material around, so every home has a source of water. The NGO supported by WaterAid was already running a housing scheme (incorporating rainwater water collection system) for its members; the water from the tanks was sold to members at some fixed price. This arrangement would continue until all the members are covered. The new project focused on rainwater harvesting (i.e. not housing) for the whole community but the management arrangements of rationing and selling water remained as before and it has been very successful. Part of the revenue raised is being re-invested in new rainwater tanks to expand the coverage. The project has been very successful and a number of individuals and even district supported projects are copying the system design and operation.

Three main conditions however led to the success of this project:

1.. The existing demand created by the need and the developed tradition of rainwater harvesting.

2.. The existence of a local NGO that provided the framework for local capacity building.

3.. Maximum utilisation of local resources (materials and human) that ensures sustainability and replication.

I believe that with proper management system based on the user community, communal rainwater systems can be successful and highly beneficial.

From: **Ddamulira Dunstan, ACORD Uganda** **dpdunstan@yahoo.com**

I have been following the on going discussion on institutional rain water harvesting with keen interest. ACORD Mbarara supports supports both domestic and institutional rainwater harvesting initiatives in its Mbarara rural programme area. The experience i have gained in this project prompts me to categorise institutions in three kinds:

1) Educational institutions (like primary schools)

2)Religious or faith based institutions(eg Mosques and churches)

3) General public institutions (like Markets and recreation centres)

Apart from General public institutions, promoting rain water harvesting on other categories and ensuring sustainability is quite easy since quite often these institutions have got well established management structures (eg school management board/committees) that can spearhead rainwater harvesting implementation and later sustainability of the facilities put in place. For general institutions sustainability requires setting up and training a committee to take care of the facility(there was a case in Uganda- Mbizzi Nya market where replacing just a broken tap on a roof tank took a lot of time)

However for religious related institutions a balance has to be taken by any R.W.H promoting agency to support all religious institutions within the vicinity so that one religion doesn't feel left out or marginalised.

Institutions present the advantage of constructing large volume tanks because they have large catchment roofs in one place to fill the tanks(ACORD has supported construction of underground tanks of capacity more than 100,000 litres on primary schools and teacher training colleges in Mbarara district Uganda) But often even these overwhelmed by the demand from the beneficiary communities. This prompts the institution's management to either ration or limit the water to a few close people. (Raising a question whether institutional tanks can be classified as communal or not).

Does any one have anything to comment on roof rainwater harvesting from shared individual roofs? Should one take them to be institutional or not? What are the challenges? [I am just sparking off a discussion!]

From: **"R. de S. Ariyabandu" <wrsrds@sltnet.lk>**

I think we have a definitional issue here. What we have been considering as institutional RWH systems are those which can harvest a large volume of water due the high availability of roof area. They can be community systems in case if they supply to a nearby village community of it can also be individual if the water is used solely by the occupants of the building. Often RWH using government buildings are not community systems though it serves a large number of persons. On the other hand individual household systems in a village community can be termed as community systems project or programme. In this case it is number of individual units serving a larger population. So you see the difference is only how you defined it. On another issue what is the progress of the water policy document? have you posted it already?

From: **"Kyung H. Yoo" <khyoo@eng.auburn.edu>**

It is not a rainwater catchment but a communal water use system from a spring. Each user pays a small token of water uses and the collected funds are used for paying the operator and maintain the system. This is a system Haiti. Management and management is the most important after a system is established. It is important for the community to manage the limited water for critical period of a year and maintain the facility for long term uses. My experience in Brasil deals with individual house RCR (roof catchment of rainwater) systems and communal water supply from an embankment. This project has not been completed but when completed the community will need to develop and enforce water management guidelines.

From: **Terry Thomas, Warwick University, UK** dtu@eng.warwick.ac.uk

Thanks for raising the problem of definition. Straightforward domestic RWH and 'straightforward' institutional RWH (where an institution collects water just for its own members' use) are both widely used. The current e-conference was intended to examine the rather rare circumstance whereby the primary objective is supply to households but the means of doing so is to use an institutional roof. The reasons for this practice might be that the roofs on the houses are unsuitable for RWH or that economies can be made by having 1 large system rather than many small ones. Unfortunately the border between this situation of water being exported from the institution and the situation where the institution itself includes 'houses' - for example teachers' houses - is very arbitrary. Moreover some systems are mixed, with some water going to institution members (such as prisoners or priests and worshippers) and the remainder to neighbouring households.

For the purposes of this discussion I suggest we exclude systems where water only goes to institution 'members' but include ones where water also goes to members' families living nearby.

From: **Chitra Vishwanath, Rainwater Club, Bamgalore, India**
chitravishwanath@vsnl.com

Happened to visit a place called MANAPAD on the east coast of South India near Kanyakumari (the southern most point of mainland India). Salinity ingress to up to 5 km has rendered most shallow wells and borewells unfit to drink from for many villages on the coast. An organisation called ANAWIM has set up 5 ferrocement tanks of capacity 10000 litres each in 5 villages. The one village that I visited had a temple roof as its catchment (about 2500 square feet), actually half a temple roof. The tap to the ferrocement rainwater tank had a lock and one of the ladies of the community kept the key and rationed out water (1 pot per family per day roughly 10 litres). This apparently was good enough for drinking water for the family. The overall system seemed to furnish enough drinking water for about 40 households for 6 months. The ferrocement tank was constructed using a steel mould and was exceedingly well done. The households were very happy with the quality of the water. Unfortunately the other half of the temple roof remains unutilised and funds have not been raised to increase coverage.

From: **Ddamulira dunstan, ACORD Uganda**

Thanks for raising those interesting observations. However the most interesting one is that in most cases people using water from institutions communally tend to use up all the water without restrictions making the systems run out of water in a very short time. My conscience is telling me that perhaps they do use up the water in the systems unknowingly (unconsciously). You see most system designs never incorporate any kind of component permitting/allowing easy monitoring of water remaining in the tanks. Perhaps if there was any easy way people could easily tell how much water is remaining in the systems then they would try to use it sparingly so as to pass them throughout the dry period until the next rains.

Isn't it high time water professional started seriously thinking about some form of WATER LEVEL MONITORING METER? It can be in form of a simple wooden stick calibrated in a simple area specific measurement (e.g. in Uganda Jerricans), floating on the water and extending out through the cover or breather in the tank roof so that can easily be observed by the users as it goes up and down following the level of the water. Perhaps this combined with other innovations can help people monitor their water usage/consumption and hence ration it depending on the availability of rains to re-fill. The problem of gutter span has also been faced our end. Fortunately for our case the tank was underground and we had to divide the span into two so that the first section near the tank is on top of the roof and the second is connected by a vertical down pipe to a ground level horizontal pipe which directs the water into the tank. Otherwise I will come back to you about the deflector plates.

From: Brian Skinner, WEDC, Loughborough University <B.H.Skinner@lboro.ac.uk>

I agree that a way of monitoring the water level can be useful, particularly for a household system. However for a communal system I don't think that your ideas will usually work. I feel that unfortunately people tend to be rather selfish and do not have a good level of self-control. Where there is an appreciable walk to the alternative source of water people will tend to take as much as they can from the nearer rainwater tank if they can do so with without other members of the community knowing! If other community members think that someone else is 'cheating' they may well join in, thinking why should only they have the easy life!

I feel that people will only restrict the amount that they collect in well-disciplined communities, that use appropriate enforcement of punishments for drawing more than allowed. Has anyone on the list experience of communities successfully using a communal tank?

[Last contribution dated 10th June 2002]

From: "Kyung H. Yoo" <khyoo@eng.auburn.edu>

I agree. One possibility would be charging the water at low but high enough rate and use the collected funds to hire a person to police and operate the system. I don't know how it would work but it could be an alternative to getting whole community thirsty during the critical dry season.

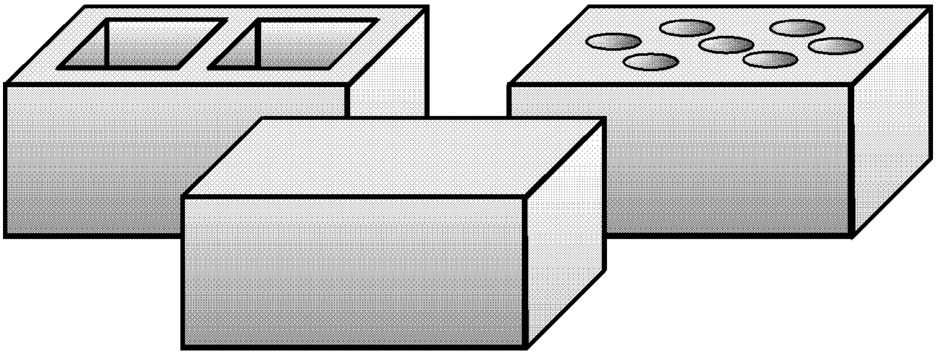
Stabilised Soil Research Progress Report SSRPR2



How does cement stabilisation work?

Author: Mr D E Montgomery
October 1998

E-mail: d.e.montgomery@warwick.ac.uk

These reports cover 'work in progress' by research students in the Development Technology Unit (DTU) of the School of Engineering at Warwick University. Their primary purpose is internal - a format for recording ideas and data in a way that allows them to be better discussed before their incorporation into theses, DTU Working Papers or external publications. However they also have a secondary purpose, that of facilitating the sharing of our research with other innovators in the field of building with stabilised soil. Each report, after some initial internal discussion and refining will be posted as a title and synopsis on the DTU web pages (home page= http://www.eng.warwick.ac.uk/dtu). Full copies can be obtained from the respective named authors.

A dedication to someone special

Sometimes at the beginning of a publication one finds a dedication to a certain person or member of the family who has been an influence in the author's life either in general or specifically in generating the work in question. There is one person in my life that immediately springs to mind who is worthy of such a dedication. Furthermore, my experience with this person is not unique as millions of others have found him to be a great inspiration, comfort, guide and friend. "What's his name?" you may be asking yourself and, "Why haven't I heard of this incredibly influential person". The sad thing is that you probably have, but you have never accepted him as such or welcomed him into your heart and life. Well, now you have an opportunity to do just that. Please read on.

The man's name is Jesus and although he was born nearly 2000 years ago his testimony still remains and his power to save is just as great. "Save from what?" you may ask, sin and the consequences thereof, or more specifically, your sins and the consequences you face when you die. As humans we demand justice to be done, and justice will be done, but on a perfect scale and to a perfect standard. That leaves us all falling short and without hope when we come face to face with a holy God. But, God in his great love towards us send his only begotten Son into the world that the world through him might be saved. Jesus Christ died for you so that you would not have to be punished for what you have done wrong. You can be spared eternal punishment in hell and enjoy love and peace in the presence of God forever. Today the choice is yours. Reject God's free gift of love at your peril, accept it and who knows you too may have the joy of writing a dedication such as this someday. Please ponder the verses below and make your choice carefully, it will be the most important decision you ever make.

"*For by grace are ye saved through faith; and that not of yourselves: it is the gift of God: not of works, lest any man should boast.*" Ephesians 2:8,9.

"*For God so loved the world, that he gave his only begotten Son, that whosoever believeth in him should not perish, but have everlasting life.*" John 3:16.

"*For whosoever shall call upon the name of the Lord shall be saved.*" Romans 10:13

"*He that believeth on him is not condemned: be he that believeth not is condemned already, because he hath not believed in the name of the only begotten Son of God.*" John 3:18.

"*Jesus saith unto him, I am the way, the truth, and the life: no man commeth unto the Father, but by me.*" John 14:6.

Abstract

After a brief study of some relevant texts documenting the production, characteristics and use of Portland cement a better understanding of its cementitous qualities has been gained. The bonding of cement is caused by the hydration of the cement particles which grow into crystals that can interlock with one another giving a high compressive strength.

In order to achieve a successful bond the cement particles need to coat most of the material particles so that upon hydration a crystalline structure is created throughout the mixture of particles. Particle intimacy is important to ensure a good number of cementitic bonds between adjoining particles and this can be helped by mixing the cement into a mixture of particles with a good size distribution. The water in the mixture needs to be monitored to guarantee sufficient hydration of the cement and also to ensure adequate workability of the mix. Too much water will leave voids in the mixture after the water has evaporated off and will reduce the final set strength of the material.

The limitations to cement besides the careful control of materials and moisture are that cement requires time to fully cure and that it is susceptible to chemical attack. Never-the-less it is a highly suitable method of stabilisation and can easily be applied to stabilise a moderate variety of different soils for use in making building materials.

Nomenclature

Aggregate: Pieces of crushed stone, gravel, etc. used in making concrete.

Brick: An object usually of fired clay used in construction, usually of rectangular shape, whose largest dimension does not exceed 300mm.

Block: A larger type of brick not necessarily made of fired clay, but stabilised in some way, sometimes with central cores removed to reduce the weight.

Cement: Ordinary Portland Cement (OPC), a finely ground clinker which sets hard after mixing with water.

Clay: The finest of the particles found in soil, usually of less than 0.002mm in size and possesses significant cohesive properties.

Clinker: A slag formed when clay and lime a burnt in a furnace together.

Concrete: The finished form of a mixture of cement, sand, aggregate and water.

Dynamic Compaction: A process that densifies soil by applying a series of impact blows to it.

Gravel: A mixture of rock particles ranging from 2mm to 60 mm in diameter.

Green: Describing the state of material containing cement and water before it reaches the critical time, after which further plastic deformation hinders the final set strength.

Gypsum: A hydrated form of calcium sulphate.

Mortar: A mixture of sand, cement and water.

Sand: A mixture of rock particles ranging from 0.06mm to 2 mm in diameter.

Sandcrete (Cured Mortar): The finished form of a mixture of cement, sand and water.

Sharp Sand: Describes the angular nature of sand particles that are very good for making concrete or mortar.

Silt: Moderately fine particles of rock from 0.002mm to 0.06mm in size.

Slaked Lime (Lime): Quicklime (calcium oxide obtained by burning limestone), that has been mixed with water creating calcium hydroxide which has further setting qualities.

Soil: Material found on the surface of the earth not bigger than 20mm in size, not including rocks and boulders and predominantly non-organic. If soil is to be used for building material it must not contain any organic material and it can be a natural selection of particles or a mixture of different soils to attain a more suitable particle distribution.

Soil-cement: Similar to mortar, but prepared from soil with a wider particle distribution.

Stabilised soil: Soil which has been stabilised (treated to improve structural characteristics) by using one or more of the following stabilisation techniques: mechanical, chemical and physical.

Table of Contents

1. Introduction

Cement is to be the primary means of chemically stabilising the soil samples during this research project. Consequently a good understanding of how cement works and how it forms cemetitious bonds with other particles would be most desirable. This report will briefly outline what cement is made of, and how it is produced, but it will spend more time detailing the bonding and curing processes in concrete. During the report it will also establish the various requirements that cement has in being able to perform properly as a stabilising medium. Finally, these theories will be applied to the stabilising of soil.

As a stabilising material cement is well researched, well understood and its properties clearly defined. Portland cement is readily available in most urban areas, and usually available in semi-urban areas, as it is one of the major components for any building construction. Earlier studies have shown that cement is a suitable stabiliser for use with soil in the production of soil-cement blocks, (International Labour Office, 1987), (p. 38). As this is established and recognised technology it provides a suitable basis for further research into the production of better soil-cement materials. Further studies hope to minimise the quantity of cement required to form soil-cement structures.

For the purposes of this report and further study it is assumed that ordinary Portland cement (OPC) is readily available in bags on location. A significant cost may have been incurred in getting the cement to where it is needed, but this report is not intended to analyse the cost effectiveness of cement over other brick stabilising methods. Instead it is to concentrate on modifying and improving the existing cement stabilising of soil, with perhaps a breakthrough in the entire block production routine.

2. Some facts about cement.

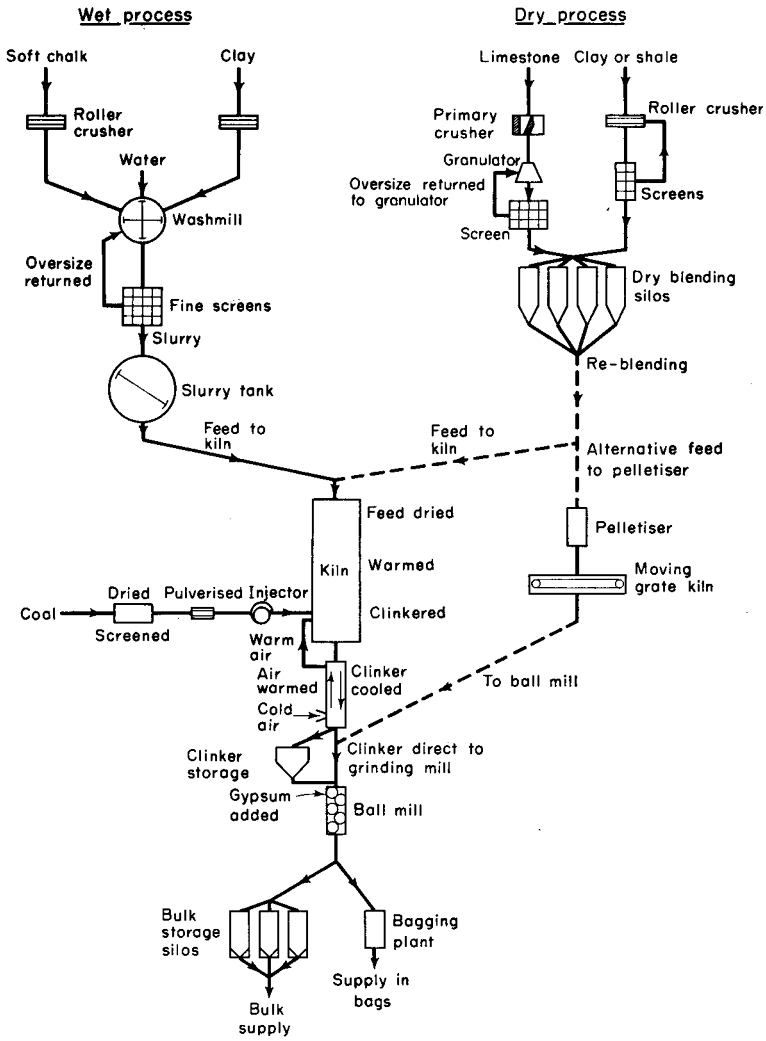
This section will concentrate on establishing the properties and composition of cement. This knowledge will provide a simple foundation for understanding the way that cement works. It will not describe in too much detail the characteristics or production of cement, as this has already been previously established to a sufficient level, (Akroyd, 1962), (p. 46-54), (United Nations, 1972).

2.1 Chemical composition and production

Cement can simply be described as being a mixture of lime and clay which is heated to about 1,500°C, and the resulting clinker has gypsum added and the sum is then ground to very fine powder. An extract from (Akroyd, 1962), (p. 50) contains sufficient detail of the chemical composition of cement itself, featured below.

	Percent (%)	Average(%)
Lime (CaO)	59 -67	64
Silica (SiO_2)	17 -25	21
Alumina ($A1_20_3$)	3 - 9	7
Iron oxide (Fe_2O_3)	0.5-6	3
Magnesia (MgO)	0.1-4	2
Sulphur trioxide ($S0_3$)	1 - 3	2
Sodium potash	0.5-1.3	1

Below is a diagram showing both the Wet and Dry cement manufacturing processes as extracted from (Akroyd, 1962), (p. 48). There has been a move from the former to the latter in recent years, as the dry process requires less energy per unit of cement output.



2.2 Relative cost to other materials

The price per kilogram of cement will vary greatly depending on the distribution network and the proximity to the cement processing plant. Cement can usually be considered to be one of the more expensive materials necessary for building construction. In the field of low tech, low cost soil brick housing, it is crucial that the total cost of the cement as a proportion of the entire structure is kept as low as possible. One would ultimately like to minimise the cement content and maximise the strength and life of the structure. Through a variety of procedures the amount of cement necessary can be reduced and these may be investigated in more depth separately later on in the research. For the moment, the author is taking previous research to suggest that a nominal 5% cement is sufficient for good stabilising of soil blocks.

2.3 Distribution problem

In the vast majority of cases OPC will not be made on site, consequently it will have to be delivered. Once cement has been manufactured, it is generally available in two forms. It can be purchased in a bulk form from a silo, or it can come in bags of 50 kg each. (A new bag size of 25kg is becoming popular in some countries.) Cement that is purchased from a silo is mixed and delivered using cement trucks. These will usually ensure that the cement arrives in good condition, ready for immediate use. However, if cement is purchased in bags, there is no guarantee what state the cement will arrive in. Cement is usually distributed in a multi-layer paper bag that only gives it a small degree of protection. If bagged cement has come a long distance and has been exposed to the elements for any period of time it is highly likely that the cement will have absorbed some moisture and will have started to set. This partial setting of the bag of cement does not render the entire bag useless but it does hinder the use of what is still OK. The good cement has to be sifted out and the remaining lumps can be broken up to make a lower quality cement.

3. Making concrete

In this section the main focus will be on the existing procedures for making concrete. There are established techniques for achieving different grades of concrete, each of which performs a specific task. The analysis of these different grades and how exactly they are all generated is not of great relevance here, but understanding the underlying principles of concrete manufacture will be helpful in later applying similar methods to stabilising soil. Some specialised grades of concrete requiring cements other than OPC, but for the ensuing discussion assumes that OPC has been selected.

3.1 Material selection and requirements

Cement can be mixed with virtually any size and shape of sand or aggregate, depending on the purpose of the concrete that is to be made. Particles are usually graded according to physical size ranging from clay particles (< 0.002 mm) up to boulders (> 200 mm). Particles smaller than 0.02 mm are considered to consist of silts and clays, too much of which will hinder the cementitous process. Particles larger than 60 mm are only usually used in large continuous structures such as dams etc. Cement is mixed in with these other particles and when water is added that starts a chemical reaction within the cement particles that grow to form an interlocking matrix. To aid the particle intimacy, a mixture of aggregate grades are mixed together giving a spectrum of different particle sizes that reduces the size of air voids in the material. This further enhances the final concrete block strength.

The concrete composition depends on the job that is being done. Each concrete mix should be designed for the purpose for which it is intended, (for example a concrete mix for a floor cast will be very different to a mortar mix for brick laying.). This requires a selection of grades of sands and aggregates to be mixed with specified quantities of cement and water. Additional ingredients can give the concrete special properties if necessary and these need to be determined and added in the correct quantity. These may affect one or more of the following; workability, strength, density, thermal characteristics, elastic modulus, durability and speed of setting.

The two characteristics of sands and aggregates that affect their performance when mixed with cement are the particle’s shape and surface texture. The shape affects the workability of the cement during mixing and placement and the surface texture affects the bond between the particles and the cement. Very large angular particles decrease the workability of the mix, whilst smaller more rounded particles do the opposite. Angular shaped particles are generally formed by crushing larger particles down to size. More rounded particles can exist naturally as their shape has been formed due to slow abrasive action between particles in the environment. Angular particles usually have a lower workability but achieve a higher strength since angularity is usually accompanied by surface roughness. Crushing or selection of angular aggregates is only necessary when a very high compressive strength (over 50MPa) is necessary, (Teychenne et al., 1988), (p. 7). For the purposes of this project a compressive strength of that order will not be necessary.

3.2 Mixing quantities and preparation

The approximate quantities of cement, sand and gravel are often found quoted in a ratio of their respective volumes, e.g.: 1:2:4; one part cement, two parts sand and four parts gravel. There are standards for mixing cement so that a required compressive strength can be reached in a given time provided that the type of aggregate and the free-water to cement ratio is known, (Teychenne et al., 1988), (p. 10).

The free-water content is calculated from the slump or Vebe time test. In simple terms the higher the free-water content the greater the amount of slump will occur over a given period. Ideally the amount of water used in the mix should also be monitored to be sufficient to hydrate all the cement and not more than is necessary to fill all the voids present in the material as further moisture drives the particles further apart. Unfortunately this yields a highly unworkable mixture and more water has to be added to form the mixture into the desired shape. Excess free-water increases the workability of the mix but will be detrimental to the final strength of the concrete. The minimum water/cement volume ratio is between 0.22 and 0.25 (Akroyd, 1962), (p. 13) for adequate cement hydration, but this is generally increased to the order of between 0.5 and 0.8 for normal mixes, (Lea, 1970), (p. 392).

The aggregates that are to be used in the concrete mix usually need to be washed before mixing with the sand and cement. The washing process removes fine particles on the surface of the aggregate allowing the cement to achieve a better bond. In the case of purchased aggregate this is usually done for you, but if excavation is part of the process then washing should be included in the preparation of the aggregate particles before mixing with cement.

3.3 The effect of compaction

It has been shown that if the particles in a cement mixture are in some way brought closer together, the greater particle intimacy results in a higher final strength. Achieving this closer particle intimacy can be done in a number of ways. We have already noted that excess water in the cement mix will drive particles further apart and will cause a loss in strength. So keeping the free-water content to a minimum is a good way of ensuring closeness between particles.

Another method is to use a vibrator, that effectively shakes the cement mixture and helps to drive any air pockets to the surface. This is usually done in concrete casts as the vibrator can be inserted into the mix and the vibrating action will permeate throughout the mix. The size and number of vibrators will depend on the size of the cast. Obviously this technique cannot be used with very small casts (where it is normal to externally vibrate the whole mould instead) and there are some other drawbacks to the method. A higher free-water content is necessary for gravity-cast concrete in order to permit the cement mix to flow into all parts of the mould. Properly mixed concrete will have the different grades of aggregate well dispersed throughout the mixture. Using a vibrator in a cast with a high free-water content can cause the larger particles of the mix to sink to the bottom, resulting in a non-uniform distribution of particles.

As yet the author has not found little information (other than previous work at Warwick) on the compacting of a green mix using a moving mass, such as a hammer or weight. This process has been hinted at in (Akroyd, 1962), (p. 196), but no details were given, as the compaction process has been replaced by internal and external vibrators to reduce the labour costs of manual compaction. It is precisely this manual compaction that is of interest to this project as the stabilised soil samples are to be compacted and hence the cement also is compacted. What we can learn from the references Akroyd and Gooding, is that compacted concrete has stronger characteristics than un-compacted concrete.

4. Curing process

By way of a simple illustration of the adhesive qualities of cement we can look at a much simpler example of Papier Mâché. Papier Mâché consists of a flour suspension in water into which paper strips can be immersed and then laid over a former to create a hard shell when it dries. Neither flour nor water have adhesive properties on their own, but when mixed and allowed to dry with a close particle particle intimacy a remarkably strong structure can be created. The flour particles become embedded into the pieces of paper, because the paper absorbs some of the water as well, and once the water is displaced by evaporation, strong bonds between the pieces of paper remain.

The analogy between Papier Mâché and cement breaks down when you add water to the structure again. Cement will retain much of its strength (e.g. 50%) whilst Papier Mâché will break down again and become weak. With Papier Mâché the bonds stay strong so long as moisture is absent, the cohesion is caused by inter-particle intimacy and that breaks down when water is added, as the particles are driven apart by the presence of water coating the surface of the particles. Cement on the other hand undergoes a chemical reaction that remains strong even after moisture is re-applied. Exactly what happens as cement bonds with adjoining particles is what this chapter will endeavour to describe.

4.1 Inter-particle bonds, Why are they formed?

Originally they were two popular theories about how OPC worked. The older of the two was a crystalline theory of Le Chatelier which dates back to 1882. This theory stated that the hardening is due to the locking together of an inter-growth of crystals hence giving the crystalline theory. The alternative theory came later in 1893 proposed by Michaelis which was the gel theory. He suggested a non-reversible gel is formed in saturated solution which surrounds the cemented particles. As the gel coagulates the cement sets. These two theories were then integrated into a combined gel/crystalline theory that describe the different stages of curing, (Lea, 1970), (p. 253-260).

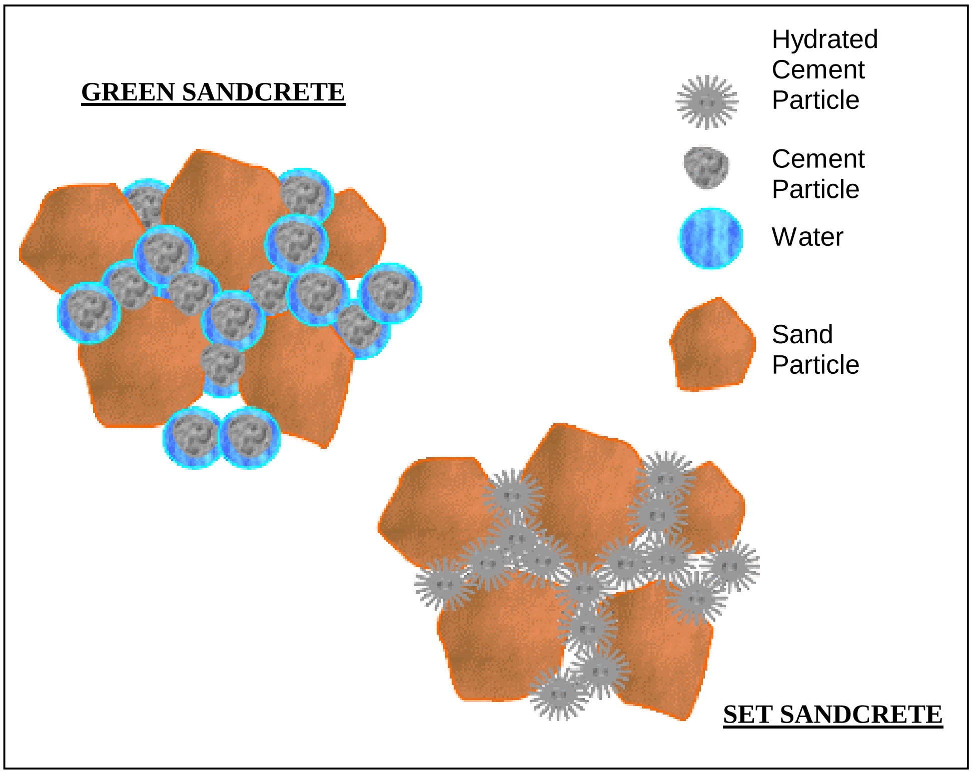
Once cement, sand, aggregate and water are mixed thoroughly the mixture gains a certain cohesion with itself. This cohesion greatly depends on the amount of free-water present as an excess of water will lead to a more runny consistency. Assuming the correct amount of water is applied to ensure complete hydration of the cement, each cement particle will be coated in water and this turns into a gel-like film. These gel-coated particles of cement are themselves coated all over the sand and aggregate particles throughout the mixing process. At this stage the cement is still workable and has not begun to set. The reaction between the water and the cement begins a crystallisation process and small single crystals begin to form.

After the “critical time” has passed, these single crystals grow into one another and a huge crystalline network begins to form. The critical time is loosely defined as the time after which further working of the cement is detrimental to the final set strength. Adjoining crystals do not chemically join, but are attracted to one another by Van de Waal forces. The small single crystals begin to inter-link to form a network of interlocking crystals throughout the mixture. If the mixture has been properly graded to include a good range of particles sizes, and these have been thoroughly mixed together with the cement, the crystalline structure will be surrounding each of the particles interlocking them one to another.

There may still be moisture present in the mixture after the crystalline network has been formed and this will slowly be evaporated to the atmosphere as the water particles are drawn to the surface by capillary action. During this drying out phase the concrete will experience a small amount of shrinkage depending on the excess of free-water present. Part of the attraction of employing blocks rather than mass concrete walling is that shrinkage takes place where, due to lack of hard constraints, cracking is unlikely to ensue. This drying out process can take some time to finish completely, but for general purposes it can be assumed that the concrete has virtually reached its’ final strength after 28 days. The final result is a chemically bonded solid mass with a very high compressive strength.

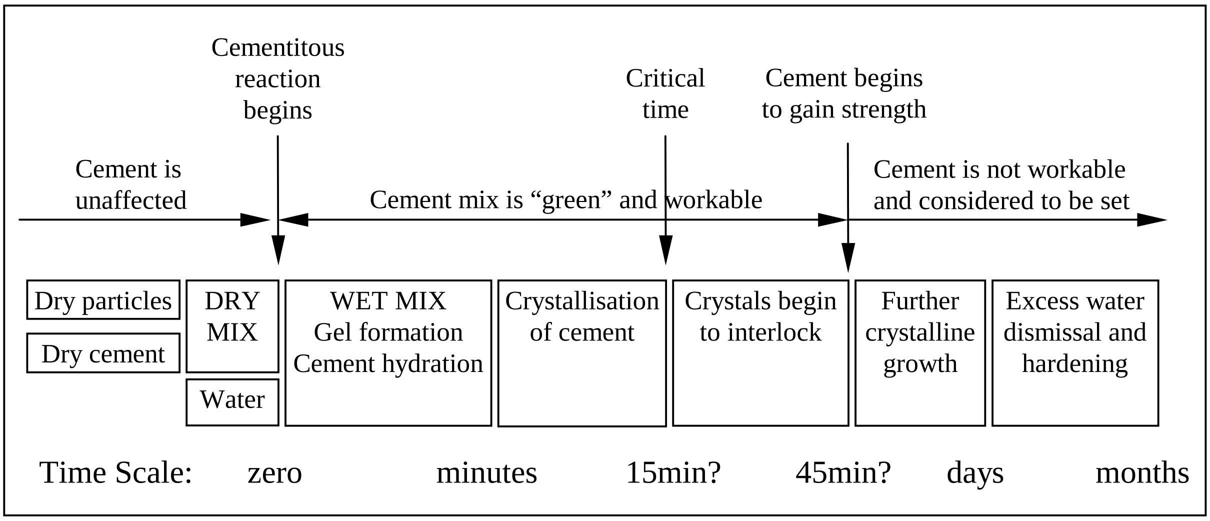
The difference between the strength available in tension and compression is suggested to be that in tension the particles are held together with relatively weak Van der Waal forces. However, in order to separate the particles in compression the forces are acting against the much stronger hydrogen bonds in the crystals that are heavily interlocked with one another. It has been suggested that the crystals do not actually bond with one another, but instead nest together giving the concrete a more mechanical bond than a chemical one. Compression intensifies this bond whereas tension opens up cracks that in turn generate stress concentrations at their ends. The final tensile strength of concrete is typically only 10% of the compressive strength and consequently if loaded in this fashion it must be reinforced with steel. For the purpose of building walls the load is almost always compressive and so this reinforcing with steel is not going to be considered further as it will be outside of the scope of this project.

The diagram below aims to help visualise the bonding process between the cement particles and the sand particles which are in turn bonded to the larger lumps of aggregate. This diagram is not to scale nor is any of the chemical changes that occur noted in diagrammatic form. It merely illustrates the particle arrangement and the presence of moisture coating the cement particles that in turn disappear leaving the strong cementitic bonds behind.



4.2 Wet strength and curing times or cycles

As mentioned above the cement mixture can still be worked up until the critical time is reached without causing a loss in the final set strength. After this point the crystallisation process begins to give the mixture a more rigid nature. The mixture has not fully set at this point, but it does have some internal cohesion as bonds are being formed. The strength of the mixture early on in the curing process is called the "wet strength" or the "green strength". Certain levels of green strength will permit the mixture to be handled in a solid form, but it will still be very fragile. Below is a time-line diagram to illustrate the setting of cement.



In the example of making blocks from concrete the mixture is placed into a mould and after a set period of time the formed block can be removed and put to one side so that the mould can be reused. The length of time that the block must be left in the mould will depend on the wet strength that is required for ejection from the mould and subsequent handling. The time to reach this point will vary depending on the speed of the cement curing and beginning the crystallisation process. This will depend on the amount of cement present, the final block density and the free-water content.

In order to maximise the green strength of the mixture one needs to ensure that the free-water content is as small as possible and to leave the mixture untouched for as long as possible to permit the cementitous action to bond the particles together. The exact length of time that is necessary to achieve this may be discovered by trial and error, but as mixture quantities and handling techniques may vary "as long as possible" may be a good initial estimate. Setting can take place in as little as 45 minutes, but useful hardening will take much longer, (Stulz & Mukerji, 1993), (p. 63). The green strength of mixed samples can be tested to give a more accurate answer, using both destructive, i.e. compressive tests, or non-destructive, i.e. scratch tests, to determine the approximate green strength of the formed mixture.

It may be possible to put the mixture through a series of curing cycles to achieve a greater overall strength over a longer period of time. The initial curing time may only be sufficient to manipulate the formed mixture and place it in its final position, in a wall for example. Further cycles of wetting and drying could then encourage any unhydrated cement particles to become hydrated and cure within the finished product. This is of particular interest where the cement content, and therefore the water content, is very low. This low water content may be able to hydrate all the cement, if given time to do so, but evaporation takes over and takes away the moisture before the cement has had a chance to hydrate properly.

The amount of hydration that is necessary to achieve the desired strength is another point in question. Tests done by Grun (Lea, 1970), (p. 268) have been done that illustrate that even after a cement sample has fully cured, it can be broken up again and rehydrated and encouraged to cure again. This evidence strongly suggests that all the cement is not hydrated in the first setting period. Therefore, in order to achieve a desired strength, in the long term, complete hydration could theoretically occur over a period of time ranging from weeks to even years depending on the circumstances.

As concrete is porous when set it would still be able to receive moisture into the surface and permit further hydration of the unhydrated cement particles. What increase in strength this would give is not clear as the porosity itself is a weakening factor due to the voids present between particles. These voids provide no structural strength and the re-hydration will only help the overall strength if has the potential of filling some of these voids with cementitic crystals. Although this is perfectly plausible, how effective it is in practice is unclear.

4.3 Moisture dismissal and shrinkage

The moisture content of a cement mixture is of great importance, primarily because too little water will cause insufficient cement hydration, and too much water will reduce the final set strength. Keeping the right moisture content during the mixing and forming stage would therefore be quite important to monitor and control, if possible. This is especially true in hot climates where the moisture content will drop rapidly if left in the environment unmonitored and uncontrolled.

In order to ensure that the cement goes through a complete hydration process, and maximising final strength, the water content needs to be minimised, whilst also preventing the existing moisture from escaping. In practice this has been done in two ways. Once the initial cement has set the formed mixture can be submersed in water during the hardening process. This guarantees that there is sufficient water present for the cement to hydrate, but since the immersion occurs after initial setting, the extra water present will not affect particle intimacy and jeopardise the final strength of the formed mixture. The other, simpler, method is to keep the formed mixture in an environment with a 100% humidity. This prevents water within the block from escaping to the surface too quickly as the surface evaporation will be almost non-existent in an environment with a 100% humidity. In practice this too can be difficult and so a compromise of sprinkling water over the formed mixture repeatedly during the hardening process helps to minimise internal moisture from evaporating too quickly.

We have already discussed the movement of water through the mixture during the curing process by mechanisms of evaporation and capillary action. What now needs looking at is the effect that this moisture movement has on the finished article. By inspection the limiting factors for shrinkage are the amount of excess water present and consequently the voids that it leaves behind, and the overall density of the mixture prior to curing.

To minimise shrinkage one must minimise the potential space between particles in the mixture. Clearly the sand and aggregate particles themselves do not shrink, and similarly the cement and formed cementitic crystals are not prone to shrinkage. This leaves the physical gaps between adjoining particles and the gaps left by excess water when it has evaporated off, being the primary cause for potential shrinkage.

The problems associated with shrinkage are mainly to do with uneven shrinkage and different relative amounts of shrinkage. If every mixture shrunk in exactly the same way and by the same amount each time, then it could be accounted for and there would be no problem. In practice the shrinkage is often uneven, due to insufficient mixing or uneven drying. The desired form into which the cement mix was placed will not be the same as what is finally achieved after the hardening process is finished, and this may not completely finish for many months.

The amount of potential shrinkage is not insignificant either. Gessner discovered that using a pure OPC-water mixture a volumetric change of over 6% could be noted in the 28 day curing time, (Lea, 1970), (p. 269). The cement samples that were used had quite a high water content using three parts cement to one part water. Previous suggestions were that the ratio should be closer to four to one or four and a half to one instead of the three to one that Gessner used. This could partially account for the high shrinkage, and a better cement to water ratio may yield much better shrinkage results, never-the-less, it does illustrate the significance of potential shrinkage that may occur during curing. As we will see later, this potential shrinkage is a considerable nuisance when trying to build structures with many slightly different formed cement mixtures.

4.4 Strength testing

The strength of a concrete structure is limited by one of two factors. Simply speaking, either the bond between the cement and the aggregate fails (cement matrix failure), or the aggregate itself fails and shears along existing fault lines within the material. Usually the former occurs because the aggregate has a higher crushing strength than cement, (Akroyd, 1962), (p. 85). A stronger bond between the cement and aggregate can be achieved if the aggregate is angular and clean, which has already been recommended earlier in this report.

The final set strength of a concrete mix is directly proportional to the water/cement ratio, provided that the workable concrete is compacted so that it contain less than 1% by volume of air voids. This relationship can be expressed as $S = A/B^x$, where S is the compressive strength, x is the water/cement ratio, and A and B are constants determined by the materials used and the conditions of the test. The table below, based on (Lea, 1970), (p. 392), shows how the water/cement ratio affects the strength of the concrete after different periods of curing.

The influence of water content on the strength of a 1:2:4 concrete based on Lea, Table 59.

TABLE 59

Water/cement ratio	Compressive strength (MPa) 3 days	7 days	28 days	90 days
0.5	16.55	24.82	35.85	48.27
0.6	11.72	18.62	28.96	37.92
0.7	7.58	13.79	21.37	29.65
0.8	4.83	10.34	17.24	24.13

4.5 Longevity, environmental attack

Well-made concrete using quality ingredients is usually considered to be a building material of a very high standard. Such concrete has a very high resistance to environmental attack of any kind, apart from major natural disasters of course. Consequently as a building material it can in theory last for a very long period of time. There are of course certain chemicals that will cause slow deterioration of finished concrete, but most of these can be ignored as their occurrence would be so improbable in wall construction that they are not worth considering. (Akroyd, 1962), (p. 247-250), gives a list of such chemicals; Carbon dioxide, Chloride, Chlorine, Chromium salts, Detergents, Fatty oils, Formaldehyde, Fruit juices and sugars, Gypsum, Hydrogen sulphide, Inorganic acids, Lactic acid, Lead, Oils, Organic acids, Salt for de-icing and Water.

Two of the above chemicals stand out as being strange in a list of things harmful to concrete; gypsum and water. Gypsum is an additive used in making cement, but it is also a sulphate and all sulphates attack concrete, so it must be included in the list. Water itself is not harmful to cement, but water often carries with it harmful salts and sulphates and these are what cause the problem. In extremes of temperature change, where frost and freezing occur water can pose a problem if the porosity of the concrete is high. If water is permitted to penetrate the surface of the concrete and this is subsequently frozen it will expand can cause damage to the concrete. This damage may occur superficially as spalling or it may cause deep internal cracking that is much more severe. These cases are worth considering generally, but for the purposes of this project such extremes are not going to be considered.

5. Application of cement to stabilise soil

By now we have a better understanding of the way that cement bonds with itself and other particles in making concrete. We also know some of the important guidelines that need to be followed when making successful mixes of concrete. Furthermore, many of these guidelines can be followed when applying the same principles to mixing cement with soil as this chapter will set about to illustrate.

5.1 Basic requirements of soil

According to the ideal specifications given by the United Nations, in “Soil-cement: Its use in Building, (1964)”, as quoted by (Gooding, 1993), (p. 263), the best soil composition for soil-cement is as follows; 75% sand, 25% silt and clay, of which more than 10% is clay. This composition will yield a sandcrete product if mixed with cement and will exhibit good structural characteristics. Unfortunately, soil with these exact characteristics will not be found easily near every potential building site and so one of two things must be done. Either the soil is tested and the required parts added to make the ideal soil, or a compromise is made and a slightly higher percentage of cement is used to ensure a satisfactory outcome whatever the type of soil is used.

Unfortunately, there is an underlying problem with randomly mixing cement with any type of soil, and it is to do with the clay fraction of the soil. Clay consists of the finest particles in the soil and can, in same way that cement does, coat the other particles when mixed with water and cause a significant cohesion after the mixture is dried. Indeed this is how the majority of earth bricks are made today. Clayey soil is mixed with water, formed in moulds, ejected and left to dry in the sun. The clay in the soil has to be protected from getting wet again, as moisture will drive the clay particles apart and cause considerable material breakdown. To do this, these formed bricks can be fired, or be placed into a structure and protected from the elements with some form of paint or render, an effective damp-course and an effective roof.

Clay and cement will work against one another if the quantities are not carefully monitored. Too much clay will result in the cement not coating all the particles sufficiently and subsequent wetting will cause expansion of the formed mixture breaking apart the cement crystals and causing breakdown. [Remember,] Cement is not strong in tension and the expansion of the clay particles cause internal expansion working against the weaker of the cementitous bonds. Also because clay is so very small (0.002 - 0mm) it is difficult for the cement to successfully coat the clay particles. Therefore, let us assume that a high composition of clay in a soil that is to be stabilised with a very small quantity of cement, makes it unacceptable.

According to (Norton, 1997), (p. 16), a suitable particle size distribution for building with earth is:

Sand/fine gravel	40 - 75%
Silt	10 - 30%
Clay	15 - 30%

The values may of course need to be more closely defined for soil-cement, and it may be the case that the clay fraction is the critical quantity. Clays can be removed from soils by washlines. However washlines may be impractical in the field because of the large amounts of water necessary and another source of soil may have to be found. Sieving the soil can also separate out the larger grains but this is also time consuming and labour intensive. Soil sieving may only be practical for removing large particles such as coarse gravel, (over 20 mm in size).

Particles within the soil will generally be rounded due to the natural environment that the soil is being excavated from. Secondary crushing techniques are assumed not to be used in developing countries because of the high cost of the complex and heavy duty machinery required to crush large aggregate into smaller angular particles. The extraction and breaking up of soil clumps will be enough of a labour intensive exercise, without having to further crush rocks up into smaller angular pieces. For the purposes of soil-cement building materials any particles over 20 mm are considered too large and should be discarded. Thus we will normally be working with soils having rounded particles in the size range clay to fine gravel.

5.2 Particle, particle interaction/intimacy

The main source of soil will be to dig it out of the ground. It will therefore be removed in dense clumps which will have to be broken up and have the cement thoroughly mixed into it. This process of breaking up the clumps will lower the overall density of the soil and reduce the particle intimacy. This will need to be reversed after the cement is mixed into the soil to ensure maximum strength and minimum porosity.

We have described already the necessity of keeping the particles closer together in the previous chapter, and also the consistency of particle intimacy throughout the mix. Keeping particles close together reduces the air voids present in a soil mixture and will generate two distinct benefits. Firstly the closer particle interaction will help to ensure good bonds between the cement and the particles, and secondly the porosity of the mixture will decrease leading to reduced levels of water penetration.

It is intended that the soil samples will be compacted by impact and this requires a degree of workability within the soil and compatible with a high speed of production. Good workability is desirable as the particles will need to "flow" past each other to achieve a uniform density through the compacted sample. Workability is determined by particle shape and the moisture content, the former depends on the soil and the latter we want to keep as low as possible.

The time between mixing in the cement and water and the final finishing impact could be the most crucial factor in compacting the mixture. One hardly wants to be breaking the cementitious bonds through the impacting process and therefore the compacting of the mixture should take place before the mixture passes the critical time. In order to achieve this, the time taken for the mixture to reach the critical time in different circumstances will need to be determined. More practically, this will probably lead to a small batch production of the cement mix so that it can be quickly compacted into finished stabilised blocks.

5.3 The curing process re-applied

The curing of the cement within the soil needs to take place in the same way that it would in a well mixed batch of concrete. Before adding moisture and allowing the curing process to begin, there should be a good particle size distribution and all the particles in the mixture should be closely packed with one another and the cement. The theory behind the bonding of the hydrated cement crystals is exactly the same with soil as it is with concrete additives. Upon the addition of water the crystals form and grow to interlock with one another leading to a high compressive strength. Full strength will not be reached for many weeks and to help the cement hydrate fully the finished mixture should be kept in a 100% humidity environment for the curing period.

5.4 Moisture attack

Most soils contain a fraction of clay as a part of their overall composition. Clay is the finest of the soil particles and can actually bond other particles together if sufficient clay and moisture is present. Clay has a very large volumetric expansion when water is added. If the moisture in unstabilised soil increases, swelling occurs. Conversely, drying causes shrinkage and therefore danger of cracking. This process leads to the breakdown of the soil and internal strength is lost making the material useless for building construction.

The balance of clay with respect to the other fractions is quite important. On one hand clay helps bond particles together, yet if another stabilising medium is not applied the clay can be instrumental in driving the particles apart should the material get wet. The common practice of firing clay bricks converts a loose particulate material into a solid ceramic. These fired bricks are no longer affected by moisture and although a modest level of porosity is still present, sustained contact with water is not detrimental to the integrity of the brick. Firing of the brick uses a great deal of energy, which either means using large quantities of firewood for small scale manufacture, or consuming fossil fuels in large-scale dedicated tunnel furnaces. The manufacture of cement also uses a large amount of energy, but that can be done away from the building site and the finished product can be delivered to where the structure needs to be erected.

6. Conclusions and recommendations for further work

Cement as a stabilising medium can be very effective if used properly. Appropriate particle size distribution, thorough mixing and maintenance of optimum moisture levels will yield a successful mix with maximum final set strength. A compromise in any of the above will result in a reduction in strength of the finished product. However final set strength is not the only requirement of a cement, adequate workability and adequate (if low) strength prior to curing are two others. These other requirements often conflict with the maximisation of final strength – for example by calling for a higher clay content.

A suitable soil can be considered to be one that has no organic material, has a clay content between 10% and 20% and has a fair range of well distributed particle sizes up to a maximum of 20mm in diameter. The moisture of the soil-cement mixture needs to be carefully controlled. There needs to be sufficient moisture for the cement to fully hydrate but no excess of water which would reduce the final density, increase porosity and reduce final strength.

The dry soil is to be mixed with the cement and the required water added. The mixture then needs to be formed and left in a 100% humidity environment within 30 to 45 minutes of mixing the cement and soil with the water. This is to ensure that the cement has sufficient water to hydrate and also that the mixture is not manipulated again after the critical time.

Curing of the mixture takes several weeks, but the green strength of the material must be sufficient to remove the formed material, handle it and perhaps even directly place it into a structure. Multi-stage curing may be possible, but the re-application of moisture may cause surface cracking and the extent of this needs to be further investigated.

Topics for further investigation

- A more detailed account of the interaction between cement and clay and why too much clay in the mixture is detrimental to the effectiveness of the cement.
- A brief study of the effect of multi-stage curing or wetting cycles on cement stabilised soil. Is an environment of 100% humidity totally necessary? or can a series of wetting cycles be just as adequate?
- How critical is the moisture content for dynamic compaction? Can a drier mix of soil can be compacted by this method better than quasi-staticly compressed soil-cement?
- If a much drier soil is used for compacting, can wetting after compacting encourage further cement particles to hydrate and hence increase the overall strength?

These questions and more will hopefully be answered later on in the project after further investigation into the available literature and perhaps after some experimental analysis of some of the interesting characteristics of soil-cement.

7. Summary

The subject of how cement stabilises soil has not been exhaustively investigated and documented during this report. However, what has been achieved is a broad understanding of the simple processes and requirements of the technique of using cement to stabilise soil. By investigating the literature available on how concrete is made, we are able to make general statements on how to stabilise soil effectively using cement as a stabiliser.

The investigation has revealed that many different factors are responsible for ensuring a good bond between the cement and the particles mixed within it. These requirements not only affect the components of the mixture used, how it is prepared, delivered into its final state, but also subsequent curing times and environmental conditions of the finished product.

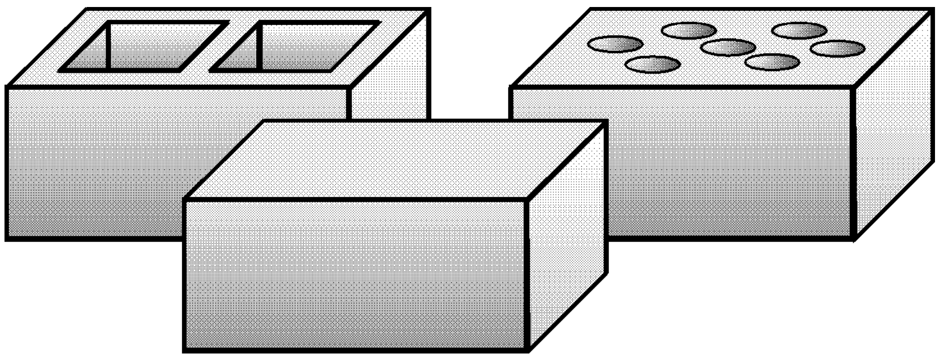
Stabilised Soil Research Progress Report
SSRPR03



Physical characteristics of soils that encourage SSB breakdown during moisture attack

Author: Mr D E Montgomery
November 1998

E-mail: d.e.montgomery@warwick.ac.uk

These reports cover 'work in progress' by research students in the Development Technology Unit (DTU) of the School of Engineering at Warwick University. Their primary purpose is internal - a format for recording ideas and data in a way that allows them to be better discussed before their incorporation into theses, DTU Working Papers or external publications. However they also have a secondary purpose, that of facilitating the sharing of our research with other innovators in the field of building with stabilised soil. Each report, after some initial internal discussion and refining will be posted as a title and synopsis on the DTU web pages (home page= http://www.eng.warwick.ac.uk/dtu). Full copies can be obtained from the respective named authors.

A dedication to someone special

Sometimes at the beginning of a publication one finds a dedication to a certain person or member of the family who has been an influence in the author's life either in general or specifically in generating the work in question. There is one person in my life that immediately springs to mind who is worthy of such a dedication. Furthermore, my experience with this person is not unique as millions of others have found him to be a great inspiration, comfort, guide and friend. "What's his name?" you may be asking yourself and, "Why haven't I heard of this incredibly influential person". The sad thing is that you probably have, but you have never accepted him as such or welcomed him into your heart and life. Well, now you have an opportunity to do just that. Please read on.

The man's name is Jesus and although he was born nearly 2000 years ago his testimony still remains and his power to save is just as great. "Save from what?" you may ask, sin and the consequences thereof, or more specifically, your sins and the consequences you face when you die. As humans we demand justice to be done, and justice will be done, but on a perfect scale and to a perfect standard. That leaves us all falling short and without hope when we come face to face with a holy God. But, God in his great love towards us send his only begotten Son into the world that the world through him might be saved. Jesus Christ died for you so that you would not have to be punished for what you have done wrong. You can be spared eternal punishment in hell and enjoy love and peace in the presence of God forever. Today the choice is yours. Reject God's free gift of love at your peril, accept it and who knows you too may have the joy of writing a dedication such as this someday. Please ponder the verses below and make your choice carefully, it will be the most important decision you ever make.

"*For by grace are ye saved through faith; and that not of yourselves: it is the gift of God: not of works, lest any man should boast.*" Ephesians 2:8,9.

"*For God so loved the world, that he gave his only begotten Son, that whosoever believeth in him should not perish, but have everlasting life.*" John 3:16.

"*For whosoever shall call upon the name of the Lord shall be saved.*" Romans 10:13

"*He that believeth on him is not condemned: be he that believeth not is condemned already, because he hath not believed in the name of the only begotten Son of God.*" John 3:18.

"*Jesus saith unto him, I am the way, the truth, and the life: no man commeth unto the Father, but by me.*" John 14:6.

Abstract

Soil is the major component of a stabilised soil block and consequently its properties are of great interest to the Stabilised Soil Block (SSB) manufacturer. Some soils are considered to be unsuitable for manufacturing SSB’s and need to be modified or discarded, whilst satisfactory soils have certain physical characteristics that can be generally suggested. The soil properties that have been found to yield satisfactory SSB’s are only a small selection of the wide range of different soil characteristics. The properties of the soil used will partly determine the way it performs under moisture attack. Other factors such as the forming technique and any stabilisation process applied will also affect the performance of the SSB during moisture attack.

The general characteristics of soil are listed in this report and special emphasis is placed on those that are known to cause detrimental effects to the SSB’s during moisture attack. If the poorer characteristics of the soil can be isolated and rectified by some means, then the result will be an enhanced product with better qualities. Those factors that cause expansion on wetting are the ones that prove to be the most negative of the characteristics. Those can be isolated into three parts, the presence of a clay fraction, the presence of porosity and the presence of moisture movement. Only with all three parts present will expansion occur and the removal or minimising of any of them will result in the removal or minimising of potential expansion of the SSB. How this can be done is the matter for another study.

Nomenclature

Aggregate: Pieces of crushed stone, gravel, etc. used in making concrete.

Brick: An object (usually of fired clay) used in construction, usually of retangular shape, whose largest dimension does not exceed 300mm.

Block: A larger type of brick not necessarily made of fired clay, but stabilised in some way, sometimes with central cores removed to reduce the weight.

Cement: Ordinary Portland Cement (OPC).

Clay: The finest of the particles found in soil, usually of less than 0.002mm in size and possesses significant cohesive properties.

Concrete: The finished form of a mixture of cement, sand, aggregate and water.

Dynamic Compaction: A process that densifies soil by applying a series of impact blows to it.

Fines: General category of silts and clays.

Gravel: A mixture of rock particles ranging from 2mm to 60 mm in diameter.

Green: Describing the state of material containing cement and water before it reaches the critical time, after which further plastic deformation hinders the final set strength.

Permeability: Describing a material that permits a liquid or gaseous substance to travel through the material.

Porosity: A measure of the void volume as a percentage of the total material volume.

Sand: A mixture of rock particles ranging from 0.06mm to 2 mm in diameter.

Silt: Moderately fine particles of rock from 0.002mm to 0.06mm in size.

Soil: Material found on the surface of the earth not bigger than 20mm in size, not including rocks and boulders and predominantly non-organic. If soil is to be used for building material it must not contain any organic material and it can be a natural selection of particles or a mixture of different soils to attain a more suitable particle distribution.

Stabilised soil: Soil which has been stabilised (treated to improve structural characteristics) by using one or more of the following stabilisation techniques: mechanical, chemical and physical.

Table of Contents

1. Introduction

Of the 29% of the earth's surface that is not covered with water, the vast majority has a soil layer on top of the underlying rock. It is this soil that supports life, man and his structures and will be the main focus of this report. Soil is a general term for particles formed by the gradual wearing away of parent rock material that is then deposited into layers onto the surface of the earth. The parent material of the rock from which the soil has been formed will largely define the composition of the soil present.

Between the top layer of soil and the rock structure there is usually a series of bands that each contain a soil with slightly different characteristics. The very top layer of soil usually contains organic material from the vegetation that has fallen to the ground and is slowly breaking down. Under this layer, one can find a mixture of organic material and small soil particles or "fines". The particle size grows as one digs deeper until the rock structure is reached. Size distribution in the soil is approximately dependent on depth. Larger particles dominate lower levels whilst finer particles the upper levels.

The basic composition of all of these layers may be the same as the underlying rock. Alternatively, material from elsewhere could have been deposited there by natural means, causing a different composition of the top layers to the bottom ones. Glaciation, floods and volcanic activity are some mechanisms through which soil from another area may be deposited locally. The composition of the small particles (sands) found in soil can generally be assessed as minerals that are silicas, silicates or limestones. As well as the solid rock particles and fragments, soil will have a proportion of water and air that fill the gaps between adjoining particles in the soil. This gives natural soil a non-homogenous and porous characteristic.

Soil that is used for building can undergo detrimental physical changes when it becomes wet. Soil will swell and contract when the water content changes and this usually leads to cracks forming in the structure. These physical changes are dependent on the characteristics of the soil both before and after processing to make the building material. The characteristics of the soil that cause these physical changes are the ones that are going to be investigated in this report. The majority of these physical changes are due to the presence off very small particles called clays. Clays perform a valuable function in the production of building blocks, but they can have a detrimental effect on the stability of the material if they get wet.

Clay is necessary to achieve sufficient green strength in a freshly formed block to enable de-moulding and handling without excessive breakage. The low moisture content and the clay particles act as a bonding agent throughout the mixture of other particles before any chemical stabilisation process has had a chance to occur. In the example of using cement as a stabiliser, a considerable period of time must pass before there is any significant gain in strength offered by the cement. A partnership of the clay and cement must be entertained, but their proportions need to be carefully monitored so that the clay gives sufficient initial strength and yet does not blind the cement particles or provoke excessive material expansion upon wetting.

2. Characteristics of soils

During this chapter the author will outline some properties of soil. These properties will include particle composition, shape, size and surface texture, some of which have standards for defining them. Ranges of values for these properties will be suggested but the basic techniques for discovering the properties of a soil sample will be described in a later chapter. This chapter will provide a summary of the characteristics that are possible to determine from a sample of soil.

2.1 Physical

Some of the physical characteristics that could be used to define soil particles are: colour, size, shape, surface texture, density and specific surface area. The variety of physical characteristics of soil particles that can be found is considered to be virtually infinite. The analysis of some of these characteristics can been done using a simple set of field tests and personal interpretation, or, more complex and accurate tests can be carried out in the laboratory. Systems for identifying some major characteristics have been developed to define different ranges of soil characteristics. The most common of these is the size distribution of the soil particles. Below is a list of physical characteristics than can define a sample of soil. See (Houben & Guillaud, 1989), (p. 30,31) for more details.

Colour: Can range from white through to black with shades of tan, brown, red, grey and even blue and green. This is however an arbitrary and trivial description that is not standardised and based entirely on personal interpretation. Good for quick visual identification and can even suggest chemical composition of the soil, but accurate measurement is not defined.

Shape: Broadly defined as three different categories; angular, sub-angular or rounded. This can be assessed using visual interpretation and/or the feel of the soil. Only used as a general descriptive term, as accurate measurement is not a viable option. The ratio of particle surface area to the surface area of a sphere of the same mass can be an indication of shape and is defined as:

$$\lambda = \frac{Surface\_area\_of\_particle}{Surface\_area\_of\_sphere}$$

Where: Rounded – $1 < \lambda < 1.2$

Semi-Angular – $1.2 < \lambda < 1.5$

Angular – $1.5 < \lambda$

Note: a four faced pyramid has λ value of 1.49.

Apparent bulk density: This is a measurement of the overall density of the soil sample including air and/or moisture present within the sample. The measurement of apparent bulk density is a trivial exercise, as one only needs the volume of a sample and its mass. Apparent density of a block is simply $\rho_{apparent} = \frac{M_{sample}}{V_{sample}}$ (measured in kg/m³).

Specific bulk density: Can be accurately measured following British Standard BS7755: 1998. This method splits up the soil into two sections and measures the density of the two sections in different ways. For particles smaller than 2 mm in size a small sample is placed in a pyknometer and the displaced water at a known temperature will give the volume occupied by the soil. The sample is also accurately weighed to give the mass of the sample. The specific bulk density is calculated from the mass of the sample and the displaced volume of water in like manner to the apparent bulk density. For particles over 2 mm in size the sample is weighed and is then suspended in water that is resting on a set of scales. The mass of the displaced water gives the volume for a known ambient temperature and the specific bulk density can be calculated from these two values, (also measured in kg/m³).

Size or texture: One of the most common methods of identifying the size of particles that can be found in a sample of soil is to use the British Standard BS7755: 1998 classification for particle sizes. This separates the soil into different fractions depending on physical dimensions by means of a number of different meshes and sieves. The sample of soil is passed through the largest mesh first and each subsequent mesh until all the soil has been separated off at a level appropriate to its size. For laboratory testing the soil needs to be dry and any particles deflocculated to ensure accurate results. The size ranges as defined by the British Standard along with their common names are listed below.

Trivial name	Size range in mm
Boulders	> 200
Cobbles	60 – 200
Gravel (Coarse)	20 – 60
Gravel (Medium)	6 – 20
Gravel (Fine)	2 – 6
Sand (Coarse)	0.6 – 2
Sand (Medium)	0.2 – 0.6
Sand (Fine)	0.06 – 0.2
Silt (Coarse)	0.02 – 0.06
Silt (Medium)	0.006 – 0.02
Silt (Fine)	0.002 – 0.006
Clay	< 0.002

Moisture content: Soil is very seldom totally dry, and how much moisture is present is important for determining the properties of the soil in general. Measuring this moisture content is done through a process of weighing and drying in an oven. Following British Standard BS1377: 1990 the sample must be weighed at regular intervals until the difference between consecutive weights are less than 0.1% of the whole sample mass. This usually means drying the sample for about 24 hours to ensure that it is virtually dry. The difference in mass from the initial weighing to the last weighing will be the mass of water. The moisture content is calculated as a percentage of the total mass of the sample before drying.

Porosity or voids ratio: A substance is considered porous if it has a matrix of voids throughout it. A very simple and common example of a porous object is a sponge. Soil is another such substance, but the porosity of soil can vary enormously depending on the particle size and distribution within the soil sample. To calculate the porosity of a sample of soil one needs to know both the apparent bulk density and the specific bulk density of the sample. The porosity or voids ratio is unity minus the ratio of the volume of soil alone to the volume of the sample, both of which will have been found when the apparent bulk density and the specific bulk density of the sample were measured. Porosity: $P = 1 - \frac{V_{soil}}{V_{sample}}$ (generally expressed as a percentage).

Permeability: A porous material becomes permeable when these air pockets are arranged in such a way so that a gas or fluid can pass through the substance. The permeability will largely depend on the porosity present in the sample. A sandy soil will be considered highly porous and will have a low resistance to the passage of water through it. A clayey soil is the opposite and will resist the penetration and passage of water. Permeability is a measure of how fast a fluid moves through a substance. The British Standard BS 8004:1986, (Craig, 1997), (p. 40) gives a list of coefficients of permeability and also tests for permeability that can be carried out in the laboratory. A falling head test and a constant head test are two ways that permeability can be measured. The flow of water through a sample is measured and described as a flow rate per unit of time. (Permeability of stabilised soil is too low to be measured by these means).

Effective surface area: Particles that are so small that they will pass through even the finest sieve usually have a different means of identification. This is called the effective surface area of the particles in question and is usually measured in m^2/g of material. This helps to distinguish between small and large clay particles for which any other classifications are useless. Three appropriate examples of this analysis are the three main types of clays Kaolinites, Illites and Montmorillonites that have approximate effective surface areas of $30m^2/g$, $80m^2/g$ and up to $800m^2/g$ respectively, (Houben & Guillaud, 1989), (p. 27).

Adhesion: Described as the ability of soil to stick to other objects at a given humidity. It will increase as the humidity increases up to a point after which it will then decrease as the humidity continues to rise. Of interest usually with soil sticking to metallic tools.

Specific heat capacity: Defined as the amount of energy required raising one kilogram of the soil by one degree Kelvin. Units are J/kgK, (joules/kilogram Kelvin).

Dry strength: Highly dependent on the quantity and type of clays present in the soil sample. Measured in MPa to crush (effectively describing the shear strength of the soil sample). The dry strength of clays varies from around 0.07 MPa to 7 MPa, (Craig, 1997), (p. 31).

Linear contraction: Sometimes described as the shrinkage of a particular sample. Linear contraction is highly dependent on the clay type and content and the water content. Standard shrinkage tests start with a soil at it's liquid limit. It is usually tested in a long narrow trough that is filled with moist soil and allowed to dry out. The contraction is limited to one direction and the linear quantity can be measured as either a percentage or as a ratio of overall length. The general rule is, the greater the shrinkage the greater the clay content.

2.2 Chemical

The chemical composition of the soil particles will be of interest when chemical stabilisation is taking place, or if the soil will be in an environment where the elements will be susceptible to chemical attack, (e.g. limestone is attacked by acid rain). Soil is generally a stable compound because it has been formed over a long period of time and any chemical changes will have already occurred to it in the environment. For the majority of cases the scientist can assume that soil will be chemically unaffected by the environment.

Composition: The soil particles will have roughly the same chemical composition as the parent rock from which the soil was formed. This chemical composition can range from salts or chalk composition through to iron and aluminium oxide composition. (Houben & Guillaud, 1989), (p. 36,37) gives more details on the many different types of soil that are present and their respective chemical composition.

Mineral content: Minerals present in the soil are unstable components that are being processed by the environment usually as a result of decaying organic matter. Any organic matter should be avoided and unstable components resulting from them should also be regarded as potentially detrimental to structure longevity.

Metallic oxides: Soil can contain a significant quantity of metallic oxides such that they are used to produce the metal through smelting the soil. Bauxite for aluminium and ferrous oxide for iron are two common oxides present in soils.

pH levels: Soils can be either acidic or basic in pH level, but they do not usually stray very far away from the neutral point. Their pH will depend on the H^+ and OH^- ions that are present and these ions will depend on the chemical composition of the particles themselves and their interaction with one another.

Sulphates: These are soluble compounds of elements and will be affected by changes in moisture. Leeching of soil can occur if water passes through it removing any soluble salts or substances with it. Sulphates can cause problems with cement and soils with sulphates present should be avoided if cement is being used as a stabilising medium.

3. Measuring soil characteristics

In the previous chapter many different physical and chemical characteristics of soil were defined. However, most of the processes for measuring each of those different characteristics were omitted, that will be the focus of this chapter. It is not necessary for all of the above characteristics to be determined for every soil sample taken. The relevant ones will be discussed and listed. Following this some techniques for measuring these properties will be described. Some techniques are restricted to the laboratory, whilst other are considered to be sufficiently accurate for field tests using limited equipment.

3.1 Some relevant properties for making SSB's

With so many different characteristics that one could discover about a sample of soil, it would be foolhardy to try and discover them all in every situation that soil is to be used for making SSB's. Only a small number of different characteristics are of real relevance to the scientist testing the soil. The chemical composition of the soil is of little importance once the absence of unstable compounds and organic matter has been established. The physical properties are of greater interest for making SSB's as these will help to determine its ease of mixing, forming, de-moulding, porosity, permeability, shrinkage, dry strength and apparent bulk density.

The particle size distribution or texture of the soil is a necessary characteristic to determine, as it will help the scientist to measure the sand, fines and clay content. These are necessary to ensure that the material being used falls within the parameters suggested for making SSB's. The moisture content of the soil is another critical characteristic as it affects a number of factors in SSB production. What moisture content the soil has in relation to its optimum moisture content is of great interest to the SSB manufacturer as this will help determine potential shrinkage. For soil mechanics the Optimum Moisture Content (OMC) is defined as the maximum amount of water that can be added to the sample that completely fills all the air voids present throughout the material and no more. The moisture content also has a marked effect on material workability, cement curing, drying times, de-mould slump and porosity.

Consequently the OMC for a soil may not necessarily be the optimum moisture content for stabilised soil material.

3.2 Field tests

Field-testing methods are many and varied, and will depend vastly on the judgement and previous experience of the person carrying them out. There also seems to be conflicting information about what certain tests reveal about the characteristics of the soil. Gooding noted these differences in his thesis and the summary below is largely taken from his suggestions for interpreting the results received from each test. Assuming that the exact characteristics of the soil are not necessary, these field tests will give the user a reasonable idea of the type of soil that is present.

Smell test: Detects the presence of organic material if a musty odour is sensed. Soil with organic material is unsuitable for manufacturing SSB’s and should be rejected. The organic layer usually exists on the top of the soil and can easily be removed to reveal more suitable soils underneath.

Visual-touch test: This test will determine the range of particle sizes present. A soil containing mostly large particles (over 2 mm in size) is a sandy and gravely soil, it will easily break up and run through the fingers. Such a soil has a low fines content and is unsuitable for making SSB’s. Conversely a soil containing no sand particles and only smaller particles that is hard to the touch, difficult to break up and reveals a fine powder that is difficult to wash off is classified as a soil with an excess of fines and clays. This too is unsuitable for making good SSB’s.

Thread test: If a mixture of sands and fines is present then the soil can be formed into a thread upon the addition of some water to increase its plasticity. If the thread can be rolled to a diameter of less than 3 mm then the fines content is too high and more sand will need to be added. If a thread of as little as 5 mm diameter cannot be formed then insufficient fines is present and more will need to be added. A thread that breaks up at a diameter of around 4 mm has a sufficient fines content for making SSB's.

Shine test: After the above tests have been carried out the shine test indicates the level of fines present in the sample. A mixture with a high fines content will achieve a shiny surface if scratched with the fingernail. This shiny surface is caused by a moderately high presence of silt and clay and is be acceptable for making SSB's. A dull surface finish will indicate a sandy composition with a low fine content and this is also suitable for SSB production.

Glass-jar test: This test will give the investigator a rough idea of what percentage of each fraction is present in the soil sample. The test requires a glass straight-sided jar to be a quarter or a third filled with soil and the remainder filled with water. The jar is then sealed and rotated end over end for several minutes to ensure that all the particles have been broken up and held in suspension within the water. The jar is then placed on a flat surface and left undisturbed for some time. A cloudy mist of very fine particles may stay in the solution indefinitely, held there by Brownian motion, but these are only particles less than 0.0002 mm, (Craig, 1997, p. 7) and can be ignored. All the other fractions should have settled to the bottom within a few days and should be easily distinguishable from one another. A sandy layer should be present at the bottom with smaller particles at higher levels. The particles in suspension fall out of solution according to Stokes' law, which states the larger the particle size the faster the decent velocity and vice versa, (Craig, 1997, p. 6). The clay and silt fractions may not be distinguishable from one another and these can often be combined to yield a simple coarse to fines ratio for the soil sample. The quantity of the different fractions can be found by measuring the depth of particles within each fraction and calculating each fraction as a percentage of the whole settled depth.

A basic analysis of the results found from the glass-jar test can be summarised as follows:

- More than 80% sand and gravel (if present) indicates very low fines content and is considered unsuitable for making SSB's.
- Between 70 – 80% sand shows a low fines content and can be used for SSB's.

- Between 50 – 70% sand shows a high fines content and can also be used for SSB's.
- Less than 50% sand indicates very high fines content and should not be used for manufacturing SSB's.

Shrinkage test: A mould of dimensions 40 × 40 × 600 mm is filled with soil near its liquid limit, (the point at which the soil passes from a solid state to a liquid state). This soil is then left to dry out slowly. The mould walls are treated with grease or a lubricant so that as the bar of soil shrinks in size it slides along the mould walls. The difference between the initial length and the final length is the linear shrinkage. This is usually represented as a percentage of the original length.

All the above field-tests it can be done on a relatively short period of time with simple equipment. The interpretation of the results is where the inconsistencies can arise, especially between different field scientists. Nevertheless these tests are sufficient as a preliminary check for initial analysis and use for even medium-sized projects. Small projects would be classified as the building of one or two dwellings undertaken by an individual or family. Larger projects would have significant funding and could justify further tests to establish soil characteristics more accurately.

3.3 Laboratory tests

The larger projects that require more careful analysis of the soil properties will find that field tests will be insufficient and laboratory testing will need to compliment these to ensure an accurate analysis of the soil present. Testing is usually only justified if a very large amount of soil will be used and an area of land is being surveyed for excavation. The survey will reveal the different properties of the soil in different locations and will help to direct the SSB manufacturer to the best source of soil for making the SSB's. Below is a list of characteristics and the methods for accurately measuring those properties.

Particle distribution: Accurate measurement of the particle distribution has already been hinted at in chapter two, where the particle size distribution or texture of the soil was defined as a physical characteristic of soil. British Standard BS7755: 1998 classification for particle sizes describes a process that separates the soil into different fractions depending on physical dimensions by means of a number of different meshes and sieves. The exact method of this should be referenced from the British Standard as such standards are updated regularly, or its local or national equivalent.

Apparent and specific density: If these two values for the soil are known then the porosity can be measured. Measuring the apparent density is straightforward as only the overall volume and dry mass is required of the soil sample. The water must be removed from the sample before weighing as it will add to the overall mass of the soil and give an inaccurate density of the soil and air mixture. Suggested measurements and calculations are as follows:

Volume of undisturbed soil sample (including air voids that may be partially filled with water) = V

Mass of dried soil sample = M

Apparent Density $\rho_{app} = \dfrac{M}{V}$

The specific density has to be measured in accordance with British Standard BS775:1998 and again this should be referenced to include current changes and modifications.

Porosity/permeability: In simple terms the volume of dispersed air voids within a sample is proportional to the porosity. Porosity can be easily calculated from the specific and apparent bulk densities of the soil sample if they are known. The porosity can be calculated both before and after processing of the soil.

Permeability can be measured as a function of the flow rate of a fluid through a porous substance. Darcy’s empirical law defines the permeability of soil, but this is only limited to one dimensional flow of water through a fully saturated soil, (Craig, 1997), (p. 39).

Darcy's law states: $q = Aki$

where q = the volume of water flowing per unit of time, A = cross-sectional area of the soil corresponding to the flow q, k is the co-efficient of permeability and i is the hydraulic gradient.

Darcy's law can also be written as:

$$v = \frac{q}{A} = ki$$

where v is the discharge velocity of the water through the soil.

4. Effect of moisture on soils

The fundamental problem with building with soil is that it will lose compressive strength when it becomes wet. This is not a desirable characteristic for walls supporting a roof structure with inhabitants underneath it. Consequently it is the responsibility of the designer to ensure that either the weakening effect that moisture has on the soil is greatly reduced, or the possibility of the soil getting wet is removed. For building with soil where there is little or no rain, then the problem is negligible, but for wetter climates it is a serious concern. Techniques used in the past to overcome the problems of building with soil in wet climates have included mechanical and chemical soil stabilisation, wall painting or rendering and use of wide roof eaves.

4.1 Detrimental characteristics

It is important to isolate the characteristics that are most useful for the SSB manufacturer to know about the soil that is being worked with, so that they can be closely monitored. These are usually the characteristics that greatly affect the resistance of the soil to moisture attack. Below is a list of these poor characteristics and how they might be improved for general use.

High porosity/permeability: These are two characteristics of soil that can cause the potential swelling and cracking that is so detrimental to SSB's durability. No matter how much clay is present, if water cannot penetrate then the clay will not swell and integrity can be preserved. Render or paint will provide such protection, but only at significant cost and regular maintenance is always required. A high porosity will permit moisture to penetrate the surface of the block and then subsequently flow into the internal structure of the soil particles distributing moisture to other soil particles. This process causes water to coat the soil particles and by the process of surface tension drive neighbouring particles further apart. This mechanism is particularly severe with the clay fraction of the soil. Reducing the porosity can be achieved by compacting the soil and therefore increasing its apparent bulk density. Porosity of the soil itself can never be reduced to zero, but a significant improvement to the resistance of moisture penetration can result through compaction.

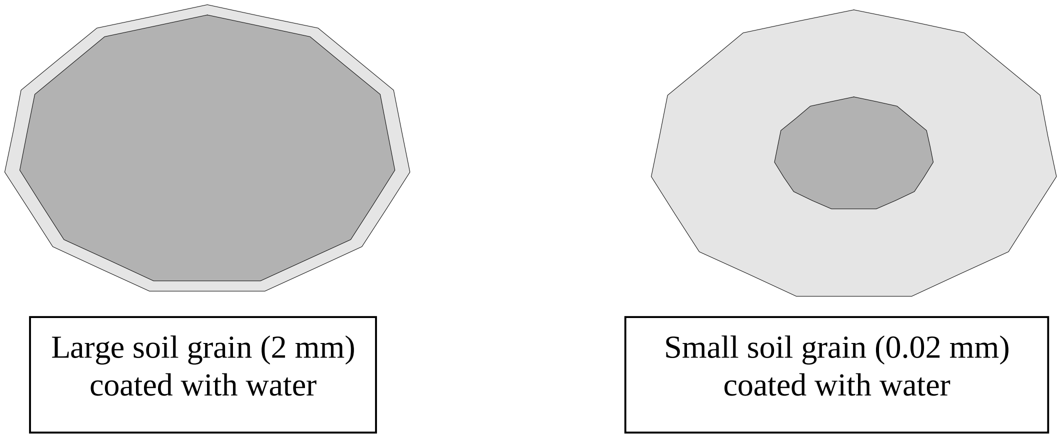
A very high level of porosity in the finished block will mean that the structure will no longer be able to keep out the elements, such as wind, rain and temperature variation. Clearly this is undesirable, as these are some of the most basic functions of a dwelling. As porosity cannot be removed completely from a basic building material such as soil, the level of porosity that is acceptable or even desirable needs to be identified. Taking the other extreme, in a hermetically sealed dwelling, there is no potential for the passage of air or moisture from the inside of the dwelling to the outside world. This is also unacceptable as humidity and oxygen levels from respiration will make the living space uncomfortable. A balance between the two extremes needs to be rationalised.

A major factor that would concern a dwelling designer is the time taken for the building material to respond to changes in climate both inside and outside the dwelling. For example, if outside has a very high humidity and the inside is kept comfortably dry, how long will it take (assuming the conditions are sustained until equilibrium is reached) for the inside of the wall to have the same characteristics as the outside. Perhaps a better analogy is using one of heat. If the outside temperature is 10°C and the inside temperature is 20°C then there is a thermal gradient of 10° between the internal and external faces of the wall. The thermal gradient exists because the wall possesses a thermal resistance and the internal temperature is being sustained by a heat source. If that heat source was removed the temperature of the wall would equalise and the gradient would be reduced to zero. The same principle can be applied to the moisture content of the wall. If the outside is wet due to rain, and the wall is porous then the moisture will migrate to the inside face of the wall saturating the wall. Ensuring that the internal face of a wall can remain dry and the wall itself can survive a 50-year storm would not be an unreasonable request for the average homeowner.

Depth of moisture penetration is another consideration that would concern the SSB builder as a small degree of penetration can be tolerated, but deeper penetration may be unacceptable in the long term. Moisture ingress affects the strength of SSB's but the effect on strength is usually not so significant to cause collapse. A more common mode of failure is spalling of the surface of the blocks as moisture has penetrated, caused expansion and subsequent contraction and cracks have occurred. These cracks permit further moisture penetration and cause more expansion and cracking to occur. These cracks if permitted to continue begin to jeopardise the integrity of the block surface initially and then the structural strength of the block itself. Over time the surface of the block falls away permitting deeper moisture penetration and progressive destruction of the block.

High fines/clay content: The smallest of the particles in the soil are the ones that exhibit the greatest expansion when they become wet. If there is a high percentage of this fraction of soil then the potential expansion will be significant as more particles become coated with water and drive neighbouring particles apart. There are two remedies for the effect of this type of soil, firstly to reduce the fines/clay content by mixing in coarser grains, or to add a stabiliser such as cement in such high quantities that the particles are restrained from moving when water is added. Both will work in practice, but the latter is an expensive exercise and the former should be attempted if possible.

The larger sized fractions of soil are generally unaffected by moisture. They will gain a thin film of water on their surface, but this will be small compared to the grain size. The smaller grain fractions achieve a similar thin film of water on their surface that is of the same order or magnitude or bigger than the grain size. The diagram below illustrates this phenomenon.



The Large soil grains will be coated with a thin layer of water, but this will not increase the size of the particle significantly. If thicker layers of water tried to coat the particle gravity would begin to have an effect and excess water would drip off the bottom of the grain. The surface tension that holds the water onto the grain surface will not be strong enough to create pore pressure that pushes other particles further away from each other. The small grains, on the other hand, will be significantly larger when coated with water and will cause a volumetric expansion of the particles. At this scale the surface tension will be strong enough to move particles further apart and to cause significant overall expansion.

High linear contraction: Again, this linear contraction is due to the presence of clays and fine particles that shrink back together when the moisture around them is removed. The contraction will also depend on the moisture content when the soil is formed and then left to dry/harden/cure. Higher initial moisture contents will result in higher overall shrinkage of the soil. Clearly reducing the initial moisture content will help to reduce initial shrinkage, but ultimately it is the clay content that will determine the amount of expansion and shrinkage. Again the shrinkage can be limited by the addition of cement to the soil. The amount of shrinkage will determine the quantity of cement that will be required to effectively stabilise the soil. As described in (International Labour Office, 1987), (p. 38-39), the cement to soil ratio is as follows for a given shrinkage as determined by the shrinkage test described in chapter 3.2.

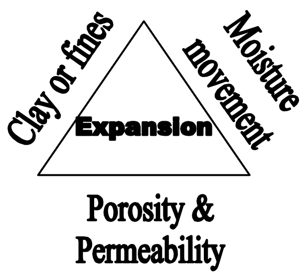
Measured Shrinkage (mm)	Cement to soil ratio
Under 15	1:18 parts (5.56%)
15 – 30	1:16 parts (6.25%)
30 – 45	1:14 parts (7.14%)
45 – 60	1:12 parts (8.33%)

Adhesion: If the soil is moist and has a high adhesion to metallic surfaces, it will cause significant problems when de-moulding. The simplest way of reducing the adhesion exhibited by the soil is to reduce the moisture content when the soil is formed in the mould.

4.2 Significance to making SSB's

The above section detailed the characteristics that the SSB manufacturer would want to avoid. In practise these characteristics are impossible to remove altogether and a compromise needs to be made somewhere along the line. This section aims to explain the effects that the above characteristics have on SSB's produced in the field.

Expansion of a SSB can only occur if three characteristics are present: Clays or fines and Porosity & Permeability and Moisture movement. If any one of those is absent then expansion and contraction will not occur, (ignoring chemical and thermal expansion and contraction). The diagram to the right illustrates the idea.



It is the job of the SSB manufacturer to minimise these characteristics in the blocks that are being produced so that potential expansion is reduced to acceptable levels. External environmental changes will cause the moisture levels to rise and fall over time. This will not have an effect on the SSB unless the moisture levels within the SSB also change. Moisture will only be able to penetrate the SSB if porosity and permeability are present. Swelling and shrinkage will only take place if the moisture reaches a fraction of clay present within the SSB and sufficient cement is not present to resist the potential expansion offered by the clay or fines. Therefore there are three factors that want to be controlled: the clay fraction, the porosity of the material and the rate of moisture movement.

Controlling the clay fraction: Too much clay results in unacceptably high expansion upon wetting or excessive amounts of cement to combat this. Too little clay causes low adhesion between particles and hence causes high breakage rates on de-moulding of the SSB's. Either situation is unacceptable and this can only be achieved by monitoring the clay and moisture content when the soil is to be formed. How closely this has to be done to achieve satisfactory results is not clear. An optimum fines content for making SSB's was suggested by the United Nations to be about 25% of which more than 10% is clay, (Gooding, 1993), (p. 263). From the literature it is unclear how much a change of say ±5% to the clay content will have on the overall performance of the SSB.

Porosity: An ideal for the level of porosity for any type of SSB would have to be zero. Since this is a physical impossibility a small amount of porosity needs to be tolerated. The greater the porosity the more susceptible the SSB will be to the elements and more specifically, the permitting of water penetration. In certain cases it is impossible to avoid water getting onto the face of the block, e.g. blowing rain, but what must be stopped is the water penetrating into the block itself. Water in the block will cause expansion and deterioration of compressive strength unless it is compensated for with a high cement content. If the level of porosity at the surface is much less than deeper into the block then this also is an acceptable situation. If water does not penetrate the surface then it will not matter if the porosity is lower where the water does not reach as this area will be unaffected. Using steel-sided moulds and dynamic compaction give good surface finishes and will result in a slightly lower surface porosity than deeper into the SSB core.

Possible moisture penetration models:

Capillary action without differential pressure - Unknown mechanism but very effective on small pored materials.

Gravitational force pushing water into pores of SSB - Surface water on SSB pushes water into SSB through pores.

Pressure difference flow - Low pressure internally in block with high pressure outside SSB drives moisture from one side to the other.

Moisture levels: More water means more shrinkage upon drying and potentially higher adhesion to metal surfaces, but some moisture is required to keep the soil in a workable state and also to hydrate any cement particles if they are used to help in the stabilisation process. Careful control of the moisture levels is also required to ensure that the soil has adequate adhesion to itself to reduce SSB breakage upon de-moulding. If the moisture level change during the life of the SSB, then moisture movement has occurred. Initially this happens when the block is dried out after it is formed. Subsequent moisture movement should be avoided. Moisture will only be able to enter or level the block if porosity and permeability are present and these can be reduced by adjusting the particle size distribution and the apparent density of the finished block.

5. Conclusions and recommendations

The characteristics that define soil are many and varied. Defining a soil with any degree of accuracy from all the different soils present in the world is a difficult task. With such a variable substance, one can appreciate the difficulties posed to the SSB manufacturer to ensure that the soil that is chosen will be acceptable for the intended task. An even greater problem is determining what effect slight changes to the soil's texture, porosity and moisture content will have on the finished product. This is not helped by the fact that these properties will affect one another as they are sometimes inter-dependant. For example, if the moisture content is high during manufacture then there will be a higher porosity when all the moisture has been removed. If the texture is carefully controlled then this will have an effect on the porosity and apparent density.

Further analysis of how different characteristics affect one another in general should be looked into more closely. A cause and effect chart displaying all the different characteristics and how each is effected by changes in different characteristics would be very helpful. It may be possible to determine that all the different characteristics are linked mathematically and any change in one property will result in changes in a number of others. This model may have to be limited to only a few simple characteristics as the overall variability and complexity of soil may be too difficult to model with any degree of accuracy.

The mechanism through which water penetrated a block is another area where further study should be undertaken. How and why water wishes to permeate a porous substance against the forces of pressure and gravity is a question that needs to be answered. The adhesion of water to surfaces and the internal cohesion that it has with itself are major factors in the situation. How these forces can be hindered so that water is less likely to penetrate a block would be very useful to know if it is possible. Water cannot penetrate certain porous objects because the pores are too small for the water to penetrate into them. At what level this occurs and whether it can be achieved by modifying soil characteristics physically is not known at the moment and should be investigated further.

6. Summary

Some physical characteristics of soil have a major influence in the potential for expansion when it becomes wet. These can be isolated into the clay/fines fraction, the porosity/permeability and the moisture movement. Only with all three factors present will expansion occur. Monitoring the clay fraction and apparent density can be easily done using simple tests, but finding the porosity and hence the potential for moisture movement is a bit more complex. Cement will hinder expansion to a certain degree, but if the root problem can be eliminated rather than trying to constrain the effect of the problem then that would be much more advantageous.

As the SSB's will be in an environment that exhibits changes in moisture and clay is an important component of the block's composition then the only factor that can be reduced is the porosity and permeability of the SSB. The porosity cannot be reduced to zero, but there may be a point at which the SSB becomes impermeable to water. This is the desired condition and this may be achieved by monitoring the particle size and distribution, the moisture content and the apparent density of the final SSB. How exactly this can be done in practice is still open to further discussion. At least now we know the offending characteristics that cause material expansion and consequently we are better equipped to minimise their effects and to deal with their consequences.

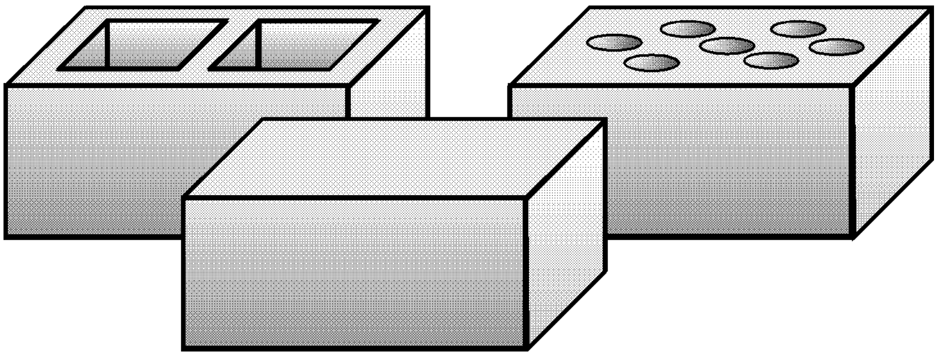
Stabilised Soil Research Progress Report
SSRPR06



Initial critique of existing papers on dynamic compaction of stabilised soil samples

Author: Mr D E Montgomery

April 1999

E-mail: esrsj@csv.warwick.ac.uk

These reports cover 'work in progress' by research students in the Development Technology Unit (DTU) of the School of Engineering at Warwick University. Their primary purpose is internal - a format for recording ideas and data in a way that allows them to be better discussed before their incorporation into theses, DTU Working Papers or external publications. However they also have a secondary purpose, that of facilitating the sharing of our research with other innovators in the field of building with stabilised soil. Each report, after some initial internal discussion and refining will be posted as a title and synopsis on the DTU web pages (home page= http://www.eng.warwick.ac.uk/dtu). Full copies can be obtained from the respective named authors.

Titles of Stabilised Soil Research Progress Reports Produced to date:

[Put printed list of current reports in place of this page.]

A dedication to someone special

Sometimes at the beginning of a publication one finds a dedication to a certain person or member of the family who has been an influence in the author's life either in general or specifically in generating the work in question. There is one person in my life that immediately springs to mind who is worthy of such a dedication. Furthermore, my experience with this person is not unique as millions of others have found him to be a great inspiration, comfort, guide and friend. "What's his name?" you may be asking yourself and, "Why haven't I heard of this incredibly influential person". The sad thing is that you probably have, but you have never accepted him as such or welcomed him into your heart and life. Well, now you have an opportunity to do just that. Please read on.

The man's name is Jesus and although he was born nearly 2000 years ago his testimony still remains and his power to save is just as great. "Save from what?" you may ask, sin and the consequences thereof, or more specifically, your sins and the consequences you face when you die. As humans we demand justice to be done, and justice will be done, but on a perfect scale and to a perfect standard. That leaves us all falling short and without hope when we come face to face with a holy God. But, God in his great love towards us send his only begotten Son into the world that the world through him might be saved. Jesus Christ died for you so that you would not have to be punished for what you have done wrong. You can be spared eternal punishment in hell and enjoy love and peace in the presence of God forever. Today the choice is yours. Reject God's free gift of love at your peril, accept it and who knows you too may have the joy of writing a dedication such as this someday. Please ponder the verses below and make your choice carefully, it will be the most important decision you ever make.

"*For by grace are ye saved through faith; and that not of yourselves: it is the gift of God: not of works, lest any man should boast.*" Ephesians 2:8,9.

"*For God so loved the world, that he gave his only begotten Son, that whosoever believeth in him should not perish, but have everlasting life.*" John 3:16.

"*For whosoever shall call upon the name of the Lord shall be saved.*" Romans 10:13

"*He that believeth on him is not condemned: be he that believeth not is condemned already, because he hath not believed in the name of the only begotten Son of God.*" John 3:18.

"*Jesus saith unto him, I am the way, the truth, and the life: no man commeth unto the Father, but by me.*" John 14:6.

Abstract

Implusion (dynamic) compaction of soil building blocks has been shown to promise certain advantages over block pressing, however previous researchers have already expressed their dismay at the general lack of information in the field of dynamic compaction of soil blocks. This paper reviews what such information is redily available. The information that is available on dynamic compaction mainly comes from the civil engineering industry from ground compaction methods. Whilst these are suitable for gaining a basic understanding of soil compaction, they are not entirely applicable to compaction of blocks confined in a mould. Modelling of the compaction process has been attempted within this field and some mathematical models are described in this report.

Dynamic compaction of soil blocks without the use of cement has been investigated to establish optimum compaction efficiencies when the energy transfer is kept constant. This has shown that between 8-32 blows gives the greatest compaction for the same total energy transfer. The research did not investigate the effect of adding cement to the compaction process, nor did it identify the moisture content to optimise dry block strength. Research done in the civil engineering industry has briefly investigated the effect of moisture on unconstrained compaction as well as the efficiency of different methods of energy transfer. These results are significant but cannot easily be applied to the research done on block compaction.

Several major gaps in the understanding of soil compaction still exist, and these need to be tackled one by one. It is of fundamental importance that thorough testing of dynamically compacted cement stabilised block be carried out in the near future. Optimisation of energy transfer can yield small increases in density, which results in much greater gains in strength. More time spent researching the optimum method of energy transfer would be a valuable exercise especially with the addition of cement which has an effect on the compaction process.

Nomenclature

Bre-pack machine: A high quality 10MPa manual block-making machine as developed in the U.K. for block manufacture in developing countries.

Brick: An object (usually of fired clay) used in construction, usually of rectangular shape, whose largest dimension does not exceed 300mm.

Block: A larger type of brick not necessarily made of fired clay, but stabilised in some way, sometimes with central cores removed to reduce the weight.

Cement: Ordinary Portland Cement (OPC).

Clay: The finest of the particles found in soil, usually of less than 0.002mm in size and possesses significant cohesive properties.

Concrete: The finished form of a mixture of cement, sand, aggregate and water.

Dynamic Compaction: A process that densifies soil by applying a series of impact blows to it.

Fines: General category of silts and clays.

Green: Describing the state of material containing cement and water before it reaches the critical time, after which further plastic deformation hinders the final set strength.

Permeability: Describing a material that permits a liquid or gaseous substance to travel through the material.

Porosity: A measure of the void volume as a percentage of the total material volume.

Sand: A mixture of rock particles ranging from 0.06mm to 2 mm in diameter.

Silt: Moderately fine particles of rock from 0.002mm to 0.06mm in size.

Soil: Material found on the surface of the earth not bigger than 20mm in size, not including rocks and boulders and predominantly non-organic. If soil is to be used for building material it must not contain any organic material and it can be a natural selection of particles or a mixture of different soils to attain a more suitable particle distribution.

Stabilised soil: Soil which has been stabilised (treated to improve structural characteristics) by using one or more of the following stabilisation techniques: mechanical, chemical and physical.

Table of Contents

1. Introduction

There is a small quantity of existing information on dynamic compaction of stabilised soil blocks, but this is limited to a few simple surveys and thesis reports. Much of the work for this project will reference these previous works as they too discovered a lack of information in this field. Other studied have provided information of direct relevance to other fields, but which can only be applied to the field of interest with a small degree of confidence.

Soil compaction is an important area of study within the civil engineering and geotechnics and this is similar to the working being carried out here. Some sources give a bit of detail on a form of dynamic compaction that is used to compact soil prior to construction, or to aid stabilisation of slopes etc. These are of interest especially if any quantitative description of the compaction process is given that would be useful in application to compaction of blocks.

Ground compaction always concentrates on a small area of ground where compaction is desired and the machinery used has to move around the area to ensure thorough compaction of the desired surface. This type of compaction could be considered analogous to the tamping down of soil in a block mould or the compaction of soil between shutters for rammed earth walling. However, simultaneous compaction of the entire block surface is not in the same category as there are no potential slip planes for soil movement under the direct compaction force. Unlike ground stabilisation the compaction force is uniform over the whole surface of the block making the two processes fundamentally different to each other. This makes the information in this field interesting, but not entirely useful. Consequently much of the research into dynamic compaction of soil blocks will be received from previous research done by Dr. Gooding and his thesis.

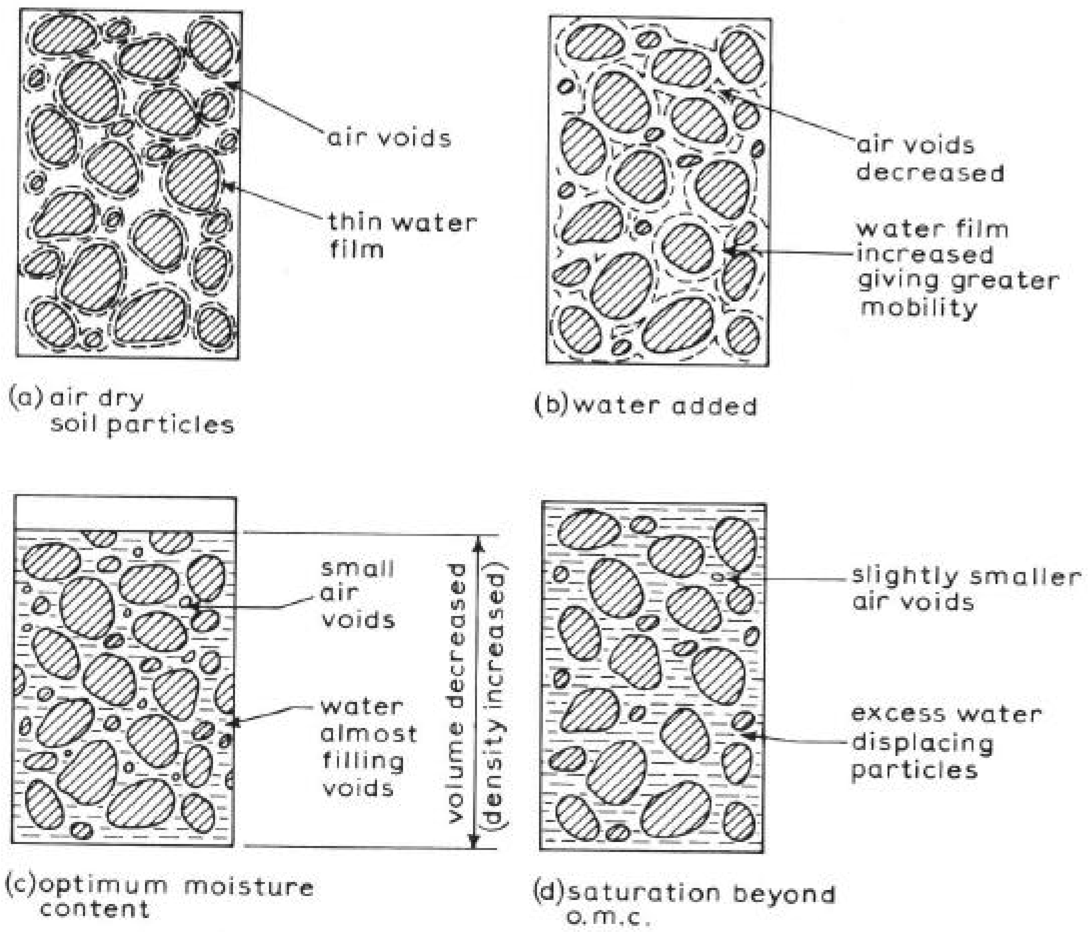
2. Principles of soil compaction

Soil generally consists of a mix of solid, liquid and gas. These are more commonly referred to as the soil particles, water and air. The combination of the volume occupied by the water and the air is called the void volume. Compaction of a soil sample is done to decrease the air voids present in the soil and hence increase the dry density of the sample. Dynamic compaction achieves this by permitting a moving mass to strike the surface of the soil sample and deliver energy into the sample that causes densification. The level of densification that can be achieved relates to a number of different parameters, the most important of which are the moisture content and the compacting energy transferred. Other factors that affect the densification are the number of blows applied to the soil and the momentum of each blow delivered by the falling mass.

2.1 Air void reduction

An air dry mass of soil will have a certain amount of spaces between the soil particles and these spaces are referred to as "air voids". This is sometimes expressed as a percentage of the total volume (air + soil) occupied by the air. Indirectly it can be represented by the "dry density" of the soil, as the weight of air in a soil is negligible compared with the weight of the soil particles. If a soil sample is compacted at it's density-optimum moisture content, by definition it will be at its greatest dry density for that compacting pressure. After such compaction, the volume occupied by the moisture will be virtually equal to the percentage of air voids present in the sample after subsequent drying out. Incidentally the density-optimum moisture content is not the same as the strength-optimum content. We must not use volumetric definition of OMC as it changes (rises) during the compaction process. We use a mass definition. Alternatively we use volume but define when it is measured, e.g. immediately after compaction.

The density-optimum moisture content (OMC) depends on the compacting energy delivered into the sample. The greater the compacting energy the lower the OMC and hence the greater the final dry density. The diagram below taken from Head, 1980, pg. 270, illustrates the particle arrangement of a soil sample at different moisture contents as well as the OMC.



2.2 Compacting methods

Several methods for dynamically compacting a soil sample exist as tests for soil compactability. These involve a mass that is raised to a consistent height above the surface of a soil sample constrained within the walls of a mould. Some impactor designs cover the entire area of the soil sample whilst others are dropped over the surface in a standard pattern. The latter technique could be analogous to tamping the soil down into a block mould, whilst the former is like the dynamic compaction tests as done by Gooding. Both tests are of interest but the former will be more helpful when trying to extend Gooding's research.

2.2.1 Soil compaction tests

The complete description of all the possible compaction tests is not necessary for the purposes of this report. A brief outline of each test is given and their possible relevance to the dynamic compaction research will be suggested. The tests described below are taken from Head, 1980, pg. 281-306.

BS Ordinary Test (or the Proctor test)

This test uses a 2.5 kg metal rammer with a 50mm diameter face that falls into a cylindrical mould of 105mm diameter. The drop height is kept at a constant 300mm to ensure consistent energy transfer between blows. The blows follow a pattern over the face of the sample to ensure repeatability and consistent compaction of the entire sample. Each sample made up of three layers of soil that has passed through a 20mm sieve and each layer is given 27 blows of the rammer. After compaction the sample is trimmed off to a set height that gives a constant volume of 1000cm^3. This is then weighed and the density can be calculated.

BS Heavy Test

This test is virtually identical to the BS Ordinary Test, with the only difference being the mass of the rammer and the drop height. For this test a 4.5 kg rammer is used and it is dropped from a constant height of 450mm above the level of the soil. Compaction is also carried out in five layers instead of three. All other dimensions and quantities remain the same.

Compaction by Vibration

This test uses an electric vibrating hammer operating at a frequency of between 25-45 Hz and a power consumption of 600-700 W. The soil is compacted in a cylindrical mould with an internal diameter of 152mm and a height of 127mm (CBR mould). The vibration from the hammer is transferred into the soil through a steel rod with a circular foot 145mm in diameter, (i.e. that nearly fills the mould). The soil is compacted in three layers by the hammer action and a steady force of 300-400N is applied to the vibrating hammer to prevent it from bouncing up and down on the surface of the soil. The final compacted height is measured using a steel ruler. The mass of the soil and mould is then weighed and weight of the empty mould subtracted from it. From these measurements of height and net weight the density can be calculated.

Dietert Compaction

Of all the compacting methods this one is most similar to the tests done by Gooding. It is a hand-operated device that uses a large cam to lift a mass of about 8kg through a constant height above the surface of the soil. The cam permits the mass to be dropped repeatedly onto a foot that rests on the surface of the soil sample transferring the energy into the soil and causing compaction. This apparatus uses a standard 50mm mould and the foot is fractionally smaller (48mm) to ensure free movement on impact. Density is calculated from measuring the height of the soil in the mould and the mass of the soil that is originally placed into the mould; the number of blows applied is recorded.

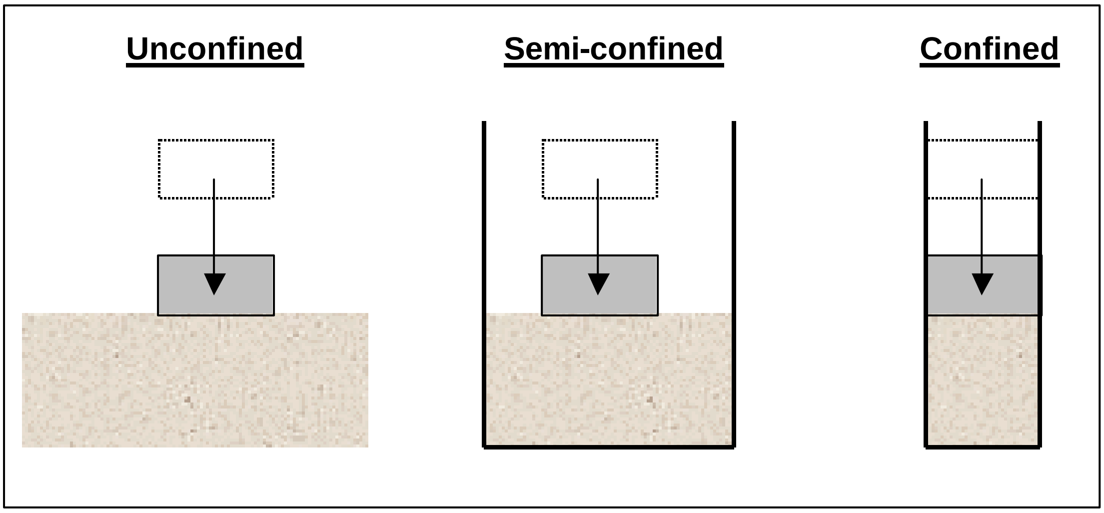
Harvard miniature compaction

In the situation where material for analysis is scarce and the soil particles are finely grained this test may be used. It uses a hand-held spring-loaded tamper and a special mould. The spring ensures that a consistent force is applied to the surface of the soil during each successive 'tamp'. This force equates to 178N and is applied through a tamper rod of 12.7mm in diameter over the surface of the soil. The mould is 33.3mm in diameter and 71.5mm high. This volume yields the useful feature that the mass of soil, in grams, is equal to its density in pounds per cubic foot.

2.2.2 Compaction test analysis

Both the BS Ordinary test and the BS Heavy compaction test show similarities to the compaction process that is of interest because they involve a mass dropping onto the surface of the soil in a mould. To compact the soil sample evenly the rammer must be dropped in a pattern over the surface of the soil. Although the soil is restrained within the sides of the stiff-sided mould it is only semi-confined to a volume. In other words, compaction applied to one area doesn't cause compaction in another and slip planes within the soil can exist. Conversely, confined compaction is similar to the Dietert compaction where the compaction occurs over the entire surface of the soil in the mould, thereby confining the volume and restricting any slip planes in the soil. Both of these compaction methods are very different to the unconfined ground compaction as used in civil engineering.

Now we can separate out any compaction test into three classes groups: confined, semi-confined and unconfined compaction. Of the three, confined compaction is of most interest as it replicates the dynamic compacting process that will be employed for block manufacture during this project. Semi-confined and unconfined compaction may be useful to investigate, but will be limited in their application to this project. Below is a sketch to illustrate the three classes of compaction.



Unconfined compaction is limited to ground compaction as used in civil engineering and no compaction tests have been described above for this case. Semi-confined compaction tests are BS Ordinary and Heavy tests as well as the Harvard miniature compaction test. Confined tests are the Dietert and the Vibrating Hammer compaction tests, although the latter uses a different means of transferring the compaction energy.

It is not advisable to compare compaction methods that use vibration with impact compaction. Vibration expels air from the mixture and does not usually crush soil samples in any way. Instead vibration redistributes particles (largest ones sink) and it does not leave compressed air pockets.

3. Previous dynamic compaction research

It has been suggested already that the information on dynamic compaction of stabilised soil blocks is very scarce. Up till now the author is only aware of two pieces of work that cover this topic, and only one of which he has been able to access. There are however, other publications that deal with the subject of soil compaction, both from a theoretical and practical viewpoint.

3.1 Mathematical modelling

In the unconfined state, a soil sample that receives an impact will compress in the localised area and send shock waves through the surrounding soil. It can be modelled as a highly damped spring with characteristics that depend on the Young's Modulus, Dilation Velocity, Poisson's Ratio, and Elastic Limit of the soil. Scott R. A. and Pearce R. W. give an equation that links these characteristics to the rate of deceleration of a moving mass in order to model the stress and movement at the impact surface.

Scott and Pearce 1976 modelled an unconfined mass of soil that has been hit by a falling weight. They investigate the effect of unsaturated and saturated soils monitoring the elastic properties, surface deflection and stress concentrations. They also suggest a model for a one-dimensional situation that may be analogous to dynamic compaction within a constrained mould. Below is an extract from their paper as found on pg. 23-26 of *GROUND TREATMENT BY DEEP COMPACTION*.

> "Loose unsaturated soils subject to steady localised surface loading deform typically as shown by the curve A of Fig. 2. The deformation is of a generally elastic nature at low stress levels and at these stresses the soils can propagate seismic waves. With increasing stress the slope of the deformation curve falls more or less sharply due to the relative ease with which voids can be collapsed at the higher stress levels.
> If such a soil is subjected to impact by a fast falling weight, the soil rigidity may play a much less important role than the soil inertia in controlling the deceleration of the weight and in absorbing the energy of the impact. An idealised representation of a compactable soil in respect of these inertial and energy consuming effects in the elasto-plastic soil is represented by the curve B of Fig. 2. The stress level of the plateau has been chosen to lie in the region of the reduced slope.

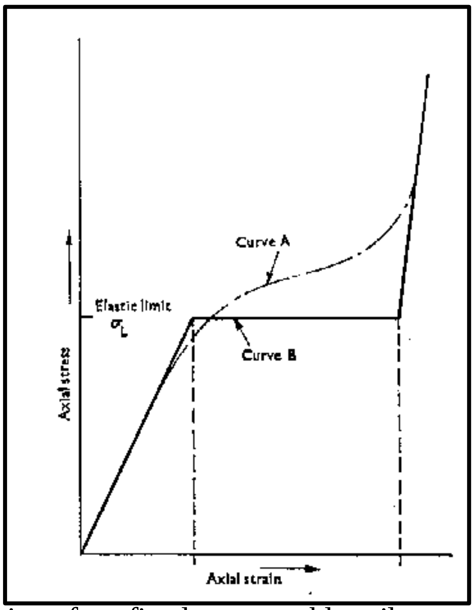


Fig. 2. Axial deformation of confined compactable soil

A three-dimensional treatment of the reaction of the soil underlying the contact is impracticable as the strains are generally so large that the shear restraints due to flanking regions of soil are not easy to quantify.
However, when the impact momentum is high the weight will punch through the upper soil layers and carry down a growing zone of compacted material of a generally cylindrical shape. For present purposes of illustration we shall discount the inevitable lateral spread of the compacted zone and use a one-dimensional description based on the approach mapped out for example by Salvadori (1960).
Immediately upon impact the stress level rises because of stress wave reaction due to the elastic nature of the first small movements of the soil at the contact surface. When the stress level has reached the level σ_L of the plateau, the soil particles at the surface have acquired a velocity v associated with a radiating stress wave which travels downwards into the medium with the seismic dilation velocity c appropriate to initial elasticity. The wave is accompanied by a pressure front in which the axial stress is given by a form of equation (1) that is,

$$s_L = rcv$$

The radiation of the stress wave is followed almost immediately by a further acceleration of the surface particles such as to bring the surface to the same instantaneous velocity V as the weight.
If z is the instantaneous position of the front of the steadily lengthening compacted material (Fig. 3) the retarding stress applied at the bottom surface of the weight is

$$-m\frac{d}{dt}(\dot{u}-v) = r_c\frac{d}{dt}\left[(z-u)\frac{d}{dt}(u-vt)\right] + s_L \qquad (8)$$

where m is written for the ratio M/pa^2 and ρ_c is the compacted density. The distances z and u can be shown to be related by the expression $z=k(u-vt)+vt$ where $k=rc/(rc-r)$. This relation can be used to eliminate z in equation (8), with the result that

$$-m\frac{d}{dt}(\dot{u}-v) + k_r\frac{d}{dt}\left[(u-vt)\frac{d}{dt}(u-vt)\right] + s_L = 0 \qquad (9)$$

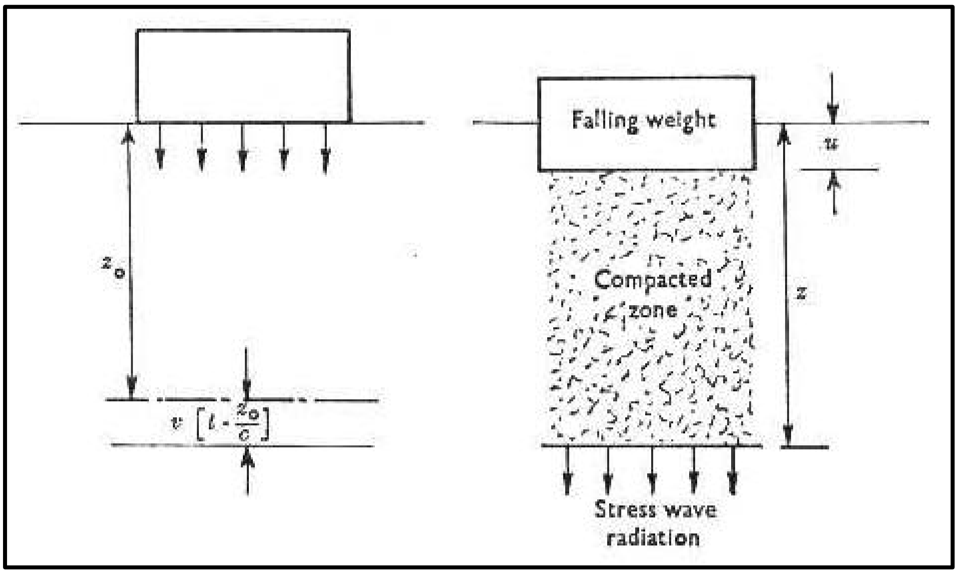

Fig. 3. One-dimensional compaction

The displacement u of the surface is obtained by solving equation (9) hence

$$u = vt + m(F-1)/k_r \qquad (10)$$

where

$$F = \left(1 + \frac{2k_r}{m}t - \frac{\sigma_L}{m^2}t^2\right)^{1/2}$$

The surface stress in the soil is then given by

$$\sigma = \frac{\sigma_L + k_r(V-v)^2}{F^3} \qquad (11)$$

Surface motion ceases after a time given by $t=m(V-v)/\sigma_L$ and at this time the final depth h of the compacted zone is given by evaluating $(z-u)$ and therefore by

$$h = \frac{m}{\rho_c}\left\{\left[1 + \frac{k_r(V-v)^2}{\sigma_L}\right]^{1/2} - 1\right\} \qquad (12)$$

It should be observed that while the stress just ahead of the compaction zone is at the elastic limit stress σ_L the stress at the surface may be considerably higher, especially at the early stages of compaction."

The author does not confess to understand all of the above nor what approximations have been made to develop such a model. Further reference to other source texts will be attempted to try and establish an appropriate model for a fully constrained soil. This model would then need to be checked with actual readings taken from the dynamic compaction process to verify its consistency. Both of these have yet to be done, but they are included in the scope of this project.

Another theoretical analysis of the impact method was found in Parsons pg 199 as follows:

"Theoretical analysis of the factors influencing the performance of dropping-weight compactors

12.27 To give an indication of the important factors to be considered in the design of impact compactors in general, and dropping-weight compactors in particular, Lewis (1957) produced a simplified theoretical analysis of the impact pressures produced on the surface of soil by a rammer. The experimental dropping-weight compactor shown in Plates 12.3 and 12.4 was used to verify the theoretical analysis.

12.28 From the well known equations of motion:-

$$V^2 = 2fx \qquad (1)$$

And $pA = Mf \qquad (2)$

where V = velocity of rammer on impact
f = deceleration of rammer on striking soil
x = deformation of soil during impact
p = pressure generated on surface of soil by the impact
A = area of rammer base
M = mass of rammer

Hence:- $$p = \left(\frac{Mk_s V^2}{2A}\right) \qquad (3)$$

where $k_s = \frac{p}{x}$

=dynamic modulus of deformation of the soil

In the case of a rammer falling freely from a height h:-

$$p = \sqrt{\frac{Mhgk_s}{A}} \qquad (4)$$

If the acceleration of the falling weight is less than g as a result of frictional losses:-

$$p = \sqrt{\frac{Mhg' k_s}{A}} \qquad (5)$$

where g' = actual acceleration of the falling rammer.

$$p = \sqrt{E_s k_s} \qquad (6)$$

where E_S = specific energy

12.29 These relations indicate that the impact pressure is a function of the energy per unit area of the rammer base (specific energy) and the deformation properties of the soil under dynamic conditions of loading. The latter factor is also likely to be a function to some extent of the area and shape of the rammer base, but little information was available on that aspect at the time that the analysis was made. If it is assumed that the dynamic modulus of deformation behaves similarly to the static modulus of deformation in that the modulus is often found to be inversely proportional to the square root of the loaded area, then:-

$$k_s = \frac{C}{\sqrt{A}} \qquad (7)$$

where C is a constant

The expression for the impact pressure developed can then be written:-

$$p = \sqrt{\frac{MV^2C}{A2\sqrt{A}}} \qquad (8)$$

where C = constant for the particular soil conditions.

Thus, if the rammer area is changed, the compaction energy provided by each blow per unit area of rammer base (specific energy) $\left(\frac{1}{2}M\frac{V^2}{A}\right)$ would have to be kept proportional to the square root of the area of the rammer base $\left(\sqrt{A}\right)$ for a constant pressure to be developed."

The author can apply these formulae to his results from the dynamic compaction of full-sized blocks that was done in 1997. The table below shows the increase in energy that was delivered by the impactor as the soil block was compacted. It also indicates the total transfer of energy into the block after a certain number of blows.

Impactor stroke (m)	0.1364	0.1571	0.1661	0.1748	0.1814	0.1866	0.1913
Energy(J) / blow		55.5	58.7	61.7	64.0	65.9	67.5
Energy increase		7.3	3.2	3.1	2.3	1.9	1.6
Energy transferred after blows (J)	0 blows 0	1 blows 55.5	2 blows 104	4 blows 221	8 blows 468	16 blows 980	32 blows 2035

Between the initial resting place of the impactor and the resting place after one blow there is a distance of (0.1571 – 0.1364) = 0.0207m. This is the deformation of the soil during impact (x). The velocity of the impactor prior to impact can be assumed to be $V = \sqrt{2gh} = \sqrt{2 \times 9.81 \times 0.1364}$ = 1.64 m/s …etc.

Below is a calculation table with the rest of the calculations for multiple blows during a compaction cycle using the above formulae.

	1 blow	2 blows	(3 blows)	(4 blows)	(8 blows)	(16 blows)	(32 blows)
Velocity prior to final impact (m/s)	1.64	1.76	1.81	1.83	1.88	1.91	1.94
Stopping distance (m)	0.0207	0.0090	0.0043	0.0044	0.0016	0.0006	0.0003
Mean deceleration (m/s²)	64.6	171	375	384	1070	2800	6380
Calculated stopping time (s)	0.025	0.010	0.005	0.005	0.0018	0.0007	0.0003
Pressure generated (MPa)	0.057	0.152	0.332	0.341	0.948	2.488	5.656
Dynamic mod of deformation	2.768E+6	1.687E+7	7.635E+7	7.835E+7	5.743E+8	3.828E+09	1.925E+10
Mean force in tonnes (final impact)	0.233	0.616	1.35	1.38	3.85	10.1	23.0

N.B. The velocities and stopping distances for the blow numbers in brackets have been linearly estimated from compaction data for multiple blows. These figures are probably accurate to ±10% and despite not being spot on experimentally they do show the continued trend.

Two things are immediately obvious from the table of results above. Firstly, the dramatic increase in force that is applied during impact between the first blow and much later ones. Secondly, the dynamic modulus of deformation for a soil compacted in a confined manner will increase as it becomes compacted. Therefore the characteristics and behaviour of the soil will change during the compaction process. This will make accurate modelling the compaction significantly more difficult than an unconfined soil with a constant dynamic modulus of deformation.

Another thing to consider from these results is the magnitude of the force that can be delivered using a bigger dynamic compaction machine. For example: a 50kg impactor with a maximum velocity of 2m/s stopping in 0.0001m will deliver an instantaneous force of 100 metric tonnes! Delivering forces of this magnitude will necessitate a secure foundation for the machine, perhaps even larger than originally anticipated.

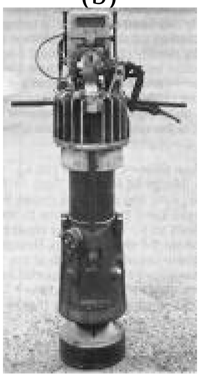
3.2 Dynamic compacting equipment as used in civil engineering

Within the field of civil engineering there are many different types of equipment that have the capacity of compacting a mass of soil. Many of these will not be of interest as they possess very little dynamic properties that help to compact the soil. Even smooth vibrating rollers and vibrating sheep's foot rollers are outside of the field of interest as compaction via vibration is quite different to dynamic compaction.

Of the remaining equipment that is regularly used in civil engineering there are no devices that compact soil in a confined fashion. At a stretch of the imagination, one could say that some pneumatic and power rammers could be classed as being semi-confined if they were compacting soil in a trench. The dynamic compaction equipment almost always compacts the soil in an unconfined state, and there are several examples of these that can be looked at.

(a)

(b)



(c)

(d)

(e)

Vibro-tampers

These devices are essentially an engine driven reciprocating rammer that bounces up and down on the surface of the soil with its location controlled by an operator. They range from 50 – 150 kg in weight and vibrate at a frequency of around 10 Hz. The amplitude of vibration can vary depending on the machine anywhere between 10 – 80 mm. A picture of a Vibro-tamper can be seen in part (a) of the above diagram.

Power rammers

A controlled explosion of a petrol/air mixture is used to force a piston ground-wards. This causes the power rammer to jump up into the air compressing the soil beneath it and compacting the soil on its descent. A photo of a power rammer can be seen in part (b) of the above diagram, and a power rammer in use can be seen in part (c). Power rammers typically have a mass of about 100 kg with a circular base of about 250 mm in diameter. These rammers are manually controlled and guided around the ground surface. They jump between 300 – 360 mm into the air and deliver a blow of between 315 – 370 J/blow. This equates to an energy transfer per unit area of compacting base of between 6.3 – 8.1 kJ/m².

A much larger variety of power rammer is the frog rammer, typically around 600 kg with a 750 mm compacting base. This machine ‘hops’ along the surface of the soil compacting it with each ‘hop’. It also moves forward with each ‘hop’ in order to reduce the directive force required by the operator. The operator turns the rammer into the direction that (s)he wants it to travel and the rammer hops along in that direction. Must be a fascinating machine to watch! Although this machine delivers 1835 J/blow it delivers a smaller 4.3 kJ/m² than the other type of rammers.

Multi-dropping weight compactor

A picture of this machine is included in part (d) of the diagram above. The unit is towed behind a suitable traction unit and is designed to provide adequate compaction in a single pass over the surface. It uses an arrangement of six 200 kg cast iron weights that are lifted and dropped onto the surface of the soil by rotating cams driven by an on board diesel engine. Each weight is lifted through 330 mm and delivers around 515 J/blow. The base of the rammers are 330 ×305 mm and therefore have a specific energy of about 5.1 kJ/m².

Mobile dropping-weight compactor

This machine is called the Arrow D500 dropping-weight compactor and is self propelled with a hydraulically lifted impactor at the front of the machine. A picture of the machine can be seen in part (e) of the above diagram. This device can lift the impactor through a variable height up to a maximum of 2.2 m. A 36 kW diesel engine drives a pump for the hydraulic system to lift the 588 kg mass to the desired height. This can then deliver a maximum of 11167 J/blow, and with a 305 × 305 mm base this equates to a considerable specific energy of 120 kJ/m^2.

All of the above information is taken from research carried out at the Transport Research Laboratory as reported by A. W. Parsons 1992. At TRL tests were carried out using the above machines on different types of soil and their different compaction abilities were noted. Some of the different types of soil that were used were; heavy clay, sandy clay, well-graded sand, gravel-sand-clay and silty clay. Different machines within the same class of compactors were assessed relative to each other in the different soil types. TRL also developed an experimental falling weight compactor that was used to help determine the efficiency of the other falling weight compactors that were available.

3.3 Research done by Gooding for his PhD

This source of information has proved to be highly valuable in the planning of future research in this field. Gooding has been the sole available reference for dynamically compacted soil samples that are compacted in a confined manner. Although Gooding thoroughly investigated the dynamic compacting process, he didn't actually stabilise any of the dynamically compacted samples with cement. The characteristics and effectiveness of the combined processes was not looked into. Other samples were stabilised using both compaction and cement but in these circumstances quasi-static compaction was always used.

3.3.1 Quasi-static compaction

Before Gooding began to investigate dynamic compaction, he looked into the process of quasi-static compaction (i.e. pressing). His research included varying the cement content, the applied pressure, mould taper, double and single sided compaction, pressure cycling and mould wall roughness. Throughout his tests he used a fabricated soil called *soil A* with a constant moisture content of 8%.

Gooding looked at the relationship between pressure verses wet compressive strength, cement content verses wet compressive strength and developed a model to estimate the wet compressive strength of a sample with known cement content and applied pressure. This model was based on actual experimental results taken from tests carried out using a range of pressures and cement contents. A small cylindrical mould specified in BS1924 was used for all of these tests. All the cylinders had their wet compressive strength tested after seven-day curing and subsequent soaking for 16 hours.

The model that Gooding developed suggests that a sample of *soil-A* with 5% cement and a compaction pressure of 10 MPa should have a wet compressive strength of around 1.6 MPa. Initial tests by the author using the Bre-pack machine have yielded blocks with compressive strengths of slightly less than this value, (1.5 MPa for a block with 4.9% moisture content). This apparent similarity has to be discounted for two reasons. Firstly, the test specimen the author used was a 100 mm cube instead of a 50 mm cylinder. And secondly, the difference in moisture contents would lead to considerably different results. Whereas Gooding was able to test the compressive strengths of the finished cylinders, the author found it more advantageous to cut the full size blocks into two 100 mm cubes. This resulted in generating two tests for the same block and it also uses a standard sample size, as used in the concrete testing procedures.

3.3.2 Dynamic compaction

Gooding investigated the efficiency of impact compaction using <u>un</u>stabilised *soil – A*. Consequently the wet compressive strength of compacted stabilised soil samples could not be measured as unstabilised soil breaks down when immersed in water. Instead each sample received the same energy but by different impact arrangements and the achieved density was measured. Density was calculated by measuring the final cylinder height (±0.05mm) and mass (±0.1g) on ejection from the mould. Each cylinder received a constant 279 J/kg and the mass of each cylinder was kept at around 1.66 kg. Other factors such as the number of blows and momentum of impactor were varied to find any optimum parameters for this technique.

Each sample received one of 1, 2, 4, 8, 16, 32 or 64 blows. The optimum number of blows (number that yielded the greatest density) was found to be at 16 blows, but it was also noted that only a 3-4% reduction in compaction efficiency occurred when this was varied from 8 to 32 blows for each of the different masses.

If different number of blows and different masses were used to compact the samples then the height through which each mass was lifted had to be varied. A lighter mass had to be raised higher to transfer the same energy per blow as a heavier mass dropped from a lower height. Similarly, if less blows were being applied then the mass had to be raised higher to transfer the same total energy. This has the effect of changing the momentum of each blow applied as momentum depends on the mass and the velocity of the mass prior to impact and velocity depends on the distance through which the mass falls. Three different masses were used in the experiments on the samples (23.35, 35.00, 46.80 kg) and it was noted that the bigger masses dropping at slower speeds were more effective. Yet, the 23.35 kg mass and the 35.00 kg mass were only 0.4% and 0.2% less efficient respectively at the 16 blow configuration than the 46.80 kg mass.

This area needs to be further investigated using cement and doing proper compressive tests to suggest better accuracy for the environment in which the samples will finally be placed.

3.3.3 Other research that was done

Gooding 1995 was involved in producing "Survey of the potential for cement-stabilised building blocks as a building material in developing countries". During this field survey of many countries he encountered a couple of structures that were made out of cement stabilised dynamically compacted material. He compares them with other structures in the area, constructed using similar appropriate techniques, with some interesting observations. Below is an extract from that survey, pg 58 covering Botswana.

> One soil-cement house is of particular interest. In 1985 a soil-cement house was constructed at the Camphill Community Centre in Otse using the Ranko Block Maker. This is a manual machine which uses impact to compact the soil-cement to high pressure. It was designed by Agas Groth, a Botswanan national. The house has now been standing for ten years without any maintenance work having been carried out and is in excellent condition. The blocks were produced with a cement ratio of 1:16 and having been well cured and laid in the wall were rendered with a low-cement bagwash. This should be compared with houses constructed by BTC for their experimental staff housing project using imported quasi-static machinery; the Hydraform and Ceratec machines which cost 60,000 P (£14,000) and 100,000 P (£24,000) respectively. The blocks were produced with a cement ratio of 1:10 and powered mechanical soil sieving and mixing were used. These houses have now been standing for only two years but are already deteriorating. In the case of the Ranko block walling production was estimated to cost between 20 and 30 % less than the prevailing price for sandcrete blocks (Enyatseng 1987). In comparison the blocks produced using the Ceratec machine were found to be 18% more expensive than stock cement bricks and 46% more than sandcrete blocks (BTC 1995). The high cost of the Ceratec blocks was attributed to the low productivity of the machine. Although this machine was capable of producing 1200 blocks/hour this figure was never achieved as two motorized mixers would have been required to continuously supply the machine with soil. If a lower cost machine were available, capable of high pressure compaction but with a useable maximum output then the economics of production would be significantly improved.

The author is currently trying to get a copy of the research work done by Agas Groth to compare it with Gooding's investigations.

3.4 The author's previous research

As part of an undergraduate degree programme the author had to do some research on a subject that was suggested by one of the resident lecturers. The author discovered that Gooding had a small project that would be suitable both for the project requirements and for the author's abilities. This project was subsequently undertaken and labelled "Design and realisation of a test rig to research the production of full size dynamically compacted soil-cement blocks". This project was completed in 1997 and achieved the following results. A full size dynamic compaction test rig was designed and manufactured. The design chosen was suited to the level of appropriate technology available in developing countries. Several blocks were produced and their densities and surface resistance was measured. Two blocks were stabilised using cement, but these were not used in the experimentation as they were only intended to be demonstrator blocks. This means that up to date there has not been any research done on dynamically compacted cement stabilised soil blocks.

Gooding quasi-statically compressed a block to 9.7 MPa and noted that it achieved a density of 2038 kg/m³. This compaction pressure equated to a transfer of 279 J/kg. By comparison, the author dynamically compacted a full size block to a density of 2040 kg/m³ by applying 32 blows to it from a 36 kg impactor. This block received a total of 2035 J from the falling impactor. For a 10-kg block this equates to approximately 204 J/kg, some 26% less energy required than the quasi-statically compressed block, which is still a significant saving. This research indicated that the savings in energy that Gooding had found could be extrapolated onto full size blocks and warranted further research.

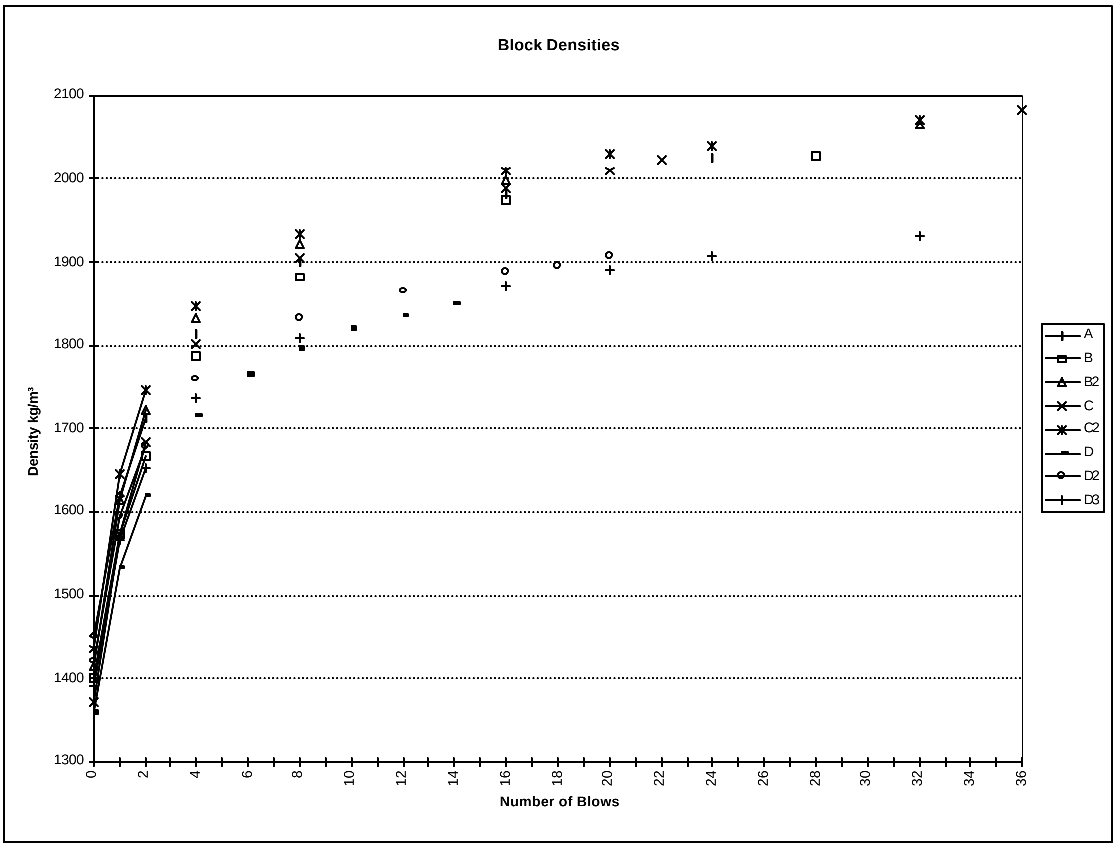
The author also did not stabilise any of the full size dynamically compacted blocks as these were trials to test the feasibility of full size compaction. Consequently there are not any known characteristics of the produced blocks apart from a handful of penetrometer tests done on the freshly demoulded block. These give little indication of the core strength and only sought to establish the level of uniformity of density throughout the block.

4. Discussion of research

The experiments done by the Research Transport Laboratory, Gooding and the author can in some way be compared with each other. The experiments described in section 3.2 can be compared to the tests carried out by Gooding, but only with the soil that is closest to the soil used by Gooding during his research, which are the sandy clays. Even this soil has a much higher percentage of clay than the soil used by Gooding, but the other soils are vastly different. It can be noted from these compaction results that greatest compaction was achieved with the experimental rig when it delivered 4, 5 or 7 blows with the same total energy transfer at the optimum moisture content as discovered by the 2.5 kg rammer test (described in section 2.2.1). The compaction was about 4% better in this configuration than the big multi-weight machine (described earlier), and about 8% better than the experimental rig delivering 2 blows, (40% of the energy as transferred compared to the 4,5 or 7 blow arrangement).

The author during his previous research also noted the slight reduction in compaction from a massive reduction in energy transfer. The graph below shows several blocks that were made by dynamic impact. Each blow had approximately equal energy after the first few blows so 40% energy of a block that received 32 blows should equate to about 12 blows. Block C2 achieved a density of around 1975 kg/m³ after 12 blows, but its density only increased to 2070 kg/m³ after a further 20 blows. Thus a decrease of 60% in energy transfer only led to a decrease in density of less than 5%.

However a small drop in density can have a significant effect on the final compressive strength of a compacted block. From Gooding's research it can be noted that a cylinder stabilised with 5% cement that was compacted to a density of 2124 kg/m³ achieved a cured wet compressive strength of 1.63MPa. Another cylinder compacted to 2032 kg/m³ (a drop of less than 5% in density) only yielded a cured wet compressive strength of 1.20MPa, (a drop of over 25% in strength). This trend of high gains/losses of strength for small increases/decreases in density fits throughout the results that Gooding received from his experiments.



Graph showing block density against number of blows received

From the above results that have been highlighted for comparison, there are a few trends that can be noted and will help in further research. Final cured strength of cement stabilised blocks is highly dependent on the final compacted density. It is also true that small changes in density can only be achieved by much greater changes in energy transferred into the block. Dynamic compaction has proved to be a more efficient compaction process than quasi-static and it also has the added advantage that it is relatively easy to increase the energy transfer by simply applying more blows.

Any quasi-static compaction machine will have a working limit and will be unable to compress to a higher compaction pressure than that. Gooding suggested that pressure cycling would yield a small increase in final density and subsequently a higher strength, pg. 137, but this is time consuming and is still highly limited. Dynamic compaction would only be limited by the time required to produce each block, and even then the impact time could be reduced by modifying the machine design. Dynamic compaction, therefore, has a much greater potential for increasing the energy transfer and consequently increasing density and final cured strength.

Furthermore there is agreement among all the sources that compaction via multiple blows is more effective than with a single or a few larger blows. This characteristic is highly advantageous with dynamic compaction as larger numbers of blows can deliver the same energy into a block as a much larger impactor falling from a greater height. This method of energy transfer is much easier to design into a machine than a very large compactor falling through a great height.

5. Conclusions and recommendations

There is still more information that needs to be found and investigated. This will continue throughout the project and will be written up in due course. Several other sources are already being sought and they will help to shed new light on this relatively undocumented field of research.

The limitations of the existing information are significant and these need to be tackled during the project if a better understanding of the dynamic process is to be achieved. Dynamic compaction of cement stabilised samples needs to be undertaken, both for cylinders and for full size blocks. These will need to be tested according to the seven day wet compressive strength test and their performance noted. It is known that dynamic compaction provides better and more efficient compaction, but it is not clear if these will in turn reap significant benefits when the addition of a cement stabiliser is included in the stabilisation process. Will a dynamically compacted and quasi-statically formed block perform similarly if they both achieve the same density and contain the same amount of stabiliser?

In order to achieve a higher density a significant amount of extra energy has to be transferred into the block. Reducing this energy transfer, or changing the way it is transferred has a marked effect on the final density that can be achieved. Small changes in density have large repercussions with other important characteristics of the finished block, such as the compressive strength and porosity. Consequently the greatest factor in the production of a cement-stabilised block is the final density and maximising this characteristic should be done in wherever possible. If cement is the expensive commodity and this has been reduced to an absolute minimum, then the application of extra energy in the most efficient manner is surely justifiable.

Optimisation of the number of blows for small cylindrical samples was done by Gooding for a constant moisture content. This optimisation needs to be extrapolated onto full size blocks to determine if there are any better arrangements for delivering a fixed amount of energy into a sample of stabilised soil. The moisture content has not been altered with respect to the cement content and this may be of significance. A lower moisture content may not yield the block with the greatest density, but it may yield a block with a higher wet compressive strength and durability. Parsons reported small changes in moisture content around the optimum to try and discover if the different compacting method yielded a different optimum moisture content. A similar exercise needs to be done with confined stabilised soil samples.

Gooding never used cement to stabilise his dynamically compacted cylinders and consequently nothing is known of the effect that the presence of cement has on the compacting process. It has been suggested in that cement will hinder the compacting process when the cement crystals are forming. Furthermore, compaction of the soil during crystal growth will be detrimental to final strength as bonds that have already formed will be broken and will need to be reformed again. It is the author's experience with the two dynamically compacted blocks that were stabilised with cement that slightly lower densities were achieved using similar compaction regimes. It was also noted that the ejection of the block from the mould was considerably more difficult than with the blocks formed without the use of cement.

6. Summary

The dearth of information on dynamically compacted soil blocks has only been a preliminary setback for the purposes of this research project. In one sense it gives complete freedom to explore any other area of the field that may be of interest as very little has been done before. The specific areas that have been covered provide adequate information and analysis and leave the author in no doubt of their accuracy. These areas do not need to be covered again, but they need extending to include other areas within the research field.

Dynamic compaction has been studied mainly for use within the civil engineering industry for ground compaction. This research gives helpful pointers to the behaviour of soil when it is compacted by an impact blow and also provides examples of equipment that are used within the industry. This research does not fit the same model as the fully constrained soil that would be used for dynamic compaction of soil blocks, but much of the data for impact delivery, energy transfer and soil deformation can be applied to this situation.

The understanding of what happens to the soil during an impact blow is still in infancy. It is dangerous to assume linear deceleration during the impact as the calculations in the latter part of section 3.1. This is probably not the case as the soil will act as a highly damped spring with variable damping and spring constants. A thorough investigation of the actual energy dissipation and resistive forces applied by the soil on impact may not be possible within the scope of this project. It would be good to know a bit more about this mechanism and the author intends to try and work this out, but he feels that the substance contained with such a study may warrant the commitment of a whole project on its own.

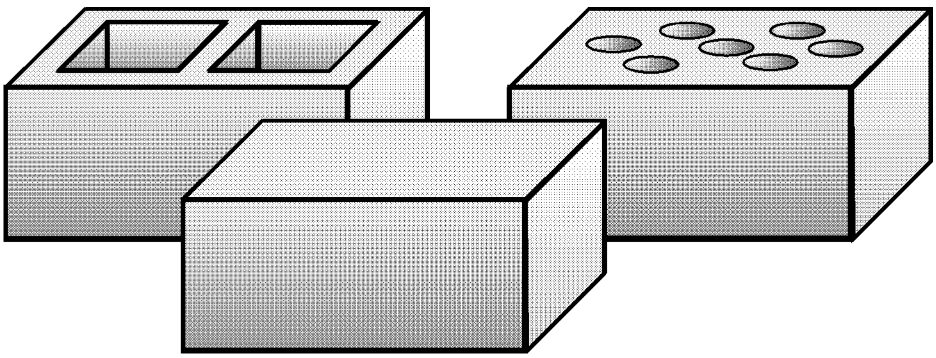
Stabilised Soil Research Progress Report SSRPR8



Minimising the cement requirement of stabilised soil block walling

Author: Mr D E Montgomery & Dr T H Thomas
March 2001

E-mail: d.e.montgomery@warwick.ac.uk

These reports cover 'work in progress' by research students in the Development Technology Unit (DTU) of the School of Engineering at Warwick University. Their primary purpose is internal - a format for recording ideas and data in a way that allows them to be better discussed before their incorporation into theses, DTU Working Papers or external publications. However they also have a secondary purpose, that of facilitating the sharing of our research with other innovators in the field of building with stabilised soil. Each report, after some initial internal discussion and refining will be posted as a title and synopsis on the DTU web pages (home page= http://www.eng.warwick.ac.uk/dtu). Full copies can be obtained from the respective named authors.

Titles of Stabilised Soil Research Progress Reports Produced to date:

[Put printed list of current reports in place of this page.]

A dedication to someone special

Sometimes at the beginning of a publication one finds a dedication to a certain person or member of the family who has been an influence in the author's life either in general or specifically in generating the work in question. There is one person in my life that immediately springs to mind who is worthy of such a dedication. Furthermore, my experience with this person is not unique as millions of others have found him to be a great inspiration, comfort, guide and friend. "What's his name?" you may be asking yourself and, "Why haven't I heard of this incredibly influential person". The sad thing is that you probably have, but you have never accepted him as such or welcomed him into your heart and life. Well, now you have an opportunity to do just that. Please read on.

The man's name is Jesus and although he was born nearly 2000 years ago his testimony still remains and his power to save is just as great. "Save from what?" you may ask, sin and the consequences thereof, or more specifically, your sins and the consequences you face when you die. As humans we demand justice to be done, and justice will be done, but on a perfect scale and to a perfect standard. That leaves us all falling short and without hope when we come face to face with a holy God. But, God in his great love towards us send his only begotten Son into the world that the world through him might be saved. Jesus Christ died for you so that you would not have to be punished for what you have done wrong. You can be spared eternal punishment in hell and enjoy love and peace in the presence of God forever. Today the choice is yours. Reject God's free gift of love at your peril, accept it and who knows you too may have the joy of writing a dedication such as this someday. Please ponder the verses below and make your choice carefully, it will be the most important decision you ever make.

David E. Montgomery

"*For by grace are ye saved through faith; and that not of yourselves: it is the gift of God: not of works, lest any man should boast.*" Ephesians 2:8,9.

"*For God so loved the world, that he gave his only begotten Son, that whosoever believeth in him should not perish, but have everlasting life.*" John 3:16.

"*For whosoever shall call upon the name of the Lord shall be saved.*" Romans 10:13

"*He that believeth on him is not condemned: be he that believeth not is condemned already, because he hath not believed in the name of the only begotten Son of God.*" John 3:18.

"*Jesus saith unto him, I am the way, the truth, and the life: no man commeth unto the Father, but by me.*" John 14:6.

Abstract

The monetary cost of low-cost walling in developing countries is greatly dependent on the expensive additives that are used to manufacture the building units and the cost of transportation of raw materials or finished products to the site of construction. Another cost associated with the production of anything is an energy cost and that can give an approximate overall measure of environmental impact. Within this paper several different types of existing walling materials are investigated for their overall cement and energy consumption. The purpose is to see how favourably they compare with high-density compressed and stabilised soil blocks using these suitable comparative measures. Assessment of suitability of local and on-site production will also be indicated for each of the materials in this study.

The study indicates that only three of the materials examined utilise less than 15kg/m² of cement, two of those are unsuitable for local production and the third uses about three times the energy in production. High-density compressed and stabilised soil blocks use slightly more than 15kg/m² of cement but have a low energy requirement for production. The other sections of this paper deal with the possible methods of further reducing the cement requirement of high-density compressed and stabilised soil blocks to a value below 15kg/m².

Several different cement-reducing methods are outlined within this paper. These include: placing voids in the block, incorporation of a cement rich-skin (either within the block itself or applied as a render), interlocking blocks requiring very little or no mortar and taller blocks that reduce the number of block courses needed for mortaring. In isolation each method does not reduce the cement demand below 15kg/m². However, it is possible to apply several of these methods together that safely brings the cement requirements to well below the target of 15kg/m² with a low energy cost.

Nomenclature

Brick: An object (usually of fired clay) used in construction, usually of retangular shape, whose largest dimension does not exceed 300mm.

Block: A larger type of brick not necessarily made of fired clay, but stabilised in some way, sometimes with central cores removed to reduce the weight.

Cement: Ordinary Portland Cement (OPC).

Clay: The finest of the particles found in soil, usually of less than 0.002mm in size and possesses significant cohesive properties.

Concrete: The finished form of a mixture of cement, sand, aggregate and water.

Dynamic Compaction: A process that densifies soil by applying a series of impact blows to it.

Fines: General category of silts and clays.

Green Strength: The strength present in a freshly formed block prior to curing.

Sand: A mixture of rock particles ranging from 0.06mm to 2 mm in diameter.

Silt: Moderately fine particles of rock from 0.002mm to 0.06mm in size.

Soil: Material found on the surface of the earth not bigger than 20mm in size, not including rocks and boulders and predominantly non-organic. If soil is to be used for building material it must not contain any organic material and it can be a natural selection of particles or a mixture of different soils to attain a more suitable particle distribution.

Stabilised soil: Soil which has been stabilised (treated to improve structural characteristics) by using one or more of the following stabilisation techniques: mechanical, chemical and physical.

Table of Contents

1. Introduction

Cement (opc) is the normal material used to stabilise soil in compressed block walling. It gives them a ‘wet strength’ they would otherwise lack. Other stabilisers are possible, but few meet the requirement of being readily and economically available in the target area for low-cost house walling, namely developing countries. However work at Warwick on micro-silica (both in its classical form and as a product of low temperature rice-husk processing) has led us to investigate its advantages as an opc additive in block-making. Interestingly, at clay contents below 15% Kaolin equivalent, lime has not proved to be a useful substitute for opc in soil block manufacture.

Cement is expensive in some countries (e.g. over $0.2 per kg in Uganda) and the ratio of (50kg) cement cost to daily wage exceeds 5 in most developing countries. It is currently uneconomic to use much cement – say more than 15 kg cement per m^2 of walling. Additives like micro-silica, while they are only used to substitute a small part of the opc, are considerably more expensive per kg and therefore even more restricted in their concentrations.

If we take as a norm a wall thickness of 140 mm, and assume mortaring consumes 30% of the available cement, then we are restricted to about 4% opc by weight within the blocks, or less than 4% if a costly additive is included. Even with very high moulding pressures (10 MPa), or high impact energies, it is difficult to produce really durable blocks with so little stabiliser.

There are however some paths we might follow that would allow us to use denser stabilisation without exceeding this cost target (of 15kg opc per m^2). One is to produce hollow or indented blocks that use less material per unit area of walling. Saving 50% of the material would allow a doubling of the cement:soil ratio. A second path is to employ non-homogenous material, increasing the concentration of stabiliser in the block faces (where deterioration is focussed) and reducing it in the block interior. A third path is to reserve much of the cement for a render, placed over hardly-stabilised blocks. A fourth is to employ dimensionally tight interlocking blocks requiring little mortar to lay.

The purpose of this Research Progress Report is to discuss the advantages, disadvantages and practical implications of following each of these paths.

2. Summary of existing materials for building

In this document we cannot provide an exhaustive list of building materials, just some of the more popular methods of providing walling at tolerable cost. Hollow and aerated concrete blocks, clamp and kiln fired brick and compressed and stabilised soil blocks (hereafter CSSB) are the main materials for consideration. Some of these materials require a thicker level of mortar to compensate for the irregularities of the blocks. Furthermore certain materials need further protection from the elements if they are to last for tolerable periods and this is usually done by applying a render to the external face of the building. Sometimes this is only done for visual reasons, but for the purposes of this investigation we will assume that aesthetics are not the primary concern and certainly not worth extra expense.

Possibly one of the most striking differences between different types of building materials is their width. Some concrete hollow blocks are 250mm (10”) wide whist the clay fired brick is usually only 103mm (4”) wide. A wider block is more stable and can be used to build taller walls with a high slenderness ratio, (width/height). A single skin 103mm wall is not considered to be stable enough except for in-fill walling between columns and beams or for relatively small structures. In our analysis of single skin brick construction we have included a buttress pillar of two bricks at 1-metre centres, which increases the brick and material requirement by 25%. It is more common to make a single skin brick wall of closer to 150mm (6”) thick and this practice can be extended to two storey construction.

2.1 Hollow concrete blocks

These are expensive due to their need for graded sand and large amounts of cement (12-17% by weight). If manufactured properly they can have a very high strength and have excellent durability. Cost reduction is achieved by removing material from the block core thus making it lighter as well. Machinery for production requires a vibrating table to settle the cement mix into the mould. Sometimes a heavy hinged lid slammed a couple of times or low pressures are applied to compress the material.

High-pressure compaction of these blocks is highly uncommon and is well out of the scope of low-cost building materials.

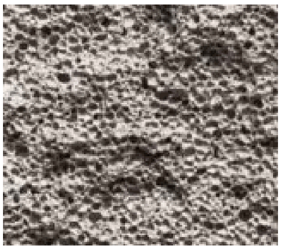
Good dimensional accuracy means that these blocks can be laid on a 10mm mortar joint. However, due to the voids in the block much mortar falls down these holes and is wasted. (In calculating the required mortar we have assumed that the mortar actually used is closer to the total surface area of the entire top surface of the block rather than just the edges where a joint is made with the neighbouring block.) These blocks are sometimes rendered for aesthetic reasons, which we will omit from any calculations for the time being.

2.2 Aerated concrete blocks

Aerated concrete is a much lighter form of concrete that omits the use of coarse aggregate and includes a high percentage of air voids in the material. A cement rich mixture has a foaming agent applied to it before the material is pumped or can be cast into suitable moulds (Neville, 1995). This material has been developed into a high performance building material and is currently marketed as aerated concrete blocks (Thermalite, 2001). The large proportion of air within the block reduces the density to around 500kg/m^3.

Although these blocks are not considered suitable for heavy-load bearing conditions, (over 7MPa), they are highly favourable to low-rise structures such as typical homes. Other features such as high wall area per block, low thermal conductivity, easily shaped by hand tools and low moisture penetration make this a highly attractive material. The production costs are reasonable as the main ingredient is coal ash from power stations, (which itself is a pozzolanic material that helps the cementitic process), but the complexity of the process makes it relatively unsuitable for small-scale manufacture. Moreover coal-burning power stations are not present in all countries



A – Aircrete B – Thermalite block C – Thin mortar joints

The above photographs show the structure of aircrete (A), it's ease of handling (B) and the high dimensional accuracy required for thin mortar joints (C). The textured surface of the blocks help to bond the to the block mortar, (if desired as it is not necessary on external walling).

2.3 Kiln fired brick

Over the centuries the process of burning clay to make brick has become more and more automated, sophisticated and complex, but not necessarily more cost effective, particularly in developing countries. (Parry, 1979) very eloquently and persuasively describes two methods of brick production in terms of cost and shows quite clearly that where labour costs are low, kiln-fired brick production would be unsuitable. Kiln-fired brick production requires a high capital investment and a significant amount of infrastructure to support production. A greater degree of material selection must be employed, staff needs to be highly skilled, spares and servicing is highly specialised and energy requirements are considerable. Production output is very high, typically 10,000 - 30,000 bricks per day and needs to be continuous if to achieve high efficiency and to achieve the greatest return on investment.

The characteristics of such kiln-fired bricks are highly desirable as the material has a high wet-compressive strength and does not deteriorate rapidly over time even in the harshest of climates (Hanson, 2001). The material is pleasing to the eye and is sought after as an attractive material for home building.

2.4 Clamp fired brick

Can be inexpensive in monetary terms because the raw materials are dug from the ground and the energy required firing the brick could come from collected firewood.

Clay fired blocks need good sources of clay for production and like graded sand must be obtained from a suitable source nearby. Forming the blocks requires a wooden or metal mould and after forming they are laid out to dry. After drying they are stacked into a clamp where fires are burnt inside (Parry, 1979). These fires raise the temperature of the blocks to the point where the particles bond together (Stulz & Mukerji, 1993). Thorough burning is necessary to fire all the blocks properly and this takes several days to achieve. The finished blocks can be quite badly misshapen and this requires a thick layer of mortar between the blocks, sometimes as thick as 20mm. Furthermore, if the blocks are poorly fired then in order to achieve adequate durability they may need to be rendered as well. Fired blocks are considered attractive and so they are not generally rendered unless necessary.

This is a particularly poor example of clamp-fired bricks and thick poorly used mortar. The result is unattractive and wasteful of cement.

However, due to the high cement content of the wall and the fired brick used it will probably achieve adequate durability.

The poor dimensional accuracy of the bricks can be clearly seen in this photograph.

2.5 Compressed and Stabilised Soil Blocks

These blocks use the same parent material as unstabilised mud but offer the significant advantage of wet compressive strength. One of the methods of stabilisation is to compact a soil sample to reduce the voids in the finished block. Compaction is achieved by applying some mechanical effort to the soil, which in turn drives out some of the air voids. Increasing the density of the material gives it a higher compressive strength and also reduces the potential for ingress of moisture into the block (Houben & Guillaud, 1989), (Norton, 1997). CSSB are further stabilised with the addition of a chemical stabiliser that helps to bind the particles together. Cement or lime are expensive additives but are generally available and although the practice of adding them to soil is reasonably popular the results can be disappointing unless it is done carefully.

Here is a good example of a wall made of stabilised soil blocks.

The blocks are approx. 0.4 × 0.2 × 0.125m and may have some voids through the centre. No render has been applied to the wall and no significant roof eaves have been used.

A solid cement rich foundation had been used to build the blocks onto. This is a high quality construction and would have been quite costly but not as much as hollow cement blocks.

CSSB can be compacted using low or high-pressures or dynamically compressed using falling weights. The greater the level of compaction the greater the compressive strength of the block and the more effective any added stabiliser becomes, (Gooding, 1993). CSSB compacted to higher densities are also usually more dimensionally consistent and therefore can be laid using a thinner mortar layer of around 10 – 15mm. Some CSSB need to be rendered in order to enhance the protection from the elements, but this can be avoided with higher levels of compaction and or higher quantities of stabiliser. Making a hollow CSSB can be done by straight-through perforations or deep and shallow frogs (Houben & Guillaud, 1989). Each of these reduces the material present and therefore reduces the stabiliser quantity necessary for each block. Removal of material from the core must be done carefully as it decreases the maximum supportive load of the blocks.

3. Criteria for comparing walling materials and assessment of current materials

There are a number of criteria we could use for comparing walling materials. For our present purposes we would like to hold ‘performance’ constant so that we can meaningfully compare some of the costs of production. Whilst different building materials have can have very different characteristics, we can suggest a minimum standard that all the materials must comply with. We have therefore chosen the following performance specification:

- bulk wet crushing strength = 1.5 MPa
- exterior surface wet crushing strength = 3.0 MPa

Blocks with this performance should be wholly adequate for low-rise housing construction up to a roof-ridge height of 8 meters (for which the bottom-course pressure < 0.15 MPa). It has been suggested that blocks that have a wet compressive strength of over 3.0 MPa can be used in tropical environments without the need for external render. We will therefore consider that a block with a similar surface strength will exhibit adequate durability for most circumstances.

Market cost is the most familiar criterion for materials comparison, but is not easy to use in situations where part of the building process is performed within the subsistence economy. A fairly universally applicable measure of resource-use in walling is ‘primary energy consumed per square meter’. This is the sum of primary energy required in the extraction and manufacture of the materials, in their transportation to site and in their final erection on site. However as the last item is comparatively small and also very difficult to estimate, we have chosen to neglect it. Transport energy obviously depends upon distance and we have chosen, for various reasons, to estimate distance as 25% of the mean spacing between points of production in one country (namely Uganda), i.e. 100km for cement and less for other materials.

For those types of walling for which cement (opc) is the main bonding agent, or is the only purchased material, cement content provides another comparative measure. The energy required to produce the cement will also be included in the energy calculations. The cement literature suggests that the energy requirements for material extraction, processing, firing and grinding for cement production is approximately 6MJ/kg.

For low-cost housing in developing countries, there is an additional criterion for comparing materials. It is their ease of access (geographical or socio-economic) to potential users. Thus a material that can sensibly be manufactured 'locally' – say on a scale of under 10,000 m^2 walling per year – is more likely to be available in an area of poor transport, and more likely to receive production investment, than a material requiring a trans-national scale of capital.

An even more severe constraint arises where the production of housing does not fall wholly within the monetary economy, i.e. where the tradition has been for householders to construct their own housing out of 'free' local materials. Actually few traditional materials meet the *wet* strength criteria listed above. However there remains a strong householder interest in making *some* use of local or on-site materials or of employing artisanal members of their own community in materials production.

3.1 Assessment results

We have therefore chosen to assess the most commonly used walling materials according to the four measures:

- Primary energy consumption in MJ per m^2 walling
- Cement usage in kg per m^2 walling
- Ranking for suitability for small-scale ('local') production
- Ranking for suitability for on-site production using mainly on-site materials

To limit the number of materials we have chosen those most prevalent in humid areas of East Africa and South Asia (excluding stone and timber walling) and added one high-tech material namely foamed PFA blocks. These are compared with two well-established variants of stabilised-soil blocks, namely low-density low-cement CSSB and high-density very-low-cement CSSB.

The table and associated notes below is a summary of a spreadsheet used to make the calculations.

Material	Dimensions (l x b x h)	Note	Energy	Cement	Suitability for production	
					'Locally'	On-site
	mm		MJ/m^2	kg/m^2	Ranking (1 = best)	
High-density CSSB	290 x 140 x 90	1	290	18.7	2	1
Low-density CSSB	290 x 140 x 90	2	420	34.1	1	1
Brick (kiln-fired)	215 x 105 x 65	3	430	8.1	2	3
Brick (clamp-fired)	215 x 105 x 65	4	1340	11.4	1	2
'Cement' block (hollow) N	300 x 150 x 200	5	430	27.0	1	2
'Cement' block (hollow) F	300 x 150 x 200	6	590	27.0	1	2
Foamed PFA-cement block	440 x 140 x 215	7	230	12.4	2	3

Notes

1. High-density (2000kg/m^3) solid blocks manufactured on-site from local soil/cement mix (5% cement), laid with 10 mm of soil/cement mortar (20% cement) and no render, (Cement transported 100km).
2. Low-density (1700kg/m^3) solid blocks manufactured on-site from local soil/cement mix (10% cement), laid with 15 mm of soil/cement mortar (20% cement) and 15mm render, (Cement transported 100km).
3. Kiln fired brick (3000MJ/1000 bricks) laid with 10 mm of sand/cement mortar (20% cement) and no render, double brick buttress column at 1m centres, (Cement transported 100km).
4. Clamp fired brick (16000MJ/1000 bricks) laid with 15 mm of soil/cement mortar (20% cement) and no render, wall has double brick buttress column at 1m centres, (Cement transported 100km).
5. Hollow (50% voids) cement blocks made from 10% cement mixed with gravel and sand from nearby source, with a 10mm mortar joint, (sand/cement, 4:1 ratio). Cement transported 100km.
6. Hollow (50% voids) cement blocks made from 15% cement mixed with gravel and sand transported from 50km away, with a 10mm mortar joint, (sand/cement, 4:1 ratio). Cement transported 100km.
7. High-tech aeration process using coal ash mixed with cement (15%) to make a very light (480kg/m^3) material. Laid with a 3mm mortar joint using cement rich paste (50% cement). Blocks transported 50km.

Of the materials listed above only three of them use less than the desired 15kg of cement per m^2 of walling, two of which are unsuitable for local production and the third has an extravagant energy requirement. High-density CSSB is the only material that uses a modest amount of cement, a low energy requirement and is suitable for local and on-site production. The following chapters will discuss other methods that may further reduce the cement requirement of High-density CSSB to less than the desired 15kg per m^2 of walling.

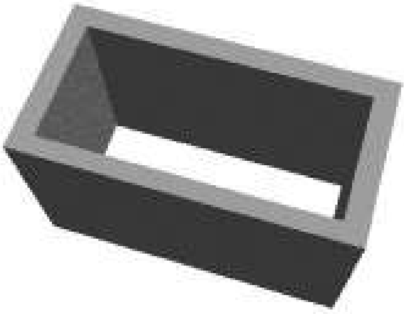
4. Perforated and indented blocks

When considering to place indentations or to perforate a block it is a good idea to determine the reasons behind existing block shapes to see what can be learnt from them. There are a huge variety of block shapes and sizes available and we shall not investigate them all. For the purposes of this study we will limit the possible shape of the blocks to those that specifically remove material from the block core to reduce material. These will include perforated blocks, deep and shallow frog indentations.

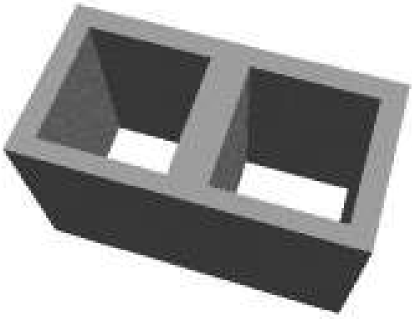
The design of a block can vary a great deal depending on the application. The standard clay fired brick includes a shallow frog that aids the process of keying the brick into the underlying mortar. This purpose of the frog is not really to reduce the overall material of the brick, but this is a beneficial result of the technique. In a similar fashion hollow concrete blocks are hollow typically for two reasons. Firstly due to their size a solid block would be much too heavy for easy manual movement and placement in a wall. Secondly the hollowness of the blocks permits the inclusion of reinforcement for more massive structures to gain sufficient strength even in areas with seismic activity.

In order to remove significant amounts of material from the centre regions of a block there must be sufficient block width to accommodate the voids left behind. Also the minimum material thickness needs to be carefully chosen so that the material does not become too weak to support the necessary loads. The drawback to including any perforations or voids in a block is that it increases the mould complexity and reduces the ease of block manufacture, particularly block ejection.

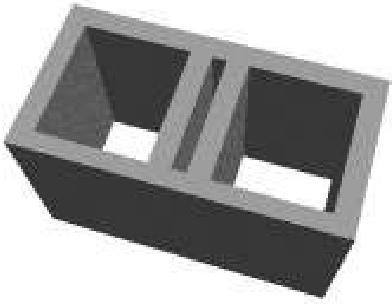
Below are a series of images depicting different types of concrete blocks with different shapes.



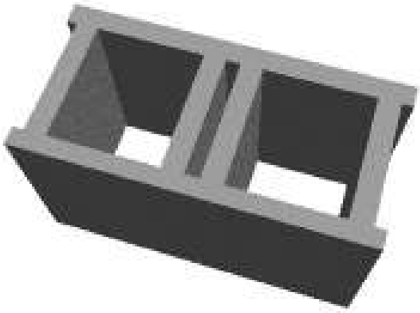
A



B



C



D

<u>NOTES</u>

Block A has the least material but mortar joints on the top and bottom surfaces are limited to the front and back face.

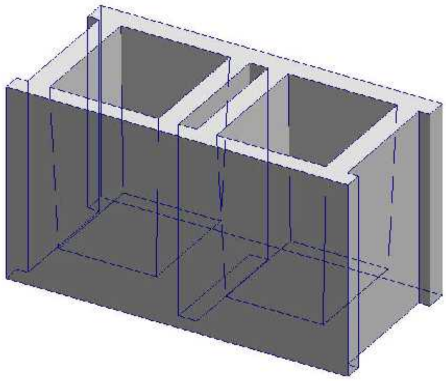
Block B overcomes this problem by putting a central web so that block tessellation can occur and good mortar contact is achieved.

Block C incorporates a double web so that the block can be more easily split into halves for wall ends etc.

Block D adds a few further flanges on the ends of the block to reduce the mortar contact area and also to help with more accurate tessellation of the blocks.

With all of the above blocks there is a significant problem with mortar falling into the holes when it is laid. A better block would have a flat surface onto which a thin layer of mortar could be placed. This idea follows the deep frog concept where a significant internal void is achieved but without going though the entire block.

An even better example of block is like the one shown below, where the internal voids don’t go all the way through. The thin lines indicate the outline of the material, more clearly showing the internal voids.



If mortar is being used to join the blocks together then a deep frog arrangement is better than the hollow section as less mortar is wasted. Chapter five of this document deals with the proposal of interlocking blocks that have no need of mortar between the courses.

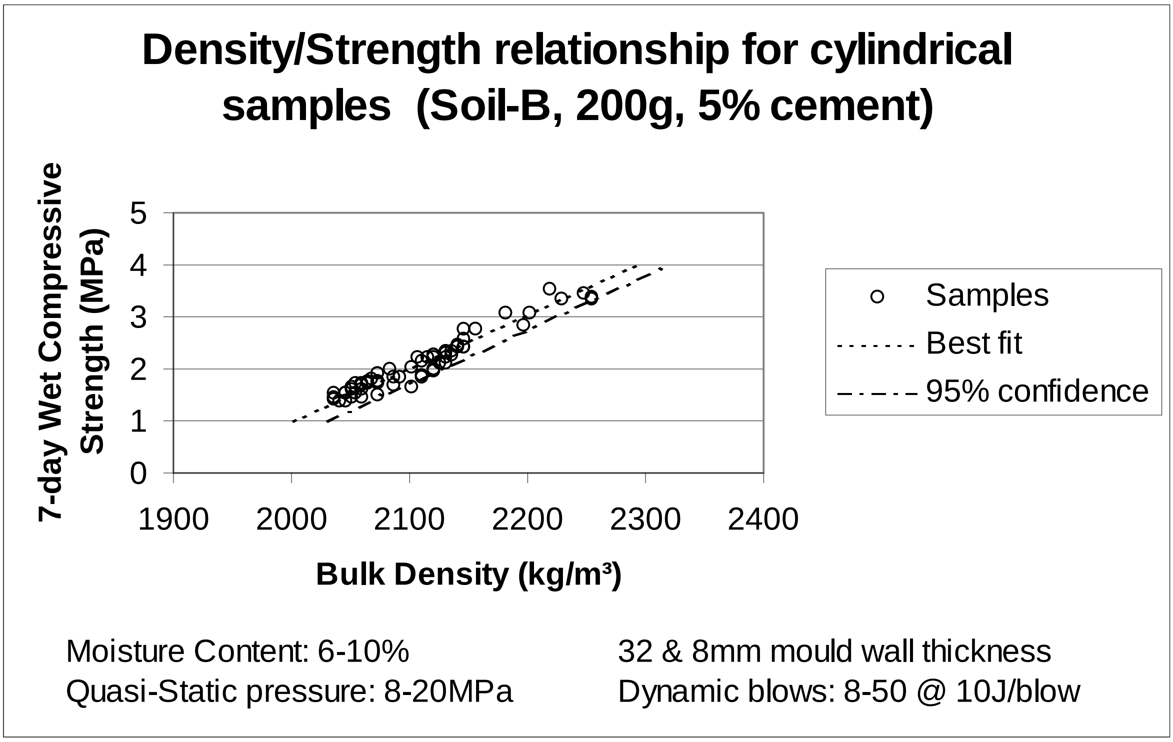
4.1 Results of material removal

In the production of low-cost building materials cost reduction is paramount, and if the cost can be reduced without jeopardising the strength of the material beyond acceptable limits then this would be a significant advantage. One obvious way of achieving this cost reduction is to reduce the amount of raw materials that are necessary to make the block, or more specifically to reduce the expensive raw materials that are necessary to make the block, i.e. opc. If the material mass of each block could be reduced by 50% then that would constitute a saving of opc of 50% in the block itself. If the material strength remained the same then the maximum load that could be applied to the block would also be approximately 50% less.

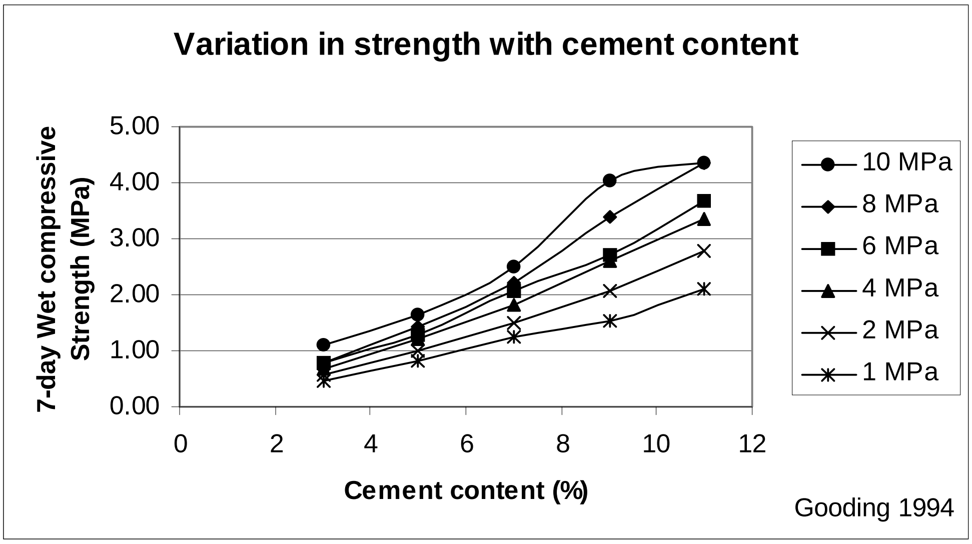
Now that we have seen a number of different types of hollow and indented blocks, we now need to assess the effectiveness and notice any implications that the addition of indentations will have. Indentations will quite clearly remove material from the core of the block and therefore reduce the amount of material required to produce each block. This removal of material also reduces the maximum load of the block itself and this should be taken into account when designing the structure.

Strengths of materials are usually given in compressive strength terms in MPa or equivalent N/mm^2. Thus block strength is directly proportional to the surface area on the compression face. In the case of a hollow block removing 50% material reduces the compressive surface area by 50%. This means that the same material will only be able to support 50% of the load. Fortunately the reduction of material from the cores reduces the mass of the block so that the mass of walling is also reduced and therefore a similar height wall can still be accommodated. In order for the block to support the same load it will need to have an increased compressive strength.

Significant indentations can only really be accommodated if the material strength is high enough and this may require the addition of more stabilisation, (compaction and/or opc). The strength of the material is dependent on the amount of compaction and the amount of opc present in the material. This relationship is not a linear one either for the compaction or for the cement. For a certain range of densities it has been found that an increase in density by 10% yields a 100% increase in compressive strength. Furthermore the doubling of the cement content has the effect of more than doubling the achieved strength of the material.



The above graph shows research results from the author's work that indicates the relationship between density and strength. It clearly shows that a small increase in bulk density can yield a significant increase in strength for the same cement content. Both the dynamic and quasi-static methods of compaction were used to make these samples the latter being much more difficult to increase the compactive effort if it is necessary.



This graph shows the change in compressive strength with extra pressure and extra cement. For the low pressure samples (1 and 2 MPa) as the cement content doubles the strength also doubles. For the higher pressure samples the fractional increase in strength for the same increase in cement is greater. This clearly indicates that the effectiveness of the cement present increases as the level of compaction is also increased.

With the combination of increasing the cement content and increasing the level of compaction it would be possible to remove significant amounts of material from the centre regions of a block without jeopardising the strength and gaining an overall reduction in costly opc.

4.2 Analysis of material removal

According the graph above a sample with 10% cement and compressed to 4MPa has a wet compressive strength of 3MPa. A standard block 0.29 × 0.14 × 0.09m and an approximate bulk density of 2060kg/m³ would have a cement mass of around 0.7kg present in it. If the level of compaction was increased to 10MPa the cement content drops to 8% to achieve the same 3MPa compressive strength. The same block has now reached a bulk density of 2160kg/m³ and would have a cement mass of around 0.58kg present in it. A more than two-fold increase in pressure results in only an 18% drop in cement content. This has already been shown to be a false economy in quasi-static compaction because this extra moulding pressure seriously increases the machinery rental and labour costs of production.

Now if half of the material present in the block is removed then the cement mass would naturally drop to 0.28kg per block which is less than half of the original value. This removal could be achieved by the inclusion of voids in the material. The higher density of the material would yield sufficient strength for forming and handling and whilst the absolute load that the block could sustain would be less, the compressive strength would still be within the required limits. This option would not be possible with blocks of lower densities, as they would not be strong enough to have such large voids placed in them and still keep strong enough for forming and handling.

4.3 Note on strength of rival walling materials

If house walls 'fail', it is usually by surface erosion, by overturning of by internal material changes like swelling. To prevent erosion we require adequate surface properties such as hardness or wet-compressive strength that are unaffected by whether or not the building blocks are hollow. To prevent overturning we look first to architectural measures such as providing adequate foundations, connecting perpendicular walls or constraining the outwards thrusts from roofs. However the block properties also affect a wall's ability to resist horizontal forces applied to its top. Increasing both block mean density (=ρ) and wall thickness (=Block width b) are beneficial. Although there are various overturning failure modes, almost all have a force threshold determined by ρb^2. For example the formation of a hinge at the wall bottom (assuming the mortar has no tensile strength) occurs when $F=\rho g b^2/2$ where F is the outward force per unit length of a wall.

The table below compares different materials by this criteria. Employing hollow blocks instead of solid ones lowers F because it lowers the mean block density ρ

Material	**Wall Thickness (b)**	**Mean Density (ρ)**	**Failure Force (F)**
	m	kg/m^3	N/m
Single skin brick	0.105	1350	74
Double skin brick	0.220	1350	327
Solid cement block	0.150	2200	248
Hollow (50%) cement block	0.150	1100	124
Foamed cement block	0.140	480	47
Low-density solid CSSB	0.140	1700	167
High-density solid CSSB	0.140	2000	196
High-density hollow (30%) CSSB	0.140	1400	137

5. Cement-rich skin

As mentioned in Chapter 3, there are several different methods that are under investigation for cement and energy reduction in the production of low-cost building materials. This chapter will briefly assess the method of putting the greatest stabilisation in the region of the block were it is needed most. This can be accomplished by either incorporating a cement-rich layer in the external face of every block, or by adding a cement render to the surface of a block which has a very low cement content.

5.1 Non-homogeneous blocks

As an alternative to reducing the cement content of the block to perilously low quantities, it may be possible to concentrate the cement in the area where it is needed most, i.e. the exterior surface. This cement rich layer would effectively be acting as a built in layer of render protecting the more fragile material behind it from the elements. For example instead of having 5% cement throughout the block one could put 10% cement in the first 20mm and have the rest of the block stabilised with only 3% cement. Providing that the cement rich layer did not suffer from de-lamination from the rest of the block, (which is doubtful if the block contains cement and the courses of blocks are joined with a cement based mortar), then this could reduce the cement demand for each block.

The production of such blocks with this cement rich layer greatly increases the complexity of the block production and construction processes. A very clear means of identification would be necessary to indicate which face of the block was cement rich, and furthermore the staff erecting the structure would need to be trained to lay the blocks in the correct manner. Homogenous blocks would also be necessary for the corners and any exposed edges, that adds another type of building material to the construction. The calculations carried out on this type of construction shows that the saving in cement is not terribly significant, (approximately 13%).

5.2 Rendered soil block construction

There are a number of reasons why a wall might be rendered. Leaving aside the aesthetic reasons, rendering is usually done to protect the walling from the elements or other forms of attack. Unstabilised walling has to be protected in humid areas and this can be achieved through the application of render. Cement-based renders do not work with an unstabilised soil wall as the coating is much too stiff to accommodate the movement of the soil wall as it absorbs and rejects moisture from the atmosphere. Lime-based renders are more suitable for this purpose. However, with more stable forms of walling, cement render is acceptable providing a good bond can be achieved to the surface of the block.

It may be possible to achieve a sufficiently high degree of surface hardness to negate the need of a render altogether as discussed earlier. This is indeed the most favourable option as the cement render is an expensive component of the walling construction if it has to be applied. In the application of render there are only really three different variables that are of interest if cost reduction is the main objective. They are the render thickness, the cement content of the render and the surface area that needs to be rendered.

The size and shape of the blocks under the render don’t have a direct effect on the quantity of render needed to cover the wall, (providing the external surface is flat). This is a pity, as larger blocks need less mortar per m^2 than smaller blocks. The same gains however are not achieved when it comes to rendering. If we assume that the thickness of the render has already been minimised and also the cement/lime content has also been minimised then the only variable left to work with is the surface area that the render covers.

A practise that has been used in developing countries is to restrict the rendering to the areas of the walling most prone to attack. This generally constitutes render application to the corners of the building and the first 300 to 600mm of walling above ground level. The vast majority of the walling is then left in barefaced brick.

This photograph shows an earth walled house with a limited amount of rendering at the lower level.

A small amount of render has also been applied to the corners of the building.

Notice too the significant roof eaves that have been constructed to protect the walls from precipitation.

If the cement was concentrated in the render on the external surface of the wall and a very small amount was used to stabilise the blocks behind the render, then this might provide a saving in cement use. If we assume that the entire wall needs to be rendered to achieve adequate durability then we can calculate the cement requirements for this type of construction. Unfortunately the calculations do not suggest that this is a favourable method of reducing the cement quantity need per square metre. Applying a 15mm render (20% cement) to a 3% cement stabilised block actually increases the cement used per m^2 by 3%. If portions of the wall could be protected by some other means and the area of rendering reduced, then this method might yield greater saving in cement use.

6. Mortar reduction methods

In the previous chapters we have seen some suggestions for minimising the cement content in the blocks and in the render, but we haven't yet discussed the mortar that joins the blocks together. The mortar used in wall construction can account for a significant part of the cement cost and if this can be minimised then this would be an added saving. Fortunately the mortar required is dependent on the size and shape of the blocks used to construct the wall and even in some circumstances the mortar may be omitted entirely like with interlocking blocks.

Mortar is necessary to carry out two basic functions, one is alignment and the other is cohesion. Due to the surface irregularities of blocks a certain amount of mortar is needed to ensure that the two faces of adjoining blocks sit well together and spread the load over the entire surface of the blocks. This layer of mortar also permits a degree of alignment so that the wall can be built to conform to a vertical face. The mortar between the blocks also creates a physical joint that will help to keep all the separate block units in the wall bonded together.

6.1 Variables affecting mortar quantity

Apart from making the mortar thinner one can reduce the mortar requirements by changing the size and shape of the block. These adjustments change the mortar requirements for each block, but also change the requirements per m^2 of walling. If the block size is increased then the mortar necessary per block increases, but the overall mortar requirement for the walling goes down. In order to determine the most important variables in wall production a spreadsheet was drawn up. It calculated the changes in cement demand for small changes in every variable that could be altered in block design and wall covering.

The table below shows all of these variables and the sensitivity that a change of that variable of ±10% gives to the overall cement requirement per square meter of walling.

	Cement (kg/m²)			
Variable	+10%	0%	-10%	Sensitivity
Block Length	34.5	34.5	34.6	0.02
Block Breadth *	37.6	34.5	31.4	-0.98
Block Height	34.3	34.5	34.7	0.06
Block Density *	36.9	34.5	32.1	-0.76
Cement content of block *	36.9	34.5	32.1	-0.76
Cement content of mortar	35.2	34.5	33.9	-0.19
Mortar Thickness	34.8	34.5	34.2	-0.08
Render Thickness	34.9	34.5	34.2	-0.11
Voids fraction of block *	32.1	34.5	36.9	0.76
Combination of four * variables	46.5	34.5	25.5	-0.89

The four main variables are 'block breadth', 'block density', 'cement content of material' and 'voids fraction'. Reducing the block breadth is not an option and we want to achieve the highest density possible to give the greatest strength.

Below is a table showing the four block variables that exhibit the greatest sensitivity to changes of 10% with the effect that each one has on the different areas of cement use, namely in the material, the mortar and the render.

	Cement mass required (kg)					Cement
Variable	Material	Mortar	Render	Total	Sensitivity	kg per m²
Standard block configuration	0.731	0.197	0.108	1.035	N/A	34.5
10% decrease in breadth	0.658	0.177	0.108	0.943	-0.98	31.4
10% decrease in material density	0.658	0.197	0.108	0.962	-0.76	32.1
10% decrease in cement in Mat.	0.658	0.197	0.108	0.962	-0.76	32.1
10% decrease in material (voids)	0.658	0.197	0.108	0.962	-0.76	32.1
Combination of all variants	0.479	0.177	0.108	0.764	-0.89	25.5

By concentrating on the variables that have a significant effect on the cement in the material and the mortar use we can suggest a combined scenario that may give a tolerable cement usage. A suggestion is shown in the table below.

	Cement mass required (kg)					Cement

Variable	Material	Mortar	Render	Total	kg/m²	Reduction (%)
Standard block configuration	0.731	0.197	0.108	1.035	34.5	N/A
25% increase in height	0.974	0.212	0.140	1.326	34.0	1
Removal of render	0.731	0.197	0.000	0.927	30.9	10
50% decrease in cement in Mat.	0.365	0.197	0.108	0.670	22.3	35
25% decrease in material (voids)	0.548	0.197	0.108	0.853	28.4	18
Combination of all variants	0.365	0.212	0.000	0.577	19.2	44

Instead of getting the cement per m² down to as low as 15 kg/m² the minimum suggested here is only 19.2kg.

Note:

Standard block to be considered as the following:

External dimensions (L × B × H) = 0.29 × 0.14 × 0.09m

Material = 2000kg/m³ (dry) with 10% cement, (NB different to Table in Ch 3)

Mortar = 1800kg/m³ (dry) with 20% cement and 0.01m thick

Render = 1800kg/m³ (dry) with 20% cement and 0.01m thick

Internal void volume = 0

This value for the cement demand per m² of walling is still too high. It is estimated that the Thermalite blocks described in Ch 2 use approximately 12.4kg of cement per m². If the mortar could be removed entirely from the example above then the total cement demand would reduce to 12.2kg per m², below our target cement consumption per square metre.

6.2 Mortarless blocks

Interlocking blocks have been available in a number of different styles for quite some time now. The designs differ but the basic principles are the same. Some form of indentation and protrusion on facing blocks form a mechanical link between the two building units. The difficulty with producing mortarless blocks is that you no longer have any freedom of adjustment during the laying process. Any alignment errors present in the lowest block course will be present in every subsequent layer on top. Not only does the bottom layer have to be set very accurately, but also every block must have a very high dimensional accuracy. An error of only 1mm in the height of a block between the internal and external face of a 150mm wide block will generate a vertical alignment error of 13mm at the top of a 2m wall. A 2mm error leads to 26mm, etc. Alignment errors approaching 25% of the block width would be of great concern as the wall stability is significantly reduced.

The other role that mortar plays is one of ensuring that the load is spread over the entire face of the block. Mortar removes any stress concentrations that would otherwise be there if the blocks were laid on top of one another. Even blocks with very high dimensional accuracy will still suffer from this. However, the process of production of stabilised soil blocks may offer a solution to both the problems of alignment and stress concentrations found in mortarless construction.

6.3 Block alignment while 'green'

When a cement-stabilised block is formed it has what is referred to as a "green strength". It is this strength that needs to be there for the block to be handled immediately after production. This strength enables the formed block to be moved from the production machine to a place of curing where blocks may even be stacked one on top of another to conserve curing floor area. Full strength of the material is not achieved for some time and the strength of the blocks at the time of production is a small fraction of the final compressive strength.

This low initial strength could be an advantage in mortarless construction. If the blocks are formed and placed directly into the wall then this may solve the two problems with mortarless construction. (The process of building walls from freshly made mud bricks is currently in use in the U.S. but these walls are not stabilised and an external render is applied to protect the bricks.) The construction of the wall in its green state enables a degree of flexibility with the material itself. As the material has a small amount of "give" to it, the different courses could be laid and as the blocks settle and begin to harden they will be taking the shape of their neighbours and therefore greatly reduce the chance of stress concentrations.

The other issue that has been raised is the one of alignment. If dimensional accuracy of ±0.5mm can be achieved then the maximum 'out of plumb' for a single storey wall would be a tolerable 13mm. However, this is a very high level of accuracy and probably not possible with CSSB production techniques. Blocks that are laid in their green state will accommodate a degree of manipulation and this may be all that is necessary to ensure that the blocks are being built in alignment with the vertical. Very slight adjustments could be made to the finished blocks during the construction process that would be impossible to do once the block has fully cured.

Even if removal of the mortar entirely is not a feasible option, the reduction of its thickness will generate great savings in cement. The thermalite blocks described in Ch 2 use a very thin mortar joint of around 3mm. The mortar is more of slurry consistency than a paste and is almost poured into position. Such a system could easily be incorporated into wall erection if the dimensional accuracy was as high as described able. Even a tolerable ±1.0mm error in the block height would still be able to use this very-thin mortar technique.

6.4 In wall curing

The process of building a wall of green uncured material generates a fresh problem of achieving a high strength successfully to an exposed material. Once the blocks are placed into the wall there is almost maximum exposure to the air and therefore to the blocks drying out. If cement is the stabiliser of choice then this drying out process must be hindered and even stopped if possible. While the blocks are on the ground or in tidy piles it is much easier to cover them and keep them moist than if they are already made into a wall.

Curing the blocks in the wall may be achievable if something could be draped over the wall that protects the block from the wind and the drying of the sun. If plastic sheets are used then this would be acceptable although would incur a greater cost even if the sheets are reused a number of times. Keeping the blocks under plastic sheets in the direct sun would have the effect of raising the temperature of the blocks and the cement within the block would achieve a higher strength faster then through normal temperature curing. This early higher strength caused by the higher temperatures would result in a slightly lower overall strength in the block once curing is finished.

The effect of temperature on pure cement is well documented and the following information just summarises some of these that may be of use in curing the blocks in the wall. The table below clearly shows that if a small reduction in final compressive strength can be accommodated then curing the material at a higher temperature can increase early strength. This may be a rather desirable side effect to construction in the humid tropics and one that should be exploited if possible.

Extracted from graph found in (Neville, 1995)

Time	Strength in MPa at curing temperature (°C)				
	20	35	50	65	80
6 hours	30	55	100	135	140
1 day	140	165	165	165	165
7 days	220	210	200	190	180
28 days	250	235	230	210	195

If three times the strength could be achieved in the material after 6 hours if it was being cured at 50°C then construction could proceed at a faster rate as well. The only problem is that we do not know if these results still apply to a material that has such a small amount of cement as would be used in CSSB production.

6.5 Tall thin blocks

The ratio of a block’s height to width is its’ slenderness ratio (height/width), (Norton, 1997), (Keable, 1996). Typically this slenderness ratio is not more than 1 but with some more advanced materials at can be as high as 2. If the height of the block is large then this will reduce the number of blocks necessary to fill the same area of walling. Another measure that we can have to assess the shape of a building block is the number of blocks required per square meter of walling. In order to maximise the use of the material therefore we want to have a high slenderness ratio and a large surface area of the external face of the block.

As mentioned in the pervious section the larger the external surface area of a block is the smaller the number of blocks needed per square metre and consequently less mortar is required. Increasing the height of the block therefore doesn’t so much as reduce the cement requirement per block as reduce the mortar requirement to lay the same area of walling.

In section 6.1 a suggested block arrangement was drawn up to try and reduce the overall amount of cement. One of the variables that were changed was the block height. This increased the amount of cement required in the material, mortar and render per block, but actually decreased the overall cement requirement per square metre. Although the decrease was quite small, if that is then applied to blocks with less cement in the material, laid with thinner mortar and without any render then significant savings can be made.

7. Conclusions and recommendations

The high-density compressed and stabilised soil block seems to be a reasonable contender in low-cost building materials. It requires less energy than all of the available competitors and slightly less cement than most of them. Variants on the CSSB can reduce the cement still further making it even more acceptable to a wider range financial capacity. Furthermore the ability for the CSSB to utilise local materials and be manufactured either on-site or very locally makes the material more suitable to cottage industries and self-build schemes.

The table below summarises the different possible variants that can be accomplished with the CSSB and how each one performs with reference to the unmodified CSSB. By combining several of these variants into a single block the material can theoretically achieve a tolerable cement requirement, (less than 15kg/m²), without excessive energy consumption. The tall, hollow, interlocking block as described below even uses less cement then the clamp fired bricks outlined in Ch 3. As this is one of the more common and more wasteful methods of making satisfactory building materials, this confirms that this variant of CSSB is a real contender.

Material	**Dimensions (*l* x *b* x *h*)**	**Note**	**Energy**	**Cement**	**Suitability for production**	
					'Locally'	**On-site**
High-density CSSB	Mm		MJ/m^2	kg/m^2	Ranking (1 = best)	
Normal	290 x 140 x 90	1	290	18.7	2	1
Hollow	290 x 140 x 90	2	220	15.1	2	1
Cement-rich skin	290 x 140 x 90	3	270	16.3	1	2
Interlocking	297 x 140 x 97	4	270	15.4	2	1
Tall	290 x 140 x 90	5	280	17.6	2	1
Rendered	290 x 140 x 140	6	300	19.3	2	1
Tall, Hollow, Interlocking	297 x 140 x 147	7	190	11.0	2	1

Notes

1. High-density (2000kg/m^3) solid blocks manufactured on-site from local soil/cement mix (5% cement), laid with 10 mm of soil/cement mortar (20% cement) and no render, (Cement transported 100km).
2. As 1. but with 30% material remove from the block core.
3. As 1. but with 10% cement in first 20mm of exterior block surface and 3% in the body of the block.
4. As 1. but with thin mortar of 3mm required.
5. As 1. but with increased block height to 140mm to reduce mortar per square metre.
6. As 1. but with 15mm render on a block with only 3% cement in the body of the block.
7. As 1. but with a combination of tall, hollow and interlocking arrangements.

Many different variants of the CSSB have already been successfully made. However, the author is not aware of any specific manufacturer that can produce the tall, hollow, interlocking CSSB variant that seems so frugal in its cement use. It is hoped that the application of compaction by impact can yield such a material without the addition of expensive machinery, but has yet to be confirmed.

Tests need to be conducted to see if such a variant of CSSB can indeed be made successfully. Following that it would need to be tested to determine whether or not it exhibits the necessary level of durability for use in the humid tropics. If these proved successful, then a pilot scheme would need to be implemented to disseminate the information and necessary technology to a suitable area where low-cost housing is needed.

AFFORDABLE WATER SUPPLY AND SANITATION

Disseminating ram-pump technology

Dr. Terry Thomas, Warwick University, UK.

FOR BOTH IRRIGATION and domestic supply, gravity feed is not always possible: water often needs lifting. The power to lift a flow of water can conveniently be expressed as

$$\text{power} = \frac{\text{constant x mean flowrate x height lifted}}{\text{duty x efficiency}}$$

where 'duty' is a time fraction (pumping hours per day) and 'efficiency' is a product of the efficiencies of the hydraulic circuit, the pump and the prime mover. Pipes are sized to give tolerable hydraulic efficiency and pumps are chosen to match the hydraulic conditions and the energy source available. Duty can also be varied to achieve better matching of the prime mover to the hydraulic circuit: high duties such as continuous 24-hour operation result in low power requirements and cheap piping (see Box on next page).

Whilst in general the power for water-lifting can come from engines, electrical mains, animals, humans or renewable (climatic) sources, in the particular context of rural areas in poor countries the choice is more constrained. In many such countries there are virtually no rural electrical mains, engines pose problems of both fuelling and maintenance, draught animals may be unavailable or difficult to apply to water lifting, renewables are erratic, complex and import intensive. Therefore human-powered lifting and transporting of water is still common, despite the very high cost of human energy (US$ 2 to 20 per kW hour).

Of the renewables, water power has the longest history, and under favourable conditions is the easiest to use. Several Asian and Latin American countries have developed the capability of building hydro-power systems. Although sites where power can be economically extracted from falling water are rather rare, they generally occur in the same terrain (mountainous) as the greatest water-lifting needs. The use of water power to pump water is therefore an interesting option. Figure 1 shows the main ways of doing this and illustrates the relative simplicity of the hydraulic ram-pump system. A typical such system is shown in Figure 2.

Ram-pumps (invented 200 years ago) are still manufactured in over ten countries and were once commonplace in Europe, The Americas, Africa and some parts of Asia. They have however been largely displaced by motorised pumping in richer countries, whilst in developing countries their use is concentrated in China, Nepal and Colombia. Ram-pump technology is not trivial: designing systems that are reliable, economic and durable (e.g. against flood, theft, silt ....) takes some experience. Generally, in rural areas of developing countries, this skill has been lost since about 1950, and the intermediaries that used to connect ram-pump manufacturers to pump users have disappeared. Old systems lie broken for lack of fairly simple maintenance: new systems are few.

Figure 1. Different configurations for water powered pumping.

For various reasons, discussed later, the potential for using ram-pumps seems to be increasing worldwide. Working, primarily in Africa, since 1985 the Development Technology Unit of Warwick University has identified several obstacles to this potential being realised, and has been trying to remove them. This paper records that experience.

Figure 2. Typical ram pump system.

The niche of the ram-pump

In suitable terrain, ram-pumps can be used to provide low-power unsupervised pumping. Typical individual ram-pumps can deliver 10 to 200 watts for lifting water; several small pumps can be operated in parallel to feed a single delivery pipe, larger pumps are available from some manufacturers. The power requirements of rural water lifting are illustrated by the following examples, which all assume pipe head losses are 10% of lift. The powers quoted are 'water watts' assuming 24 hours pumping.

domestic supply to a prosperous house (500 litres per day lifted 75m)	5W
village supply (l0,000 litres per day lifted 50m)	62W
irrigated garden (0.5 hectare) (35,000 litres per day lifted 20m)	87W

As the ram pump's system efficiency including its drive pipe is 50% to 75%, the hydro-power inputs for the examples above need to be up to twice the figures shown. The ram-pump is therefore well power-matched to these applications. These inputs are obtained at comparatively low drive heads - typically 10% of the delivery head - so the drive flows to ram-pumps are typically twenty times their delivery flows. (In the examples above the drive flow would be typically 7, 140 and 500 litres per minute respectively). This high flow requirement is clearly a constraint on location. On the positive side, however, no ram-pump user can extract more than a small fraction (e..g. 5%) of any source flow, the bulk of it being passed on downstream to other users: this has some social advantages.

Three other technical constraints require mention. Firstly there is only a limited range of head ratios (delivery height divided by drive head) of 5 to 30 over which a ram-pump is efficient and economic. Secondly neither drive head nor delivery head should exceed the particular pump's rating (often 20m and 100m respectively, but much less for cheap plastic ram-pumps). Thirdly it must be acceptable that the water lifted is derived from - and hence is of the same quality as - the drive water: a ram-pump cannot derive energy from a dirty stream to pump water from a different (cleaner) source.

Disregarding social and organisational factors, we can therefore describe the technical niche of the ram-pump as moist hilly rural areas where there is no mains electricity but a need for lifting water from streams or springs. The source must be of adequate quality and have a flow many times that to be lifted.

The problem of minor technologies

One of the more accessible concepts from 20th Century physics has been that of 'critical mass'. If the mass of a radioactive material or the size of an organisation is below some threshold its activity dies away; above that threshold the activity sustains itself and may even grow. For most technologies there is similarly a critical scale of application below which the activities needed to sustain it may die away. Such activities include manufacture of components, training of new users and specialist maintenance.

In the case of ram-pump systems, specific skills are needed in manufacture, system design, installation and operation. The skills are not especially high and overlap those needed to manufacture, install etc. other devices. Sometimes such skills are preserved in inanimate form. Thus many ram-pump manufacturers employ steel castings whose foundry patterns were made decades ago. Documents preserve design procedures. Existing installations are available as models for new systems. The critical throughput to sustain commercial manufacture is perhaps 50 pumps per year, it is usually achieved via selling into more than one country. A throughput of only one or two new systems a year might sustain system design and installation skills in a general water contractor. However, a specialist installer might need to put in at least 20 pumps a year to survive.

Box Continuous pumping versus discontinuous pumping

Water and wind powered pumps, and some electric pumps, are best operated for 24 hours per day. Solar, human and animal-powered pumps are limited to about 8 hours per day. Diesel pumps are typically run for only 2 hours per day in rural areas because they are usually over-powered for their applications. These differences in duty (load factor) have implications for pipe and storage costs. Pipes are sized so as to give a 'tolerable' friction head loss (FHL). What is tolerable depends on the means available to supply this head loss, for example pump power or the slope of the pipe. We know that, for a given length of pipe, FHL is proportional to Q^2/D^5, where Q is flowrate in the pipe and D is its diameter. Also pipe cost (per meter) is typically proportional to D^2. These relationships give the table below, which is based on a specified daily flow.

	Pumping for 24 hours/day (taken as datum)	Pumping for 1 x 8hrs/day	Pumping for 2 x 1 hr/day = 2hrs/day
Power to overcome FHL	1	x27	x1728
Energy to overcome FHL	1	x9	x144
Pipe D for constant FHL	1	x1.5	x2.7
Pipe cost for constant FHL	1	x2.4	x7.3
Typical storage ÷ daily throughput	0.4	0.5	0.4

In reviving an old technology or introducing a new one, the 'critical mass' throughputs need to be estimated. If they are higher than the area of sales or of installer operation can sustain, any intervention to promote the technology will ultimately fail. More important, if the likely demand is thought to be close to such a threshold of sustainability it is worth effort to lower the threshold.

With the technology of hydro-electricity we are used to having separate organisations making turbines, designing systems, building them and operating them. Maintenance may require a fifth agency. Even though some of these organisations operate internationally via local agents, such complexity entails uncertainties that tend to raise the critical size for each of them. Micro-hydropower utilisation has lagged behind its apparent economic potential for these reasons in most countries. Ram-pumping faces similar difficulties.

Often there is a key agency that effectively leads the others involved in a technology. For example a manufacturer of equipment may set up training for its installers, users and maintainers; alternatively a consultant may co-ordinate and supplement the existing skills of the other parties. A low value rural technology does not lend itself to the latter approach.

Experiences in Africa

The author and his DTU colleagues have been trying to revive ram-pump usage in Africa since 1985. An early analysis suggested that foreign (e.g. European) manufacturers selling a few pumps a year via agents could not and would not provide adequate training for local installers. Moreover imported pumps are expensive and difficult to source spares for. In colonial times there were few technical alternatives for water lifting to plantations, mission hospitals and large schools and it was worth the cost of bringing a ram-pump installer from another continent. Today that is an unacceptably expensive option for a village or farm needing pumped water or for a small-scale pumped irrigation scheme.

In the absence of a design consultant (again unlikely for this scenario), the options for sustainability appeared to be

either to build up the design capability of installation contractors

and/or to encourage local manufacture by an organisation also capable of providing back-up to installers.

The DTU chose the 'and' option, first spending several years in developing simple and cheap pump designs suitable for provincial manufacture and codifying system design and installation procedures. Since 1990 the DTU has been training both producers and installers from nine African and one Asian country, usually using its demonstration centre in the Eastern Highlands of Zimbabwe. There is an ongoing debate about what is the right level of manufacturing technology (hand tool, workshop with electricity, factory), whether manufacture and installation should be undertaken by the same organisation, whether low-lift irrigation or high-lift water supply should be given priority, whether installer training should be directed towards governmental, NGO or private organisations and what fraction of possible sites are 'easy' sites suitable for beginners to tackle.

The results have been mixed. Easy sites (with modest lifts, plentiful water, favourable stream geometry and well-organised customers) are perhaps only a few percent of technically feasible sites. The process of system design has proved intimidating to technicians for whom even sizing a pipe for gravity flow is at the limit of their understanding. The input of (expatriate) man and woman power to bring an installation organisation up to the level of competence and confidence to stand alone with this technology has been expensively high. The 'successes' have been with unusually well-resourced NGOs. Commercial manufacture, for example in Kinshasa (Zaire) and Mutare (Zimbabwe) has been started but self-sustaining manufacturer-installer arrangements have not been developed. Of some 30 pumps installed, too many have been 'demonstrations' rather than built to meet real water needs.

Clearly training on courses alone is not enough. Installers and manufacturers need to be visited and helped / encouraged with production of their first systems. A ram-pump has a certain 'something-for-nothing' magic about it that impresses onlookers and causes any installation to yield many enquiries from neighbouring villages or farms. However the technology's uncertainties, using very cheaply produced pumps in the hands of novice installers, makes it much easier to apply to individual 'rich' farms or institutions than to villages or communal dry-season gardens.

Ram-pump technology has a fascination for enginers and users out of proportion to its current commercial importance. The DTU's 1992 book on system design must have sold more copies worldwide than there have been new systems built! A 1993 day school on ram-pumps in Sri Lanka attracted fifty engineers but so far has resulted in no new systems.

Prospects

Ram-pumping will never be a major technology comparable with motorised pumping from rivers or hand pumping from boreholes. Its particular niche is described above: worldwide there is a potential for between perhaps 10,000 and 200,000 systems. Much of that potential lies in areas where there are currently no system design skills. Availability of pumps need not be a major problem (despite the DTU's local manufacture strategy in Africa), since even though good imported machines cost over \$10,000 per kilowatt the pump itself rarely accounts for more than 40% of system costs.

Certain trends worsen the prospects for ram-pumps. Worldwide, water sources are becoming both dirtier and weaker. Some historical ram-pump systems no longer operate because of declining drive flow. Clean spring water is usually associated with very low power levels - in Rwanda for example, the DTU had to design for 80 metre lifts from drive flows under 10 litres per minute, which is on the limits of the technology.

Factors increasing likely demand are the movement of rural populations uphill (under population growth pressures), the expansion in micro-irrigation, the introduction of local ram-pump manufacture (especially in S. America) and the availability, apparently for the first time in decades, of both trustable handbooks and training courses.

In Africa the prospects for ram-pump usage seem to depend largely on the confidence of potential installers. Despite much individual innovation there, Africa is not a continent where organisations readily take risks with unknown technology. Elsewhere in the developing world continuation of the current slow expansion of ram-pump usage will depend upon developments in photo-voltaic pumping, its most immediate rival.

The scope for technical improvement of a simple device already used for 200 years is rather small. However, modern materials may permit the pressure vessel (required to smooth the pulsating flow through the delivery valve into a steady flow up the delivery pipe) to be replaced by a pressured bladder. This will allow pumps to be operated slightly under water which has advantages for both efficiency and reliability. Understanding of the causes of erratic pump behavious and of inefficiency is now better than in the past, which designers of pumps and 'trouble-shooters' of systems can draw upon. It is not possible to totally design away temperamental behaviour, during for example system start-up, but its incidence can certainly be reduced.

For the ram-pump to fully occupy its niche, efforts must continue both to simplify the design of reliable systems and to propogate design skills. Although water-powered pumping will never attain the simplicity of "drop the suction pipe in the stream and switch on" that motorised pumping offers, as users of a renewable energy source, ram-pumps may have time on their side.

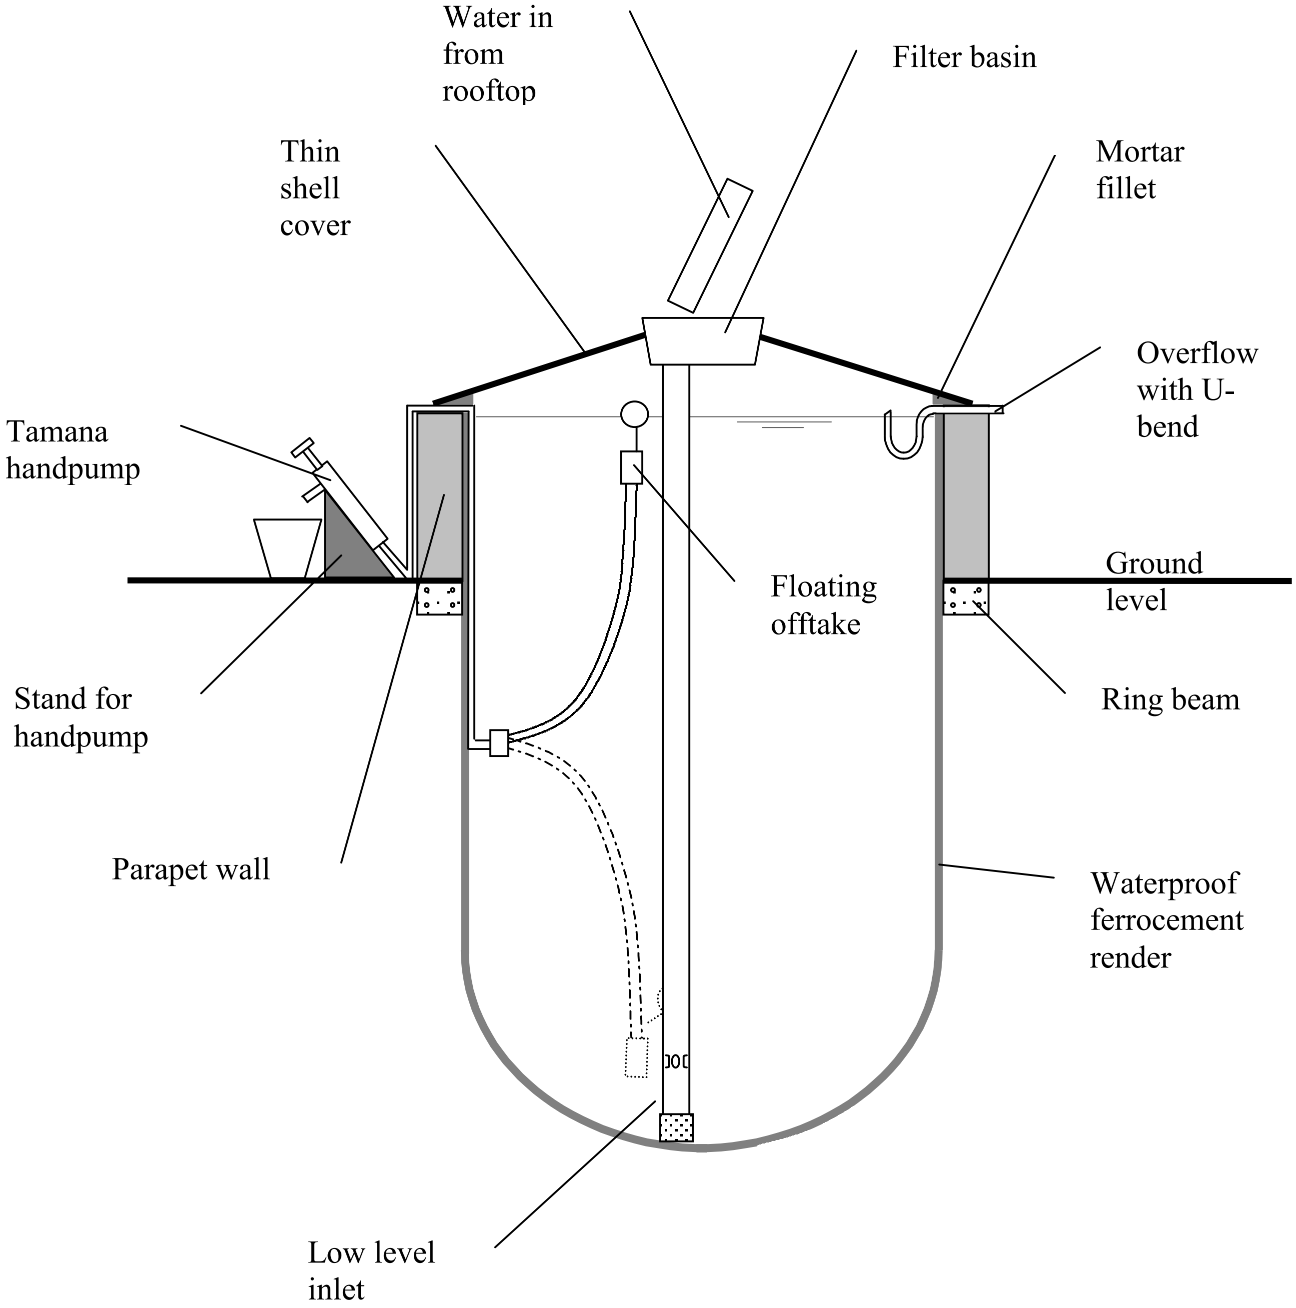

Figure 1- The Partially Below Ground (PBG) Tank

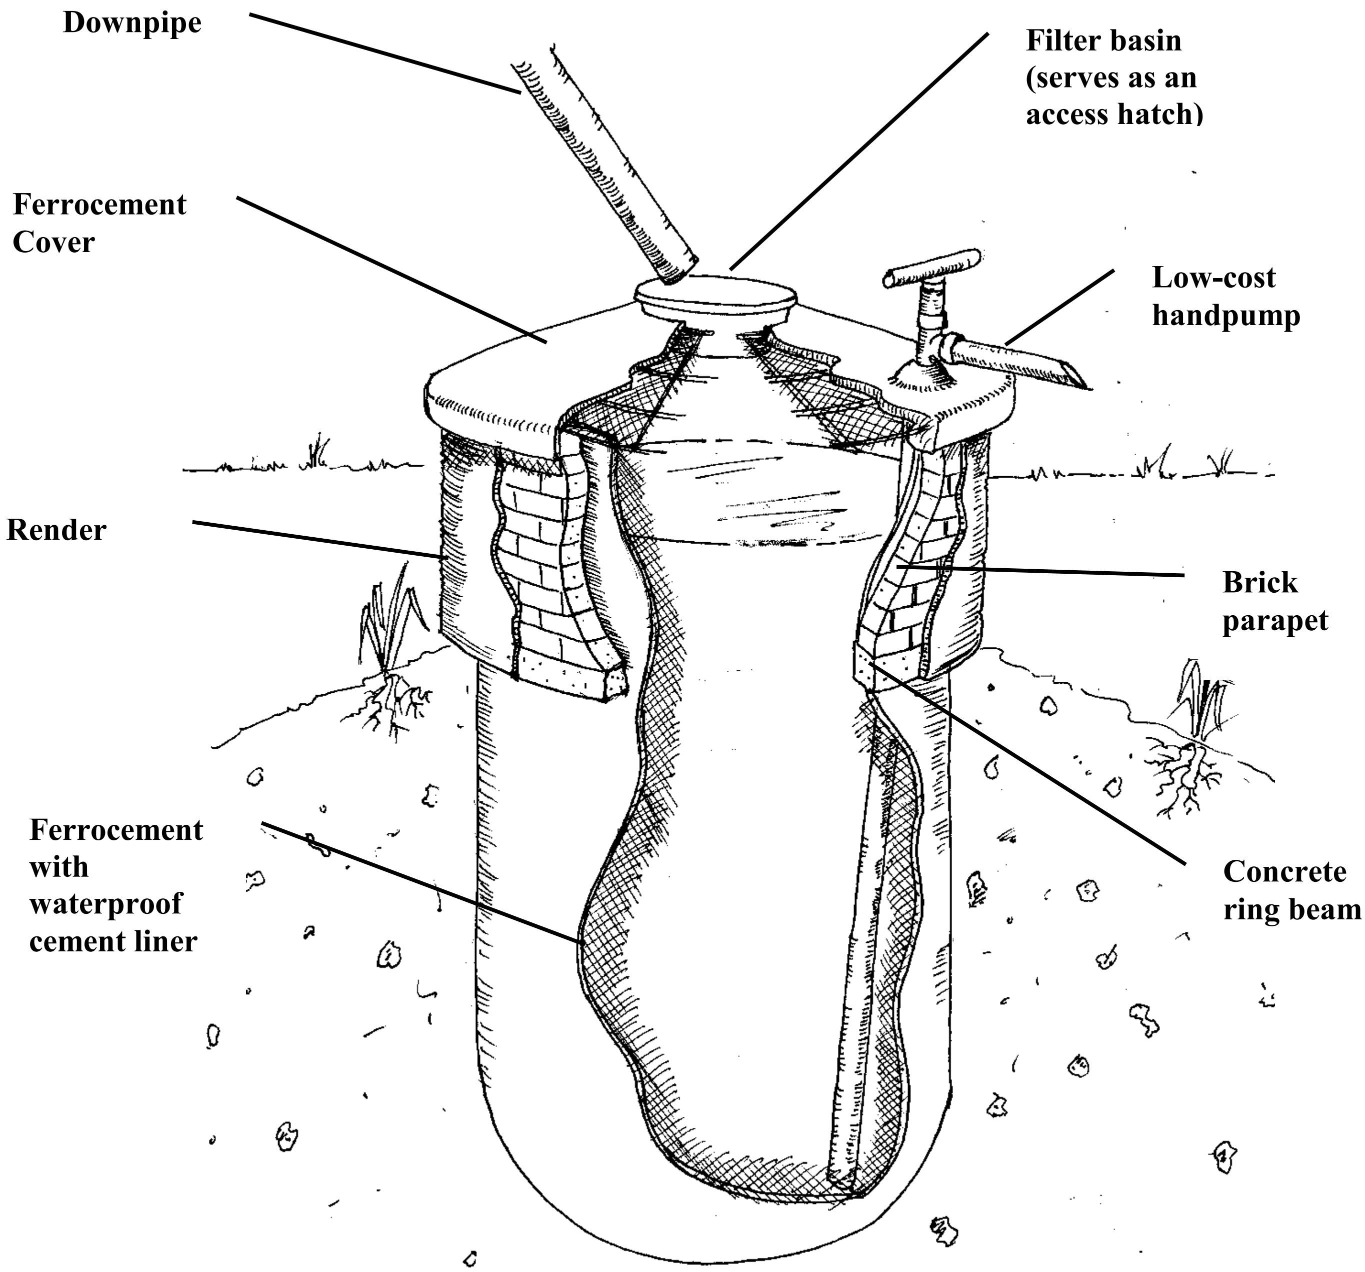

Partially below ground tank sketch

Introduction

Tanks for rainwater storage come in many shapes and sizes. The main distinction between tank types are size, shape, material and whether they are sited above or below ground.

Some of the relative merits and drawbacks of above and below ground tanks are listed in Table 1 below.

Table 1. Pros and Cons of Tanks and Cisterns

	Tank	Cistern
Pros	• Above ground structure allows for easy inspection for cracks or leakage • Many existing designs to choose from • Can be easily purchased 'off-the-shelf' in most market centres • Can be manufactured from a wide variety of materials • Easy to construct for traditional materials • Water extraction can be by gravity in many cases • Can be raised above ground level to increase water pressure	• Generally cheaper due to lower material requirements • More difficult to empty by leaving tap on • Require little or no space above ground • Unobtrusive • Surrounding ground gives support allowing lower wall thickness and thus lower costs
Cons	• Require space • Generally more expensive • More easily damaged • Prone to attack from weather • Failure can be dangerous	• Water extraction is more problematic – often requiring a pump • Leaks or failures are more difficult to detect • Contamination of the tank from groundwater is more common • Tree roots can damage the structure • There is danger to children and small animals if tank is left uncovered • Flotation of the cistern may occur if groundwater level is high and cistern is empty heavy vehicles driving over a cistern can cause damage

The partially below ground (PBG) tank incorporates the merits of both above and below ground tanks in one simple, low-cost design. The PBG tank takes advantage of the support given by the soil, to do away with the need for a structural component below ground level. At the same time protection is given against contamination by surface runoff and damage by vehicles.

To date (November 2000), about 20 of these tanks have been built in SW Uganda using render linings, often without the chicken mesh. The reports from the field have been good, and feedback suggests that the tanks are easy to construct by masons with some training, at a reasonable cost. A training course for masons was held Kyera Farm, Mbarara, Uganda in June 2000 and 8 local masons were trained in the art of constructing the PBG tank. The instructions given here for manufacturing the tank were developed for this training course.

WARNING: The PBG tank is suitable for construction where the soil conditions are stable e.g. in the lateritic soils of East Africa. If there is any doubt about the stability of the soil, then seek further advice. Working in soils that are unstable can be very dangerous, even fatal.

Instructions are given in a step-by-step guide and these should be followed carefully, especially the tips relating to curing and quality of workmanship. It is worth bearing in mind, however, that materials availability varies from place to place, and so where a given material is not available, a substitute can usually be found and the necessary amendments made.

The instructions given below are for the construction of the PBG tank without the cover or handpump (although the cost of the cover is included in Table 2). **Instructions for the manufacture of the cover and the handpump are given is separate documents – TR-RWH 04 and TR-RWH 09 respectively.**

Neither is any detail given for sizing the tank in terms of demand and supply. This information can be found in many RWH texts or on the DTU Web Page at http://www.eng.warwick.ac.uk/DTU/rainwaterharvesting/index.html

Tools and materials required

Tools – the tools listed below are for the construction of the PBG tank without the cover or handpump.

- 2 shovels
- pick
- 2 buckets
- masons hammer
- wheelbarrow
- plastering tools (if plastic liner is not being used)
- bricklayers trowel
- spirit level
- handsaw for making wooden profile
- bucket on a rope for lifting out soil
- wooden mallet (can be home-made) for tamping walls

Materials
The following are the materials required for a 10.8 cubic metre, ferrocement lined tank.

Table 2 - Materials requirement for the 10.8 cubic metre ferrocement lined PBG tank										
Item	Tank component									
	Ground leveling and ring excav'n	Ring beam	Excav-ation	Parapet wall	Parapet - external render	Internal render - first coat	Internal render- second coat	Cover	Placing cover	**Totals**

Instructions for manufacture

1. Finding a suitable site
   1.1. The first step is to find a suitable site for the tank. Some pointers for what constitutes a good site are given below:
   - Close enough to the dwelling to avoid long lengths of guttering and downpipe (some suggest siting the tank mid way along the length of a building to reduce gutter size– this is fine if water from one side of the building only will be fed into the tank)
   - Reasonably flat where possible – otherwise the ground will have to be levelled before marking out
   - Away from areas where surface water will gather (i.e. depressions)
   - Away from trees – the roots of trees can be problematic
   - Away from areas where animals will wander – or else the tank should be fenced off
   - Not so close to the dwelling that the foundations of the dwelling are undermined
   - Somewhere convenient for extracting water e.g. close to the kitchen area

   1.2. The ground should be suitable for digging and for siting such a tank. There should be no large stones, bed rock or sheet rock close to the surface, and one should be sure that the groundwater table in the area is several meters below the bottom of the tank. This information can often be gleaned from locals who may have tried digging wells, sinking boreholes or digging garbage pits.

Figure 2 - Showing the cleared ground and the markings in place for the ring beam

2. Deciding what depth the tank will be
   2.1. As mentioned earlier, the sizing of the tank in terms of supply and demand is not given in this document. It is assumed that the sizing of the tank has been carried out correctly.

   2.2. The nominal diameter of the tank is given as 2m. All the sizes given in these instructions are for a tank of 2m nominal diameter. The actual internal diameter is slightly less than this.

2.3. The actual volume of the tank is dependant, therefore, upon the depth of the tank. Table 2 below shows the volume of the tank for a number of given depths (the depth is total depth from the top of the parapet wall, which is 1.0m high).

Table 4 - depths and volumes for PBG tank			
Volume (cubic metres)	Depth of cylindrical section to be dug	Add 1m for the parapet wall and 0.95m for the hemisphere	Total depth of tank (given from top of parapet to base of hemisphere)
8.0	0.55	1.95	2.5m
9.4	1.05	1.95	3.0m
10.8	**1.55**	**1.95**	**3.5m**
12.2	2.05	1.95	4.0m

3. Casting the ring beam

3.1. Mark out two circles with inner and outer diameters of 1.9 and 2.2m respectively (i.e. radii of 0.95 and 1.10m respectively). This gives a ring beam of width 0.15m (150mm)

3.2. Dig between the lines to a depth of 150mm keeping the trench neatly trimmed and clean. A machete can be used for trimming the walls of the trench to get a good, clean finish. When completed clean out any loose earth from the trench.

Figure 3 - Casting the ring beam

3.3. Make a concrete mix of **1:2:4** (cement : sand : aggregate), using the quantities shown in Table 5. Be sure the concrete is well mixed and then place the mix into the trench being sure that any air voids are removed by 'vibrating' the concrete with a stick. Remember that wet concrete mixes will have lower final strength, so keep the mix workable but not too wet.

Table 5 - Quantity of material required for the ring beam	
	Approximate quantity required
Material	**Kg**
Aggregate (<50mm)	120
Sand (clean, graded)	60
Cement (Ordinary Portland)	30
Water (clean)	Enough to make the mix workable

3.4. The ring beam should be covered and cured for 7 days before any further work is carried out (keep the concrete wet during the curing period). Keep the beam covered with polythene during this time and wet the concrete at least twice a day.

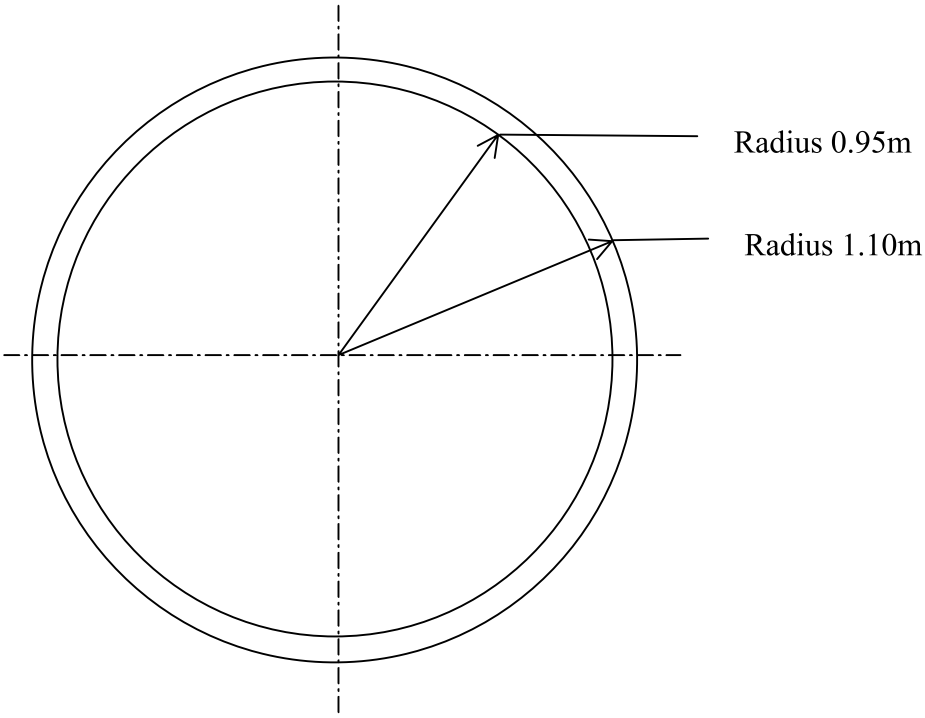

Figure 4 – Dimensions for marking for the ring beam

4. Excavating the hole
    4.1. When the beam has cured the hole can be dug. Use Table 4 to decide what depth of hole is required. The sides of the tank should be kept reasonably vertical. This can be checked occasionally using a plumb line or a masons spirit level.

    4.2. As a rough estimate of the time and manpower required to dig the hole, use the figure of 1 person-day per cubic metre of excavation.

    4.3. The bottom of the hole is shaped like a hemisphere or an inverted dome. This shape is easily dug with a shovel. A rod can be placed centrally in the ground and a piece of string used as a guide if there is any difficulty.

Figure 5 – Excavation of the tank

Figure 6 - Plumbing the walls to keep them vertical

5. Building the parapet wall
   5.1. The parapet wall is built to a height of 1.0m. It is recommended that bricks be cast and fired especially for the construction of the tank to the dimensions shown in Figures 7 and 8 below. Where this is not possible, it is recommended that a standard 100 x 75 x 225 fired house-brick is used, although other (larger) sizes can also be used.

Figure 7a – Showing the mould used for casting the bricks used for the parapet wall

Figure 7b - The bricks with profiled ends

5.2. The number of bricks required depends on the actual brick size, but assuming the dimensions are as given above, then 24 bricks per course will be required. For a height of 1.0m this will be a total of 240 to 270 bricks (10 or 11 courses depending on thickness of mortar used). This represents 6m^2 of brickwork.

5.3. Bricks should be laid with a mortar mix of 1:6. When placing the final course of bricks two small gaps should be left, one for handpump pipe, which will be placed later, and the other for the overflow pipe. This should also be cast into the wall at this stage.

5.4. The overflow trap (see Figure 9) allows overflow water to escape from the tank while preventing mosquitoes from entering the tank. The U-trap is filled with water and so mosquitoes cannot pass. A mosquito mesh also prevents mosquitoes entering the overflow pipe. The trap is made from 50mm (or similar) plastic pipe. If the U-trap is not used then mosquito mesh should be fitted over the end of the overflow pipe. The tank owner should be advised to replace this if damaged or removed.

5.5. When complete, the parapet wall can be externally rendered. This is not essential but makes the tank look better.

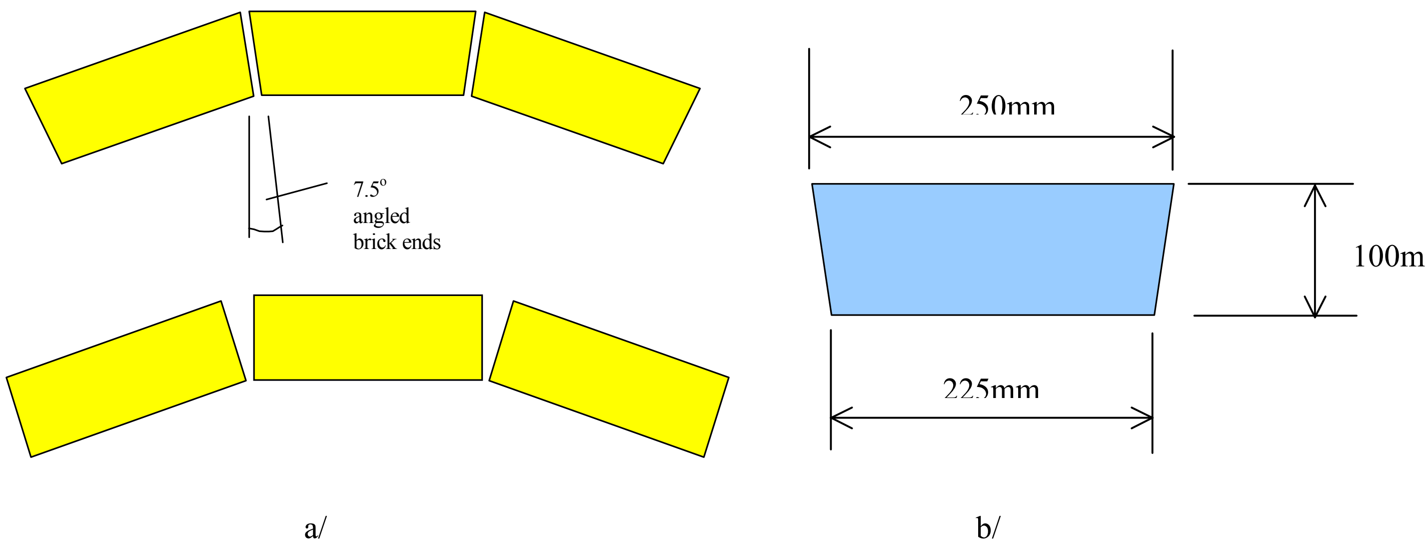

Figure 8 - a/ where bricks are cast and fired specially for tank construction, they can be cast with a slight angle at each end. To minimise the amount of mortar used the bricks should be cast with an angle of 7.5° on each end of the brick b/ showing actual dimensions of brick cast for tank construction

5.6. Material requirement for wall

Table 6 – Quantity of material required for the parapet wall		
	Approximate quantity required	
	Wall	**Render**
Material	**kg**	
Sand (clean, graded)	300	25
Cement (Ordinary Portland)	50	125
Bricks	300	
Water (clean)	Enough to make the mortar workable	

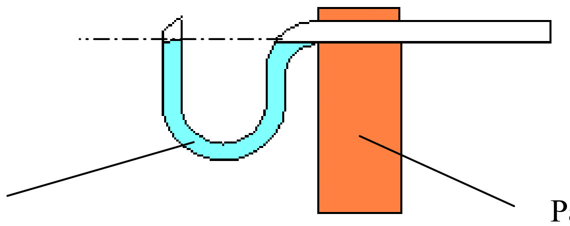

Figure 9 – The U-trap

5.7. Allow 2 skilled person-days and 2 unskilled person-days for building and rendering the parapet wall.

Figure 10 - showing the construction of the parapet wall

6. Lining and water-proofing the tank
   6.1. Any sharp stones or roots protruding from the wall should be removed. Where holes have appeared due to stones having been removed, these should be filled with clay soil and tamped hard and level with the surrounding surface.

   6.2. It is very important to achieve a waterproof lining for the tank. As mentioned earlier, one of the drawbacks of an underground tank is that it is difficult to detect leaks. We, therefore, need to be sure that the tank is well lined and will not leak under normal usage. Good workmanship here is essential.

6.3. Ferro-cement render. This technique is based on the well-known ferrocement technology that has been well documented (see Watt, 1978 and Gould and Nissen Peterson, 1999). The technique involves using a composite of cement render and galvanised chicken wire mesh. A water-proofing compound (readily available in most countries) is added to the cement render. The procedure for application is given here:

- A thin coat (~ 1cm) of 3:1 cement render is applied evenly to the wall of the tank. When the render has started to set (after about 30 minutes), score the render lightly to provide a key for the next layer.
- This first coat is allowed to cure for 2 days. The top of the tank should be covered with a plastic sheet during this time and the walls regularly and liberally sprinkled with water.

Figure 11 - showing the rendering in progress

- A layer of 1” chicken wire mesh is then applied to the render. This mesh is fixed to the render using galvanised fencing staples. Care should be taken to lay the mesh as flat as possible onto the render.
- When the chicken wire is in place the second coat of render can be applied. This is again a 1:3 mix, but includes a waterproofing agent, which is added during the mixing. Any proprietary waterproofing agent can be used and the manufacturer's instructions followed regarding the quantity to be added. The second coat of render should be applied in a similar fashion to the first – about 1cm in thickness (although it may be thicker in places to cover the chicken mesh). This second coat of render should be cured for 7 days as described above.
- The gap around the overflow pipe should be sealed using a waterproof mortar. This is done before the cover is fitted.

Scaffolding or ladders should be used when rendering the walls of the tank. See Figure 12

Material requirement for render:

Table 7 – Quantity of material required for the ferrocement lining (1:3 mix – approx. 21m^2)	
	Approximate quantity required
Material	**kg**
Sand (clean, graded)	600
Cement (Ordinary Portland)	200
Water (clean)	Enough to make the mix workable
Waterproofing agent e.g. Leak Seal Waterproofing Compound @ 2%	As per manufacturers instructions
Chicken mesh (0.9m wide)	24m length
Staples	1 kg (fencing staples)

Figure 12 - Ladders and boards used to provide a working platform

7. Fitting the handpump
   7.1. More detail of the handpump is given in another DTU publication – TR-RWH 09 "Low-cost handpumps for water extraction from below-ground water tanks - Instructions for Manufacture". The fitting and fixing procedures are dependant on the type of pump used.

8. Making and fitting the cover.
   8.1. The manufacture of the cover is discussed in a separate document TR-RWH 04 " Low-cost, thin-shell, ferrocement tank cover - Instruction for Manufacture". The cover is made independently of the tank and is fitted when complete.

Figure 13 - The tank with cover in place

8.2. The cover is easily lifted into place by 4 – 6 people. It weighs in the region of 200kg and the lifting height is 1m. Care should be taken when lifting the cover and proper safety precautions should be observed.

8.3. The cover will be mortared into place. A 2cm thick mortar is placed on top of the parapet wall and the cover is placed onto the mortar. The mortar is smoothed to seal the cover onto the wall. The mortar is also smoothed on the inside of the wall / cover joint to form a continuous waterproof lining.

9. The filter is part of the cover. When the cover is manufactured, a plastic basin is used to form the access opening. This basin is then left in place, filled with coarse gravel and covered with a fine cloth. The cloth filters out any coarse debris and should cleaned when dirty and replaced when damaged. It is easy to monitor the condition of the cloth as it is in clear view on top of the tank. The owner of the tank should be made aware of this.

Figure 14 - Showing two types of handpump (DTU and Tamana), filter basin and externally rendered parapet wall, on this demonstration tank at Kyera Farm, Mbarara, Uganda. The guttering has not yet been fitted.

10. Guttering and pipework
    10.1. The guttering and downpipe are not specified. This is due to the wide variation in the styles available. This is left to the discretion of the installer.

    10.2. In the general diagram in Figure 1, a low-level inlet is shown. This helps to prevent disturbance of the water and directs sediment to the bottom of the tank. The floating intake then takes water from just below the water's surface, where is cleanest. This arrangement is not essential but it is desirable, especially where the water is used for potable supply. The fitting of the low-level inlet again is left to the discretion of the installer. The floating intake is discussed in TR-RWH 09.

11. Maintenance. The maintenance of the tank is quite simple. The following steps should be followed:

- The tank should be cleaned annually - at the end of the dry season, the tank should be emptied and any debris in the bottom of the tank removed.
- The filter should monitored to make sure that it does not become blocked. If the cloth becomes damaged it should be replaced.
- The overflow should be covered with mosquito mesh at all times.
- The tank and associated guttering and pipework should be kept in good general repair. Any damage or faults should be rectified as soon as possible.
- The maintenance of the pump is discussed in TR-RWH 09.

Single-skin, externally reinforced, brick tank

Instructions for manufacture

Development Technology Unit
School of Engineering
University of Warwick
Coventry CV4 7AL
Tel: +44 (0)1203 522339
Fax: +44 (0)1203 418922
dgr@eng.warwick.ac.uk
http://www.eng.warwick.ac.uk/DTU/

DTU

October 1999

Introduction

The single-skin, externally-reinforced brick tank is designed to minimise material input. The single-skin brick wall, normally having insufficient hoop strength to withstand the stresses imposed by the internal water pressure, is externally reinforced with packaging strap to give adequate hoop strength to the tank. This reduces the quantity of brick required to build such a tank, with brick only, by more than half. The capacity of the tank is approximately 6 cubic metres, with an internal diameter of 2.0m and a height of 2.0m.

These instructions are based on the procedures used to manufacture a tank at the Vipassana Meditation Centre in Herefordshire, UK, during the summer of 1999. Figure 1 shows the main components of the tank (the external render is not shown in order that the strapping and brickwork configuration can be seen clearly). These instructions go through the construction procedure step by step, but it should be remembered that where identical materials are not available (e.g. using different brick sizes) then allowances may have to made to compensate for this.

Tools required for the construction process

Tool	**Number needed**
Shovel	2
Bucket	2
Trowel (large)	1
Trowel (small)	1
Float	1
Spirit level	1
Hammer	1
Tape measure	1
Ladder (trestle type)	1
Wheel barrow	1

Total time required for tank construction:

Skilled - approx 4 days
Unskilled - approx 4 days

Also needed

- Clean area for mixing mortar (preferably hard surfaced)
- Plastic sheeting for curing (5m x 5m)

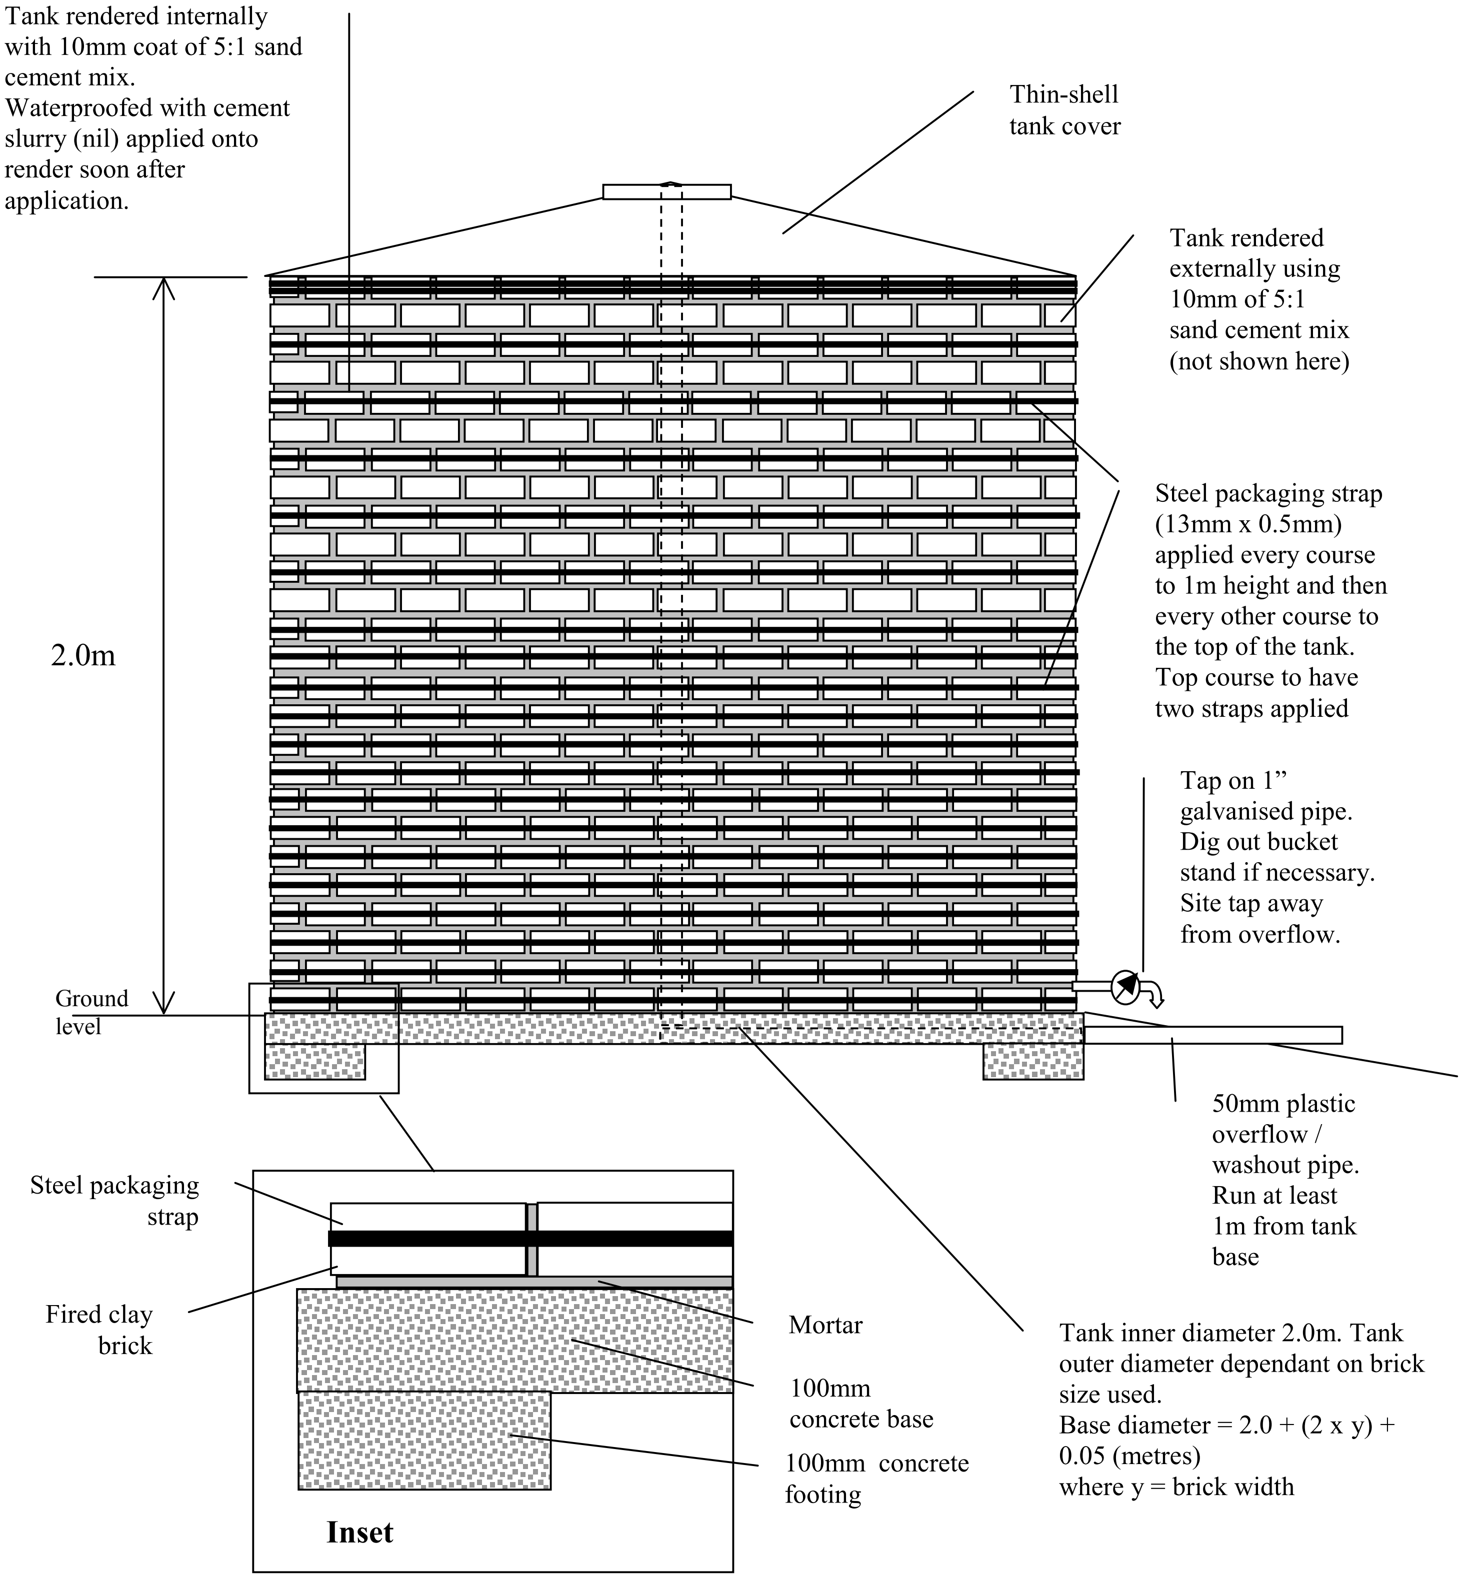

Figure 1. Sketch (not to scale) of the SSER tank, showing the main components

Laying the foundations

Material requirement (approximate)

- hardcore (for base) 1.5 tonnes
- sand 0.5 tonnes
- aggregate 1.0 tonnes
- cement 5 x 50 kg bags
- 75 mm plastic pipe 2m
  1 x 90^o elbow

(we used 63mm solvent weld rainwater downpipe, but any similar pipe will do – it has to be of sufficient diameter to act as overflow)

Time required: skilled 0.5 days
unskilled 0.5 days

Find a suitable location for the tank i.e. close enough to the catchment area to conveniently transport the water, an area with suitably firm ground with no risk of subsidence, etc. If the ground is sloping slightly take advantage of this to site overflow pipe later. If the ground is flat the base may have to be laid above ground level to allow overflow water to run off. If the latter is the case, some form of shuttering will be required (bricks can be used and reclaimed for use in the wall later).

Assuming there is sufficient slope to take the overflow pipe out as required, dig a circular hole to a depth of 250mm and to a diameter that is two metres plus twice the width of the brick being used and then add 50mm (0.05m) (see note below).

Diameter of base = 2.0 + (2 x y) + 0.05 metres

where 2.0m is the internal diameter of the tank
y is the width of the brick being used
0.05m gives a 25mm border around the base

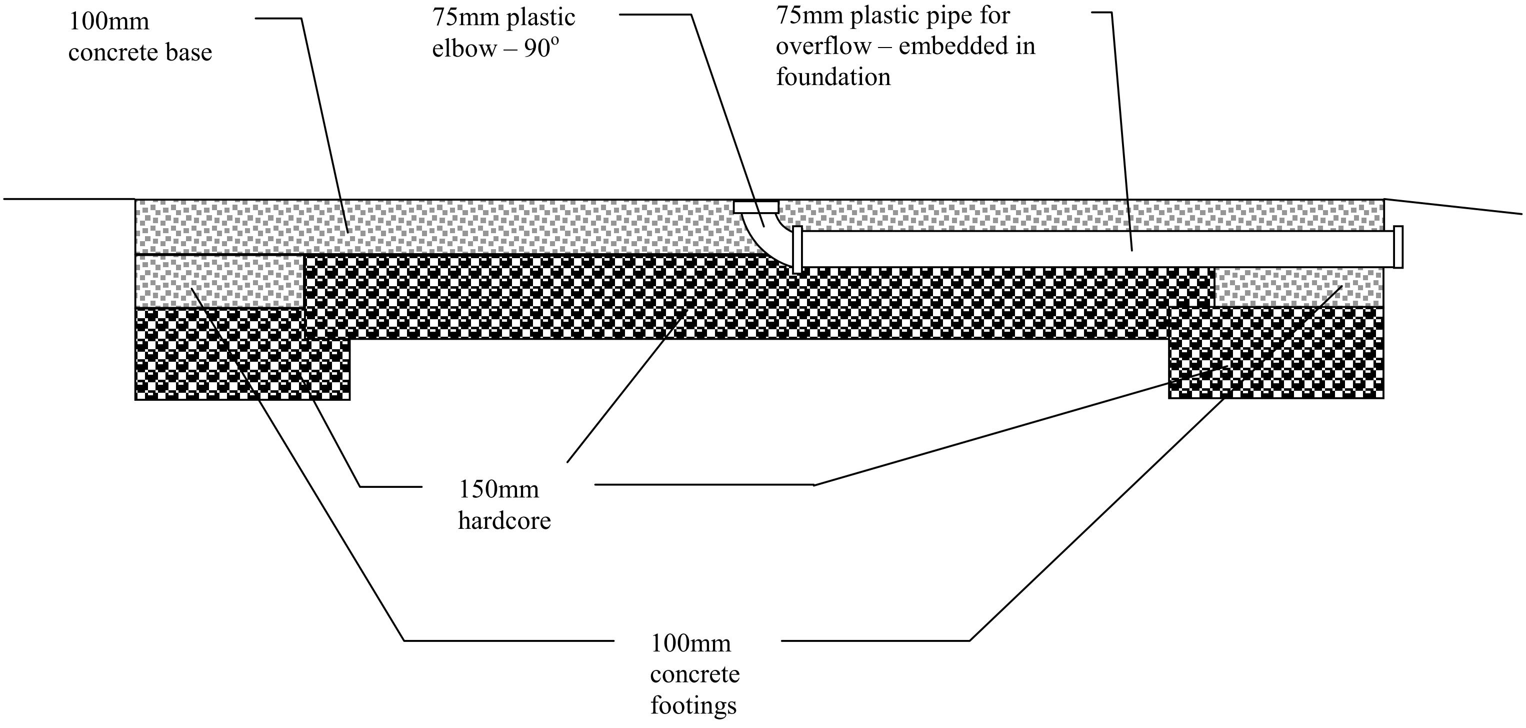

Figure 2 – details of the tank base

The footings are then dug to a further 100mm depth. The width of the footings again depends upon the width of the brick being used – allow for the 25mm border around the tank, add 50mm inside the tank wall and also make an allowance for the stone that will make up the under-base. Lay the stone to a depth of 150mm.

The overflow pipe is now placed such that it will sit partially in the stone (one third of its depth) and partly buried in the concrete (two thirds of its depth). There should be a very slight gradient on the pipe. The elbow is at the centre of the tank. Make a good seal between the elbow and the pipe.

Then peg out the area ready for the concrete. A peg is placed at the centre of the tank, next to the elbow. Pegs are then placed at regular intervals around the perimeter of the tank at the same level.

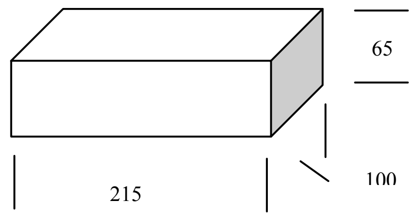
Make the base in one session. Use concrete of mix 4:2:1 (aggregate: sand: cement). Level using a tamping board using the pegs as a guide.

Building the tank wall

Material requirement:

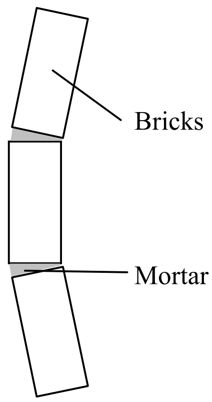
- bricks 800 (using brick dimensions shown)
- Cement 3 x 50 kg bags
- Sand 1 tonne

Time required: skilled 1.5 days
unskilled 1.5 days



Brick dimensions used on prototype

The tank wall is built simply by forming whole bricks into a circle. The bricks are not cut to shape. This leaves a slight angle between bricks but this causes no problems and is compensated for when rendering. The verticality and cylindricality of the wall can be maintained in one of two ways:



1. By using a spirit level – if the wall is set up at the base to be round and the walls are kept vertical then the tank will be perfectly cylindrical.

2. By placing a length of pipe in the elbow and bracing it in the vertical position. A length of is then loosely tied around the pipe and measured to give the desired length. This is then used as a guide for the tank construction.

Note: if the first method is used the elbow should be protected to prevent mortar falling in during construction.

The wall is built up to the required height i.e. 2 metres and a trestle ladder is used to pass mortar into the tank for building. Working from the inside is easiest – stock up enough bricks inside to finish the wall at an early stage.

The wall should then be properly cured by covering the whole with polythene sheet for 7 days and wetting the walls daily.

Applying the steel packaging strap

Kimarakwija – you will have to source a supply of packaging strap and purchase a tensioning tool and crimping tool from Kampala. Quote for the cost of the trip to Kampala, as well as the tool and crimps, in your tender. The full kit for this includes:
- steel strapping (comes in rolls of several hundred metres)
- tensioning tool (for pulling the strap tight around the tank)
- crimping tool (for crimping the strapping once in place)
- dispenser (optional tool for easily dispensing the strap – makes this job a lot easier)
- crimps (usually in a box of 1000 – for crimping the strap)

Time requirement:

- skilled 0.5 days
- unskilled 0.5 days

The strap is applied to the brick masonry specimen using a manually operated tensioning tool. Once fully tensioned the strap is crimped using specially designed crimps and crimping tool and then the tensioning tool is removed. It can be seen from Figure 8 below that the tensioning tool holds the strap away from the wall in order to allow access for the jaws of the crimping tool. When the tensioning tool is removed there is some loss of tension in the strap and so packing is placed under the strapping (pieces of broken stone can be used) before the tool is removed to prevent this loss of tension.

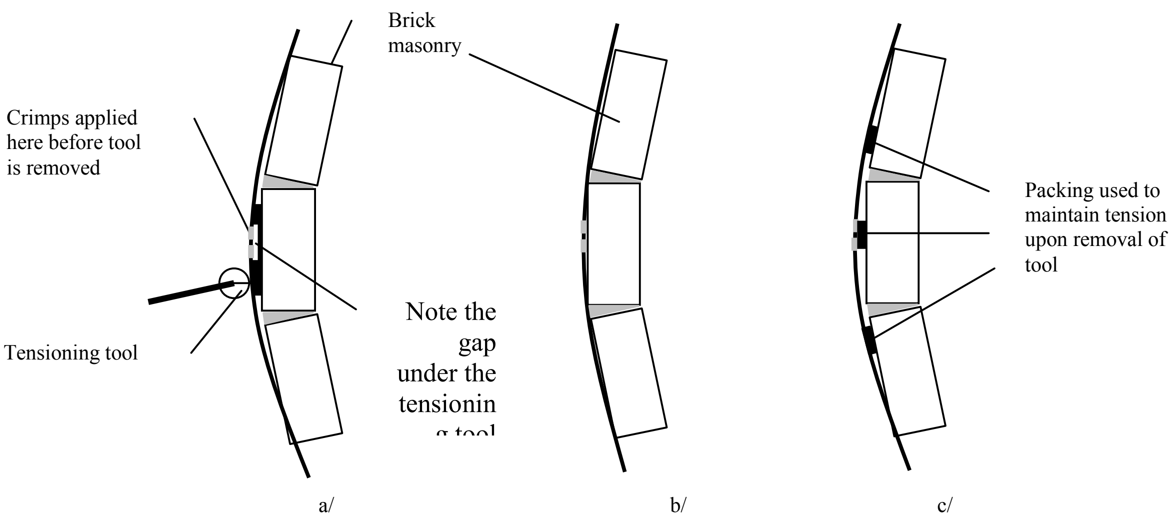


Figure 8 – showing tensioning and crimping arrangement for steel strapping a/ during the tensioning and crimping process b/ when crimping is complete and the tensioning tool has been removed and tension reduced c/ maintaining tension by using packing

The strapping is placed on every course of bricks for the lower one metre of the tank and then every other course for the upper metre. There can be some difficulty in applying the strapping on the lower two courses because of the difficulty of access for the tool. This can be overcome by digging a small hole in the ground where the tool access is required. This can be filled later.

Covering the tank
The tank is covered with a thin shell ferrocement cover. This is mortared into place. (this has been quoted for separately)

Rendering the tank
Material requirement:

▪ Cement	2 x 50 kg bags
▪ Sand	400kg (mix 4:1)
▪ Mortar plasticiser	1 litre (where available)
▪ Water	as required

Time:

▪ Skilled	1.5 days
▪ Unskilled	1.5 days

The tank is rendered both internally and externally to a thickness of 10mm (which varies due to the uneven surface caused by the angled bricks). A 5cm fillet is built up between the wall / base junction. The mix is 4:1 (sand:cement). The internal surface is then painted with a cement slurry.

Other (with detail to follow)
- A filter can be placed in the tank cover. This can be the usual bucket of gravel.
- A 2.5 metre length of pipe is required to run from the elbow in the base to the cover. This is slotted at 2m height to act as the the overflow (more detail to follow).
- Tap and galvanised pipe – I haven't yet given any information about the siting of the tap and the dugout for tap stand. Please make an estimate for this in the quotation. More information will follow

Strap dispenser

Strap showing crimps

Tank with straps in place (note the double thickness at the bottom – we do not want this any longer). The straps are painted with red oxide paint in this photo to prevent rusting as the tank will sit without render for some time during the testing phase.

Low-cost, thin-shell, ferrocement tank cover

Instructions for manufacture

Development Technology Unit
School of Engineering
University of Warwick
Coventry CV4 7AL
Tel: +44 (0)1203 522339
Fax: +44 (0)1203 418922
dgr@eng.warwick.ac.uk

November 2000

Introduction
The thin-shell ferrocement tank cover is designed in such a way that it can be manufactured without the use of a mould or shuttering. It can also be manufactured remote from the tank to which it is to be fitted and moved into place once complete. The aim is to reduce the cost of the tank (cover) by eliminating costly shuttering or moulds and by reducing the quantity of material used to manufacture the cover. It also means that the cover can be removed at a later date for maintenance, refurbishment or cleaning, should this be a necessity. The cover can be manufactured by two persons (one skilled and one unskilled) in a single day (with some time required after that for curing) using tools required for the construction of a simple cylindrical ferrocement tank.

The design is based on a frame known as a reciprocal frame, that has spokes that, when loaded, put little radial loading onto the structure on which it sits. The frame is covered with a wire mesh that is then rendered with a sand cement mix.

Details of the construction process are given here for a 2.0m diameter cover that has an inspection chamber opening of approximately 0.5m. The cover pitch is 25^{o}. Strength tests have proved acceptable up to this diameter. No guarantee is given for greater diameters. The spoke angles have to be recalculated for different diameters – this is one disadvantage of the cover design.

Benefits of the thin-shell ferrocement tank
- ♦ low cost – reduced use of materials
- ♦ no shuttering or mould required
- ♦ strong and lightweight – the tank cover is designed to be strong (through good quality control) and light at the same time
- ♦ good quality control can be achieved through easy working environment
- ♦ can be manufactured by two people in a single day (one skilled and one unskilled)
- ♦ no clambering on top of tanks required during construction
- ♦ can be cured easily – in the shade and at ground level
- ♦ can be batch produced at one site

Tools and materials required

Tools
- hacksaw
- pliers
- tin snips
- masons trowel (small)
- masons trowel (large)
- plasterers float
- shovel
- buckets (2)
- wheel barrow (optional)
- vice (handy if available)
- workbench (again, handy if available)

Table 1 – Materials required for cover

Item	Quantity
Cement (OPC) – kg	50
Sand – kg	150
6mm rebar – m	20
8mm rebar – m	20

Instructions for Manufacture

Stage 1 – making the frame

- Choose a location with plenty of space to work. The procedure requires bending long lengths of reinforcing steel and so a clear working area is essential. Also a ground space of 2m diameter will be needed where no other activity will be carried out for a week (while the cover is cured). Preferably choose a covered area, so that curing can take place out of the sun and/or rain.

- The first step is to set up a jig for bending the reinforcing bar. The jig is made up of two steel pegs or nails about 5cms long, set about 5cm apart. The steel is placed in the jig and bent as shown in Figure 1. The jig needs to be fixed so that it cannot move when the steel is bent. A workbench is ideal where the pegs can be put into the vice. Alternatively the pegs can be driven into a heavy piece of timber and this arrangement can be used effectively. Steel re-bar (8mm) can be used to form the pegs, but slightly heavier steel is better.

Tip:
When bending the re-bar it does not bend exactly where it makes contact with the jig peg. The bending takes place a cm or two on the pulling side. This has to be allowed for when bending. The bending radius can be quite large because of the thickness of the steel. This doesn't present any real problems here.

♦ The next step is to bend the 8mm reinforcing steel into hoops. Four hoops, diameter 0.55m, 1.0m, 1.5m and 2.0m are required. To make the procedure easy, a peg can be knocked into the ground and used as a centre around which the four circles can be drawn using string and a marker (also mark the positions of the 8 spokes at 45^{o} intervals for later use). The steel can then be bent gently in the jig to match the circles. The hoops ends are tied with two or three pieces of tie wire. For this the steel is cut slightly oversize to allow for tying. The cutting lengths are given in Table 3. Where the cover is to be fitted to an existing tank the outer hoop should be bent to fit the mean radius of the top of the tank wall and any irregularities in the shape should be taken into consideration.

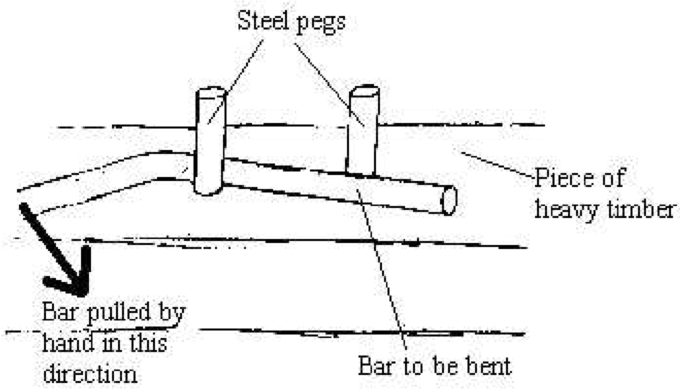

Figure 1 – Jig for bending steel reinforcing bar

Figure 2 – Workbench fitted with bending jig – the angles for the spokes are marked on the jig to make the process quicker and easier

Figure 3 – Marking out the hoop diameters before bending

Figure 4 – Tying the hoops using tie wire and a nail

Figure 5 – One of the spokes

Table 3 – Cutting list for steel hoops (8mm steel)	
Diameter	Steel cutting length (add 0.2m for overlap for tying in all cases)
0.55m	1.72m (1.92m)
1.0m	3.14m (3.34m)
1.5m	4.71m (4.91m)
2.0m	6.28m (2.48m)

- At this point all but the outer (largest) hoop can be put aside until later.
- The next step is to bend the spokes. These are from the **6mm steel** bar. There are eight in number and are bent in the jig to the dimensions shown in Figure 7. The cutting length is 1.33m. To aid the bending, the angles can be marked out on the jig (see Figures 1 and 2) beforehand and then the bent steel can be matched against the marked angles. The angles to mark are:

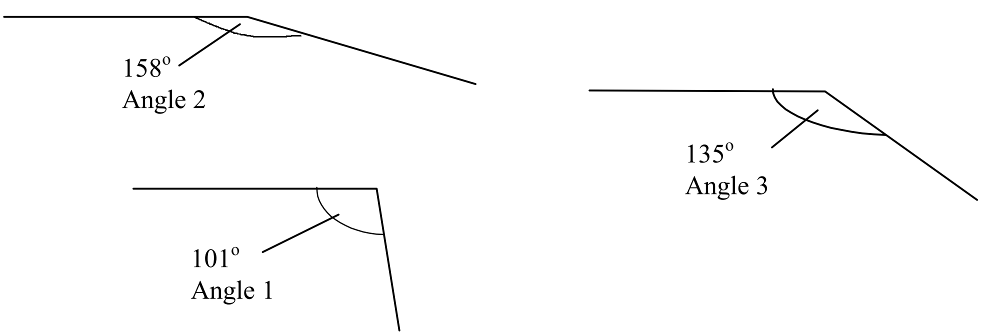

Figure 6 – Angles for spoke bending

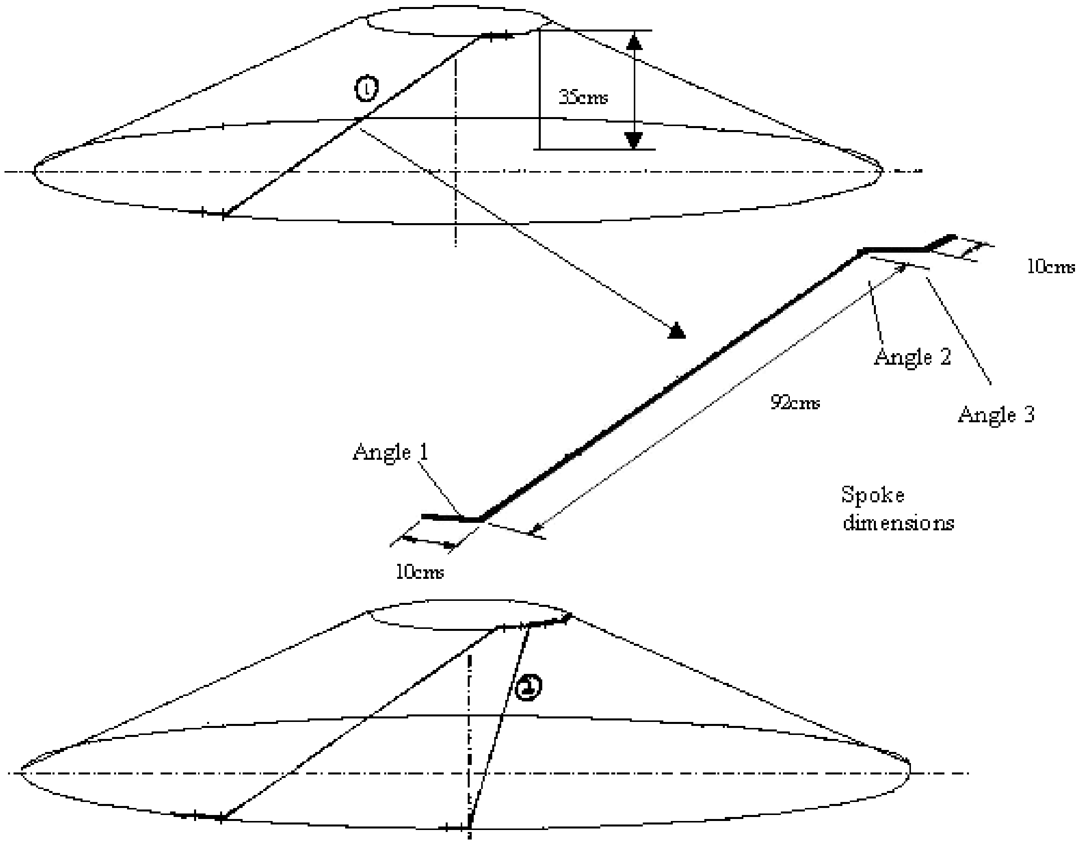

Figure 7 - Dimensions and locations of spokes

- ♦ It is recommended that Angles 1 and 3 are bent first. These are bent in the same plane. The spoke is then turned through 90^{o} and Angle 2 is bent.
- ♦ Eight secondary spokes are also cut from 6mm steel bar to a length of 75cm. These are wired to the frame as shown in Figure 8 and support the mesh to reduce the 'panel' size.

Figure 8. Assembly of the frame

- Now the spokes are placed one by one inside the outer hoop (as shown in Figure 8.) to slowly form the cover frame. It is convenient to have the outer hoop sitting on the ring marked out earlier with the position for the 8 spokes marked also. THE INNER RING IS NOT USED AT THIS POINT – There is no inner ring. This is made up as the separate spokes are joined together. (See Figure 9). Spoke one is placed on a support (a box or piece of wood) which is 35cm high. This is the height of the frame from the ground to the plane of the circular access hatch.

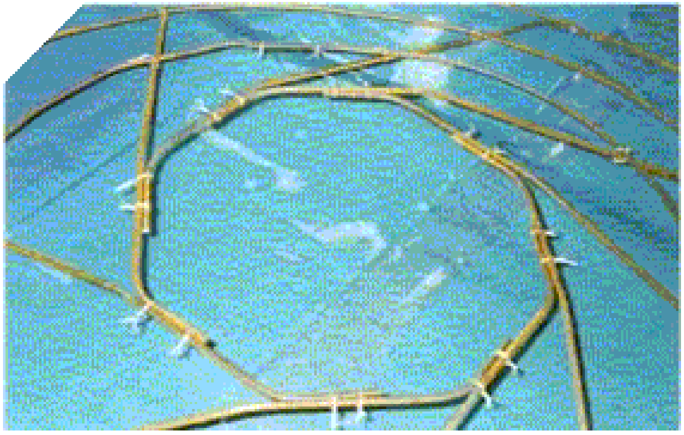

Figure 9. Showing the formation of the inner ring from individual spokes

- Tie the first spoke to the inner side of the outer hoop as shown in Figure 10.

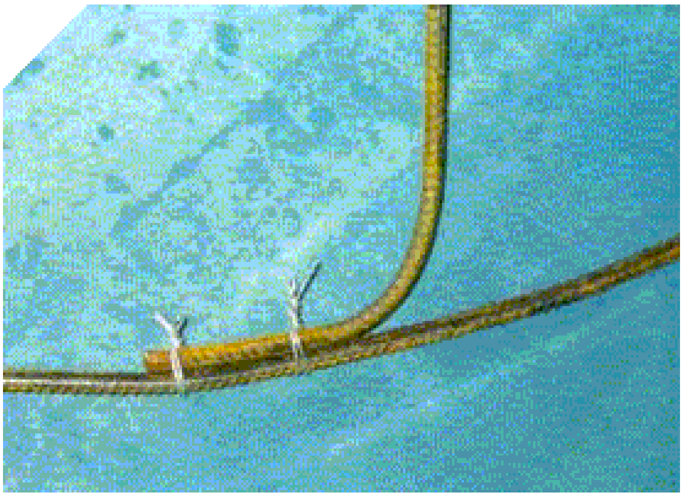

Figure 10. Showing arrangement for tying spoke to outer hoop.

- Place the next spoke 45^{o} around the perimeter hoop (these spacings were marked earlier) and tie it to the first spoke as shown in Figure 9. Continue in this way until the final spoke is tied to the first spoke and all eight spokes are in place.
- Put the two inner hoops in position and tie them in place (Figure 8). The small inner hoop that was formed earlier will be used when the access hatch lip is made later.
- The frame in now ready to have the chicken mesh or coffee tray mesh attached.

- Use chicken wire (0.5 inch mesh size) or coffee tray mesh (4mm mesh size) of 0.9m roll width. If chicken mesh is used, 9.6 metres length is required and two layers of chicken netting are applied. If coffee tray mesh is used then only one layer and 4.8m length are required.

- Eight pieces of chicken wire or 4 pieces of coffee tray mesh are cut to the dimensions shown in Figure 11. Two pieces can be cut from a 2.4m length of netting if cut as shown. A template can be drawn on the ground to aid cutting.
- Coffee mesh is easier to use, is firmer, and due to the small mesh size very little mortar is lost through the mesh during rendering. It is approximately twice the price per metre length and so the overall cost is similar as only one layer is required.

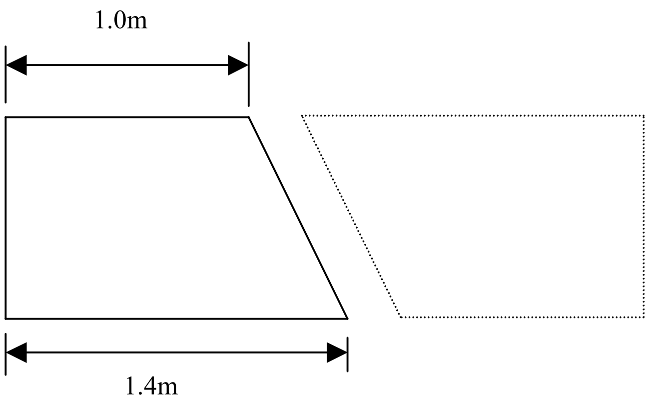

Figure 11. Cutting size for chicken mesh

- The pieces of netting are placed on the frame as shown in Figures 12 and 13 and the overlapping edges tied in place, pulling the wire as tight as is possible without distorting the mesh.

> Tip: for chicken mesh, a screwdriver can be used to pull the loose wires or end loops through holes in the mesh to tie the mesh in place. Use the rough edges of the netting to tie the folded edges into place. Use as little tie wire as possible at this point, as the netting will tied securely when the second layer is in place.

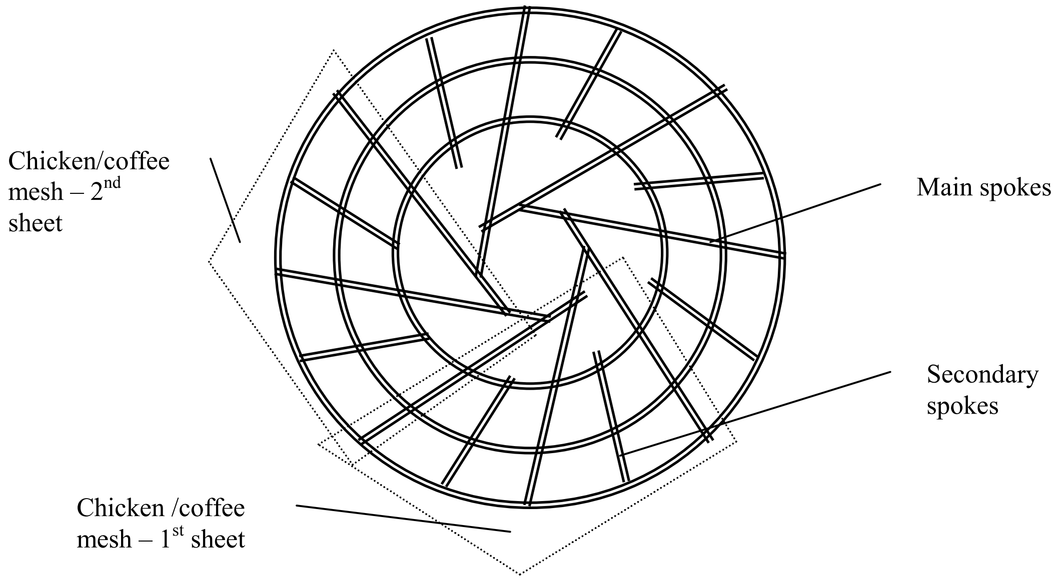

Figure 12. Pattern for application of chicken mesh

Figure 13. Applying the chicken mesh.

- ♦ When the first layer of chicken mesh is complete start the second layer one spoke (90^{o}) out of phase with the first and complete in the same manner.
- ♦ Carefully check that the mesh is as flat as possible and, if using chicken mesh, that both layers are close together. Tie the netting at regular intervals using the tie wire so that the netting is close to the steel bar. Bend all tie wires into the plane of the cover. Remember that we are trying to keep the cover as thin as possible and protruding wire ill have to be covered with mortar.
- ♦ The cover is now ready for the rendering (Figure 11).

Stage 2 - Rendering the cover

- ♦ It is important to use good quality materials and to maintain good standards of workmanship throughout the rendering process. The aim is to apply a layer of mortar to the chicken mesh that is as thin as possible. This, in practice, will vary between about 15mm and 25mm with an average thickness of about 20mm. The first coat is applied from the top and second coat applied from below.
- ♦ Put a plastic sheet on the ground so that render mix which falls through during rendering can be reused.
- ♦ Elevate the frame so that work can be carried out from above or below. Waist height is most suitable. The frame should be raised on 6 posts or boxes so that it is stable and can withstand the forces applied during rendering. A support should also be placed in the centre to prevent the centre sagging under the weight of the render (see Figure 14).

Figure 14 – the completed cover frame set on 6 supports and ready for rendering

♦ Render preparation: a mix of 1:3 (cement:sand) is used. A sharp sand should be used i.e. not a fine sand but sand with a moderately large grain size. There should be no silt or other contaminant in the sand. Ordinary Portland Cement (OPC) is used. The quantities should be carefully measured using a container – a bucket for example (do not measure using a shovel as this can be very inaccurate).
♦ The consistency of the render is very important. It should be dry enough not to fall through the netting while being plastic enough to be workable with a trowel. A mortar plasticiser will improve the workability of the render.
♦ Adding a plasticiser means that the water:cement ratio can be kept low while still keeping the render plastic. This ratio should be kept to approximately 0.4 by weight (i.e. 10 parts cement to 4 parts water by *weight*). Low water content not only gives a render which is easily applied to the mesh, but also gives improvements in strength and permeability of the cured render. In practice it is difficult to control the water:cement ratio because there is usually an unknown quantity of water in damp sand and plasticity is often achieved before the minimum measured ratio is met. The practical method involves experimentation to achieve the desired plasticity with minimum water content. The plasticiser should be used according to the manufacturers instructions.

Figure 15 – applying the top coat of render to the cover

♦ Keep mixes small because the render 'goes off' quickly. It may be wise to make a dry mix which is sufficient for the whole job and then add water to small amounts as required.
♦ Applying the render: this is fairly simple. Use a plasterers float and a small trowel. Put the float behind the mesh and work the mortar through the mesh onto the float as shown in Figure 12. Wipe the float away so that the mortar is slightly smoothed on the underside. Work small areas – take one 'panel' at a time and complete it. Some of the mortar will fall through onto the plastic sheet – this can be picked up immediately for reuse. Remember that the aim is to apply a very thin layer of mortar. The technique can be easily learned with a little practice.

♦ A basin of approximately 0.5m diameter is used to form the access hatch. The basin can later be left in situ and can act as the filter. These basins usually have sloping sides and so the basin can be inserted until it fits tightly.
♦ A lip is then built up around the basin to about 50mm deep and 50mm wide. The remaining steel hoop is built into the lip.

- Once the first layer of mortar has been applied the cover should be left for a day to allow the render to gain strength.

Figure 16 – showing the lip being built up around the basin – note the steel hoop in place

- After one day the underside can be rendered. Again use a 1:3 mix and keep the render quite thin, just covering the steel bars and wire mesh.
- The cover is then cured for 7 days. The tank should be wetted twice daily and covered with plastic sheeting to prevent evaporation of the curing water. It is essential that curing is carried out properly.
- A coat of 'nil' (pure cement water slurry) can be applied to top and bottom after two days of curing.

Figure 17 – Showing the underside of the cover after rendering is completed

Figure 18 – Curing the cover under plastic. The cover is wetted regularly during curing.

Putting the cover in place on the tank

- When the cylindrical tank body is being constructed, some thought should be given to the method of fixing the cover to the tank. If the cover is to be fitted to a thin walled ferrocement tank four (or more) tie wires should be left protruding from the tank wall and these are tied to the cover when it is in place. For brick, block or masonry walls, the cover can be laid on a bed of stiff mortar and then blended with the tank as shown in Figure 19.

- The cover can be lifted into place by four or six strong people. Special care should be taken not twist the cover or put any undue stress on it as this could cause it to crack.
- If the tank wall is quite high then a raised platform should be constructed (from earth or timber) to stand on.

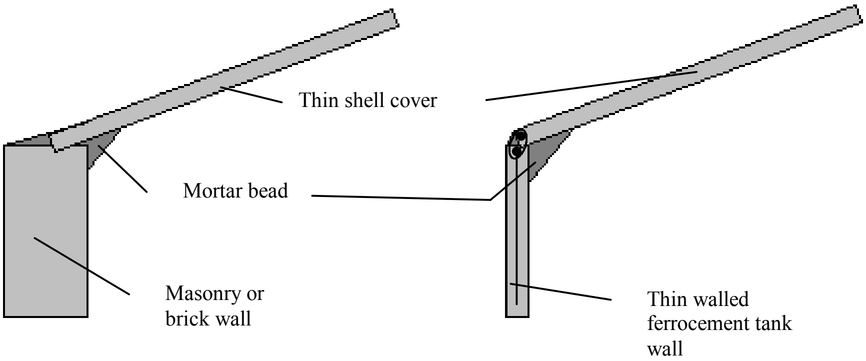

Figure 19 - Blending the cover with the tank wall.

Figure 20 – A completed cover fitted on a partially below ground tank in Uganda

Tank testing

Tests were carried out on the tank cover in the UK. The cover was uniformly loaded to 1000kg and there was minimal deflection. It was also point loaded to 160kg, again with minimal deflection and no visible sign of cracking or damage.

Figure 21 - Tank cover loaded to 1000kg

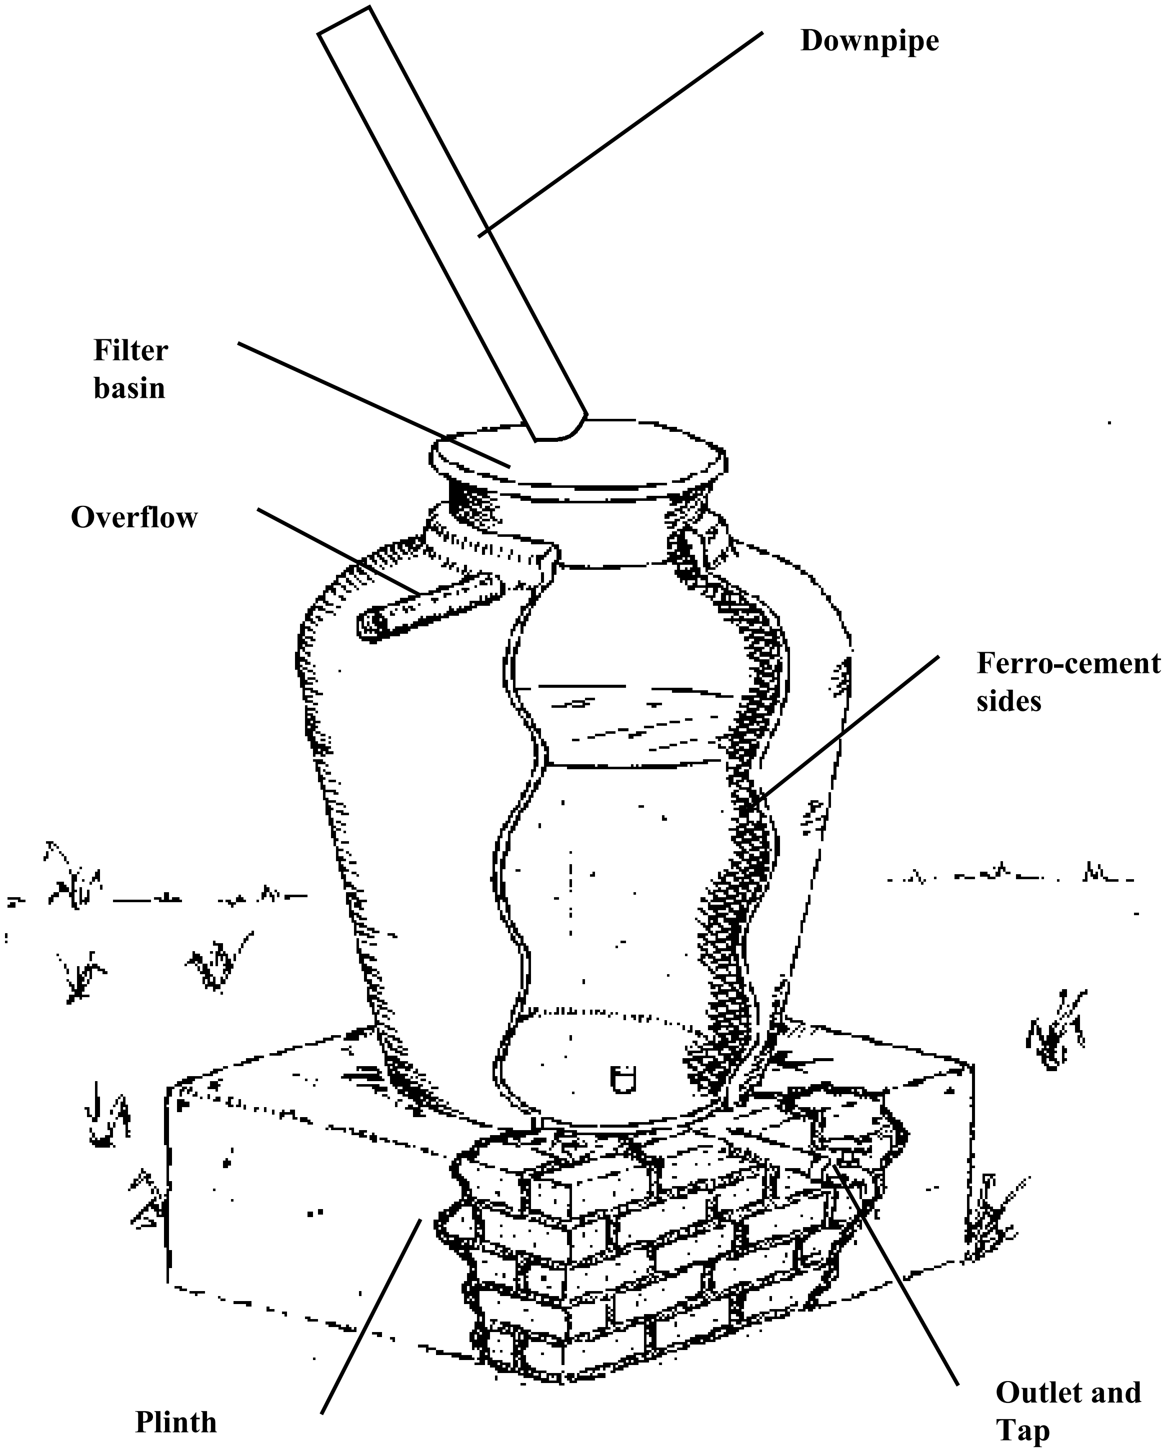
Contents:



Cutaway drawing of a ferrocement tank

1. Introduction

This manual gives guidelines for the manufacture of a 500 litre Ferro-cement Jar, which was based on a jar built at Kyera Farm, Mbarara, Uganda during June and July 2000.
The jar basically consists of a brick plinth, a Ferro-cement shell, and a filter basin.
This is a well proven technology that has been successful in Thailand, these were traditionally made from a rendered bamboo mould but now they use chicken mesh, 10 million jars were built in Thailand between 1985 and 1992.

2. Merits and drawbacks of the Ferro-cement Jar

Pros:

- Has the potential for small/large scale production by artisans.
- Very low maintenance.
- Repairs can be easily carried out.
- Low cost.
- Suitable for most ground conditions.
- Good protection against mosquitoes.

Cons:

- The level of skill required is quite high (based on recent experience in Kyenjojo, Uganda)

3. Ferro-cement Jar specifications

Table 1 gives the specifications for the jars main features:

Table 1 Ferro-cement Jar specification

Jar external diameter	0.84m (approx. at the widest point.)
Jar internal diameter	0.80m (approx. at the widest point)
Jar height	1.25m (approx.)
Jar capacity	Approximately 500 litres
Jar lining (inner surface)	Waterproof render
Wall thickness	20mm
Wall composition	Chicken mesh sandwiched between inner and outer coat of render
Water extraction	Gravity via tap
Plinth	Brickwork 0.8 x 0.8 x 0.5m
Top	PVC filter basin

N.B. See page 11 for Jar and plinth dimensions

4. Material and labour requirements

Table 2 Material and labour requirements for the jar.

	Units	Ring beam	Base	Infill	1st coat	2nd coat	Water extraction	Totals
Cement (OPC)	kg	10	12.5	6	20	20		68.5
Sand	kg	20	75	30	60	60		245
Aggregate <50mm	kg	40						40
Bricks (household size)	no		100					100
Rubble	kg			75				75
Chicken mesh 0.5" x 0.9m roll width	m					3.2		3.2
GI Pipe 1"	m						0.5	0.5
GI Elbow 1"	no						1	1
PVC Pipe 1.25"	m						0.5	0.5
Tap 0.5"	no						1	1
Reducer 1" - 0.5"	no						1	1
Basin	no						1	1
Labour (skilled)	days							2
Labour (unskilled)	days							4

5. Tools and equipment required

- Spade or shovel
- Hoe
- Spirit level (600mm)
- Bucket
- Trowels
- Plasterers float
- Tape measure (3m)
- Tin snips or wire cutters (for mesh)
- Pipe wrench

6. Jar Costing

Table 3 gives a breakdown of the materials used for the jar and their costs

Table 3 Jar costing

Item	Unit	No reqd	Unit cost	Total (UGS)	Total (US$)	Total (£)
Cement	kg	68.5	300	20550	13.70	9.26
Sand	kg	245	20	4900	3.27	2.21
Aggregate <50mm	kg	40	25	1000	0.67	0.45
Bricks	no	100	42	4200	2.80	1.89
Rubble	kg	75	0	0	0.00	0.00
Chicken mesh 0.5"	m	3.2	1667	5334.4	3.56	2.40
GI Pipe 1"	m	0.5	4200	2100	1.40	0.95
GI Elbow 1"	no	1	1500	1500	1.00	0.68
PVC Pipe 1.25"	m	0.5	1667	833.5	0.56	0.38
Tap 0.5"	no	1	5000	5000	3.33	2.25
Reducer 1" - 0.5"	no	1	1500	1500	1.00	0.68
Basin	no	1	1000	1000	0.67	0.45
Labour (skilled)	days	2	5000	10000	6.67	4.50
Labour (unskilled)	days	4	3000	12000	8.00	5.41
	Material costs			47918	31.95	21.58
	Total cost (incl. labour)			69918	46.61	31.49
	Cost per litre stoarge			96	0.06	0.04
	Cost per litre storage (incl. labour)			140	0.09	0.06

Notes

- Mould cost not included - cost of mould is approx. 6000UGS (US$3.38) and may last for up to 10 or 15 jars depending on care taken during manufacture
- Larger sizes of jar - say up to 1500 litres - can be achieved by experimenting with the mould size
- Sawdust can be obtained from local sawmills
- The volume is obtained by using a bucket of known volume and counting the appropriate number of buckets of sawdust
- Some transport costs included (i.e. for sand, aggregates and bricks)
- Cost of bucket slab not included

7. Site selection

It is important to select the right site for the jar so that it will remain a reliable source of water for years to come.

Some pointers for what constitutes a good site are given below:

- Good ground stability (i.e. not sandy soils).
- Jar should be close enough to the dwelling to avoid long lengths of guttering and downpipe (some suggest siting the jar mid way along the length of a building to reduce gutter size– this is fine if water from one side of the building only will be fed into the jar).
- Reasonably flat where possible – otherwise the ground will have to be levelled before marking out.
- Away from trees which may undermine the foundations and cause cracking.
- Away from areas where animals will wander – fence off if needed.
- Not so close to the dwelling that the foundations are undermined.
- Somewhere convenient for extracting water e.g. close to the kitchen area.
- It must be a suitable distance away from vehicle access as this may cause ground movement, fence off if necessary.

8. Manufacturing procedure for the jar

- Prepare a level piece of ground approximately 1.0m square.
- Mark out an inner and outer square with sides of 0.85m and 0.0.55m respectively as shown in Figure 1.

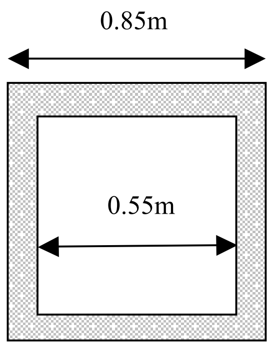


Figure 1 Inner and outer squares for the plinth foundations

- Carefully excavate between the two squares to a depth of 10cm. (NB if soil tends to be unstable excavate to 20 cm deep and fill with aggregate 10cm deep, alternatively make a larger deeper ring beam)
- Fill the excavation with a concrete mix of 4:2:1 (aggregate: sand: cement) and cover with damp grass/leaves and leave for two days.Start building the brickwork, with a plinth outer size of approximately 0.8m, on top of the concrete ring using a mortar mix of 5:1 (sand: cement) to a height of 0.55m as shown in Figure 1. Leave a gap in the top course of bricks for the outlet pipe.

- Fill the centre of the plinth with rubble/aggregate, compacting it well to prevent later settling.

Figure 1 Brickwork plinth

- Cut off a length of ∅3/4" GI pipe and fit on a ∅3/4" elbow at one end and a ∅3/4" to ∅1/2" reducer and a ∅1/2"tap at the other. Local plumbers can thread the GI pipes, alternatively a low cost method of threading ∅3/4" PVC pipe is explained in Appendix 1.
- Cut off a piece of pipe 25mm long pipe that has been threaded at one end and fit this to the elbow. This will give the jar a settling zone, but it can also be removed for washouts.
- Dig out a channel in the rubble and place the pipe in so that the tap and the elbow are vertical. N.B. make sure the top of the elbow is 3cm above the level of the rubble.
- Apply a 1cm layer of mortar to the top of the rubble and flush with the edges of the plinth, apply a layer of damp material and cover with plastic sheet, leave this to cure.
- Prepare a disc of mortar 0.6m diameter by 1cm deep on to the plinth base.
- Cut out a ring of chicken mesh to a diameter of 0.75m and turn up the edges 0.1m, so that it leaves a base diameter for the jar of 0.55m.
- While the disc of mortar is still damp lay the chicken mesh on to the top of this and then apply another layer 1cm deep to the mesh this should be level with the top of the elbow.

- Cut out and sew up a polypropylene or hessian sack to the dimensions shown in Appendix 2.

Figure 2 The filled polypropylene sack mould

- Fill the sack mould with sawdust (rice husk, coffee husks, sand or any other similar available material) and compact it as it is being filled. When full tie it up at the top and pat the sides to produce an even symmetrical shape then place this on the prepared base of Ferro-cement as shown in Figure 2. The capacity of the jar can be determined by filling the sack with buckets of known volume, simply count the number of buckets to until 500 litres is achieved.
- Place a medium sized basin centrally on top of the mould with a short length of PVC pipe for the overflow. Apply the first coat of mortar of 3:1 mix with a waterproof additive (quantity as per manufacturers instructions) to a thickness of 1cm as shown if Figure 3, (the thickness may vary as the irregularities of the mould shape is compensated for)

Figure 3 Overflow, filter basin and first coat application

- When the first coat has been applied cover with a damp cloth and a plastic sheet, leave for 24 hours, making sure the cloth is kept damp.
- Wrap around the jar a suitable length of chicken mesh to cover the whole area up to the filter basin pull the mesh tight and fix with short lengths of wire to secure in place as shown in Figure 4.
- Apply the second coat of mortar (make this layer smooth by rubbing over with a small wooden hand float) also apply mortar around the tap outlet to secure it to the base and jar side as shown in Figure 5.

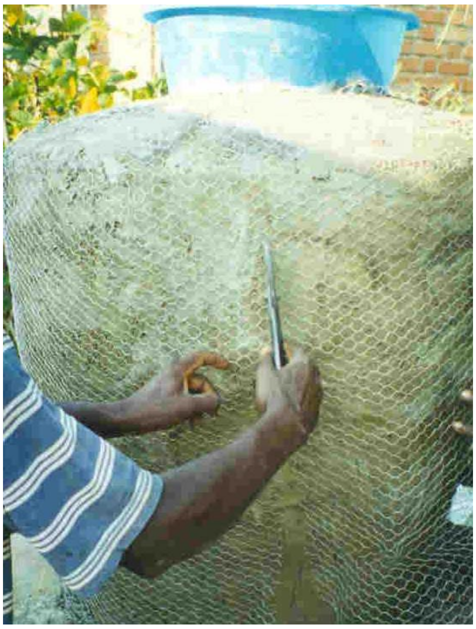

Figure 4 Applying the mesh on top of first coat

- Cover the shell again with a damp cloth and a plastic sheet, leave for 48 hours.
- When the shell is firm carefully remove the filter basin and untie the mould bag, and carefully take out the contents.
- Fill the bottom of the jar with enough water to come up to the level of the outlet pipe and replace the damp cloth with the plastic sheet and leave for 7 days to cure.
- Make a series of about twenty holes in the bottom of the basin using a hot nail or a drill (Ø6mm) for the rain to enter the jar. Fill the basin with aggregate (about 20mm) to about one third full.
- Cut out a section of clean cloth that will cover the basin and have sufficient to overhang down the sides, then tie around the sides of the basin with string or rubber inner tube strip to hold the cloth in place.

Figure 5 Detail of the outlet fixing

- Lower the basin on to the top of the jar.
- Fix the appropriate gutter to the roof and place the downpipe directly on to the cloth.
- Cut out a small piece of mosquito mesh and fit this on to the end of the overflow pipe with string/twine etc.

9. Care of the jar on completion

Once the jar is finished and has cured for 7 days, fill with 125mm (5”) of water each day so that the structure is gradually loaded rather than all at once.
It may be noticed that the jar will leak slightly somewhere around the sides, it is best if this is left for at least a week, as quite often the jar will eventually seal itself if the hole is small (based on masons personal experience in Uganda). However, if it shows no sign of sealing or the hole is quite visible, empty the jar and make the repair with a nil mix (i.e. purely a cement and water mix) from the inside of the jar.
It is important that there are no gaps around the filter and cover, or around the filter where light can enter as this will not only encourage the growth of algae but may be an entry point for mosquitoes both of which should be avoided. The water may have a cement taste at first so either rinse out well several times or use the jar for washing rather than cooking for the first few times.

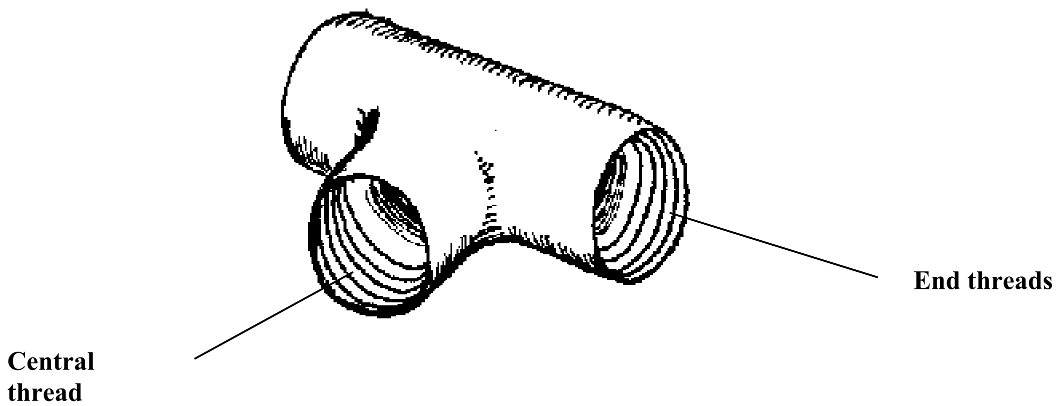
Appendix 1: Low cost threading of PVC pipes using a standard galvanised iron (GI) pipe fitting

There are many occasions were threads are required on PVC pipes so that other fittings can added to the pipe. This often involves the use of expensive threading equipment, which is not always available when needed and the charge for this service can become expensive when it is done repeatedly.
The method described here was tried out in Uganda after finding the problems mentioned above and was found to be a useful and successful solution that was very low cost. Though it requires some tools, a little bit of skill and some patience, once it has been made it will last for many threading operations and re-sharpening is simple to do.
The following example is for a ∅½” PVC pipe but the same procedure is carried out for other sizes:

Tools required:

One hacksaw blade (preferably with 24 teeth per inch)
A small (6”long) triangular file (the width across the faces should preferably be no more than about 3/16”or 4mm)
Pipe grips or a vice.
10” rough flat file.

The reliability of the threads for higher pressure applications has not been checked and care will be needed when trying this out.



1. Take a normal GI ∅½” Tee fitting as shown in Figure 1 and make three equally spaced saw cuts with the hacksaw blade in the central part of the Tee to just beyond the roots of the thread as shown in Figure 2.

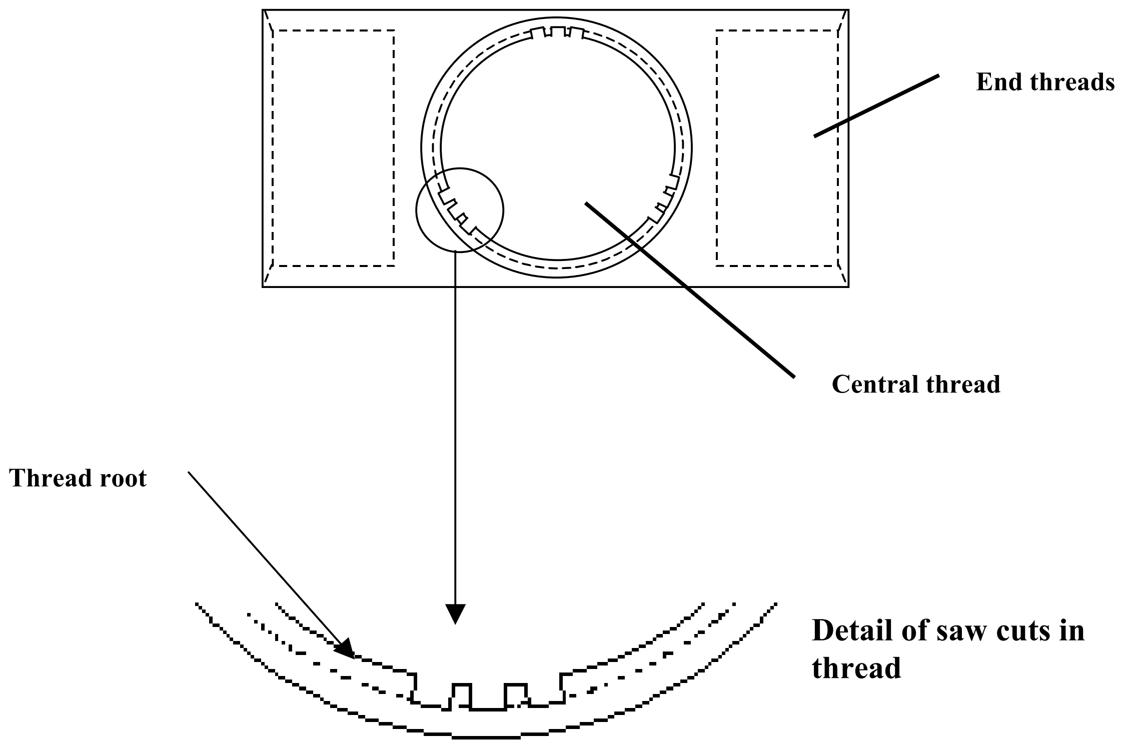


Figure 2 The GI Tee with the saw cuts equally spaced round the central thread

2. Make additional saw cuts as close as is practically possible to the first thread so that it is slightly wider than one of the faces of the triangular file, this is to ease the burden of filing.
3. Proceed to file each of the saw cuts so that the roots of the thread can no longer be seen.
4. File the left-hand side of the slot, as this will be the cutting edge, so that the profile is the same angle as the file i.e. 60° as shown in Figure 3.

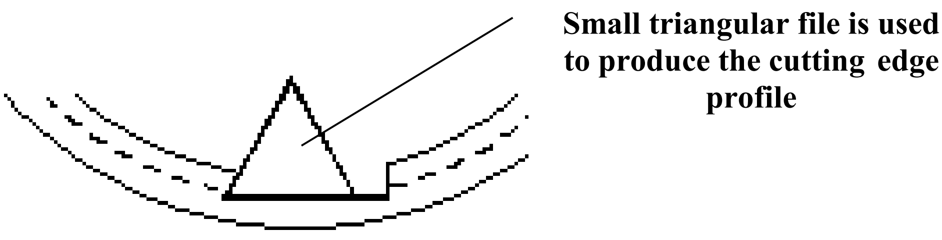

Figure 3 The GI Tee with detail of the cutting edge profile on thread

5. Using a rough file chamfer the end of the pipe to be threaded to the dimensions shown in Figure 4.

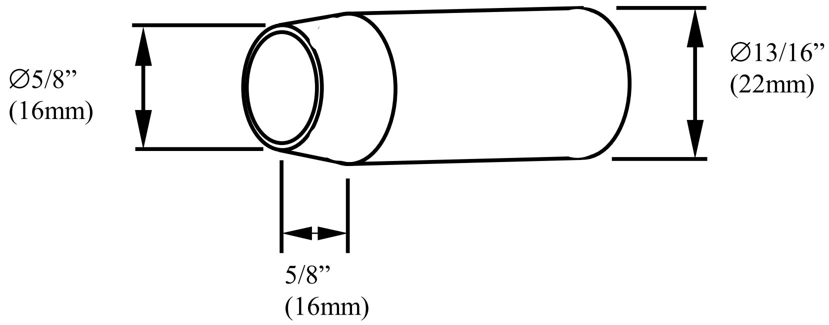

Figure 4 Chamfer dimensions for the ∅1/2” PVC pipe

6. Hold the pipe firmly in an upright position (using a vice or pipe grips) and apply a generous amount of grease or Vaseline to the thread cutter or to the pipe end. This will reduce the friction while thread cutting.
7. Place the thread cutter on top of the pipe and gently start to turn/thread it on to the prepared pipe, making sure that the top of the GI fitting is level as shown in Figure 5.

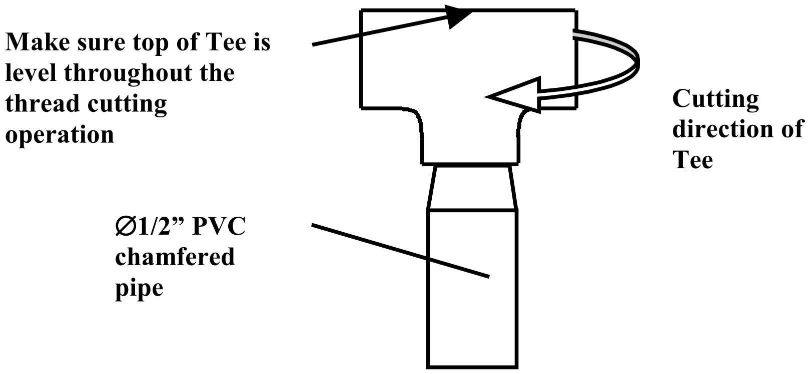

Figure 5 Starting the thread cutting

8. Turn several times (by inserting a screwdriver or steel rod through the Tee) then remove and clean out the thread of any plastic that has built up. For every revolution of the thread cutter turn back again half a revolution, this will break off the material being cut and avoid clogging of the cutting edge space.
9. Repeat the operation until a sufficient length of thread has been cut.

Re-sharpening the cutter is simply done by filing the cutting edge with the small triangular file until the blunt edge has been removed.
Polythene bags cut in to thin strips and wrapped round the thread is a good low cost substitute for PTFE tape.
Please note that it may take several attempts before a satisfactory thread has been made so practice on spare pieces of material until confidence and the quality is built up.

Cutaway sketch of the Brick jar

Introduction

This manual gives guidelines for the manufacture of a 700ltr Brick Jar, which was based on a jar built at Kyera Farm, Mbarara, Uganda during June and July 2000.
The jar consists of a brick outer section, a waterproof internal render and a thin mortar cover with a filter basin.

1. Merits and drawbacks of the Brick Jar

Pros:

- Low manufacturing time.
- Very low maintenance.
- Repairs are easily carried out.
- Suitable for most ground conditions

Cons:
- Cost per litre storage is higher than the Plastic Tube tank

2. Jar specifications

Table 1 gives the specifications for the jars main features:

Table 1 Brick Jar specification

Jar internal diameter	1.0m
Jar external diameter	1.2m
Jar height	1.6m
Jar capacity	Approximately 750 litres
Jar lining	Waterproof render
Water extraction	Gravity via tap
Top	Mortar shell with PVC filter basin

3. Material and labour requirements

Table 2 Material and labour requirements for the jar

	Unit	Ring beam	Walls	Infill	Render	Water Extraction	Cover	Totals
Cement	kg	10	37.5	10	25		10	92.5
Sand	kg	20	225	40	75		30	390
Aggregate <50mm	kg	40						40
Bricks	no		300					300
Rubble	kg			75				75
GI Pipe 1"	m					0.5		0.5
GI Elbow 1"	no					1		1
PVC Pipe 1.25"	m					0.5		0.5
Tap 0.5"	no					1		1
Reducer 1" - 0.5"	no					1		1
Basin	no					1		1
Labour (skilled)	days							2
Labour (unskilled)	days							4

4. Tools and equipment required

- Spade or shovel
- Hoe
- Tape measure (3m)
- Spirit level (600mm)
- Bucket
- Trowels
- Pipe wrench

5. Jar costing

Table 3 Jar costing

Item	Unit	No reqd	Unit cost UGS	Total UGS	Total US$	Total £
Cement	kg	92.5	300	27750	18.50	12.50
Sand	kg	390	20	7800	5.20	3.51
Aggregate <50mm	kg	40	25	1000	0.67	0.45
Bricks	no	300	42	12600	8.40	5.68
Rubble	kg	75	0	0	0.00	0.00
GI Pipe 1"	m	0.5	4200	2100	1.40	0.95
GI Elbow 1"	no	1	1500	1500	1.00	0.68
PVC Pipe 1.25"	m	0.5	1667	833.5	0.56	0.38
Tap 0.5"	no	1	5000	5000	3.33	2.25
Reducer 1" - 0.5"	no	1	1500	1500	1.00	0.68
Basin	no	1	1000	1000	0.67	0.45
Labour (skilled)	days	2	5000	10000	6.67	4.50
Labour (unskilled)	days	4	3000	12000	8.00	5.41
	Material costs			61083.5	40.72	27.52
	Total cost (incl. labour)			83083.5	55.39	37.43
	Cost per litre storage			81	0.05	0.04
	Cost per litre storage (incl. labour)			111	0.07	0.05

Notes
1. Some transport costs included (i.e. for sand, aggregates and bricks)
2. Cost of bucket slab not included

6. Site selection

It is important to select the right site for the jar so that it will remain a reliable source of water for years to come.
Some pointers for what constitutes a good site are given below:

- Good ground stability (i.e. not sandy soils)
- Jar should be close enough to the dwelling to avoid long lengths of guttering and downpipe (some suggest siting the jar mid way along the length of a building to reduce gutter size– this is fine if water from one side of the building only will be fed into the jar)
- Reasonably flat where possible – otherwise the ground will have to be levelled before marking out
- Away from trees which may undermine the foundations and cause cracking.
- Away from areas where animals will wander – fence off if needed
- Away from areas where surface water will gather (i.e. depressions)
- Not so close to the dwelling that the foundations are undermined
- Somewhere convenient for extracting water e.g. close to the kitchen area.

- It must be a suitable distance away from vehicle access as this may cause ground movement, fence off if necessary.

7. Manufacturing procedure for the jar

7.1 Making the jar cover

This will take a week to cure so this needs to be made first.

- Prepare a level piece of ground of 1.1m diameter (same as jar outside diameter) on which to make the cover for the jar.
- Mound up and compact soil on the prepared ground to a height of about 25cm and make a well in the centre for the filter basin as shown in Figure 1.

Figure 1 Mould for brick jar cement cover

- Cover the mound with plastic sheeting and place a series of bricks around the mound at a diameter of 1.1m as shown in Figure 2.

Figure 2 Mould ready for the cement render

- Render the plastic sheeting with a mortar mix of 3:1 (if the sand is low quality use chicken mesh on sandwiched between two layers of render) cover with grass or leaves and keep damp until cured which will take about seven days.

7.2 The Brickwork section

- After finding a suitable location for the jar make sure the ground is level for 1.5m in diameter.
- Place a stake in the centre of the area and mark out an inner and outer circle using a piece of string and a nail. The radii of these are 45cm and 65cm respectively.
- Excavate between the two circles to a depth of 10cm. (NB if soil tends to be unstable excavate to 20 cm deep and fill with aggregate 10cm deep, alternatively make a larger deeper ring beam)

Figure 3 Checking the level of the concrete ring beam

- Fill the excavation with a concrete mix of 4:2:1 (aggregate: sand: cement), as shown in Figure 3, and cover with damp grass/leaves and leave for two days.
- Start building the brick jar on top of the concrete ring using a mortar mix of 5:1 (sand: cement).
- After 0.55m height of brickwork fill the centre of the jar with rubble/aggregate. (this can be neglected if a sump for the jerrican/bucket is made instead)
- Insert a ∅3/4" GI pipe through one of the brickwork joints for the tap outlet, on which is fitted a ∅3/4" elbow at one end and a ∅3/4" to ∅1/2" reducer and a ∅1/2"tap at the other. Alternatively use a PVC pipe which can be threaded by the method described in Appendix 1

- Render the base of the jar with a mortar mix of 4: 1 (sand:cement) to 2.5cm deep, ensuring that the top of the elbow is level with the base.
- Continue building the brickwork up to a height 1.55m above the ground, periodically checking that the diameter is constant all the way up. On the last course of bricks fit in a short length of ∅1 ½” PVC pipe (or nearest size available) for the over flow as shown in Figure 4 and cover the end with a piece of mosquito mesh.
- Once the mortar between the brickwork has set render the inside of the jar with mortar mix of 4:1 to a depth of 1cm. Scratch this coat with a nail for a good mechanical key whilst it is still damp and leave for one day.

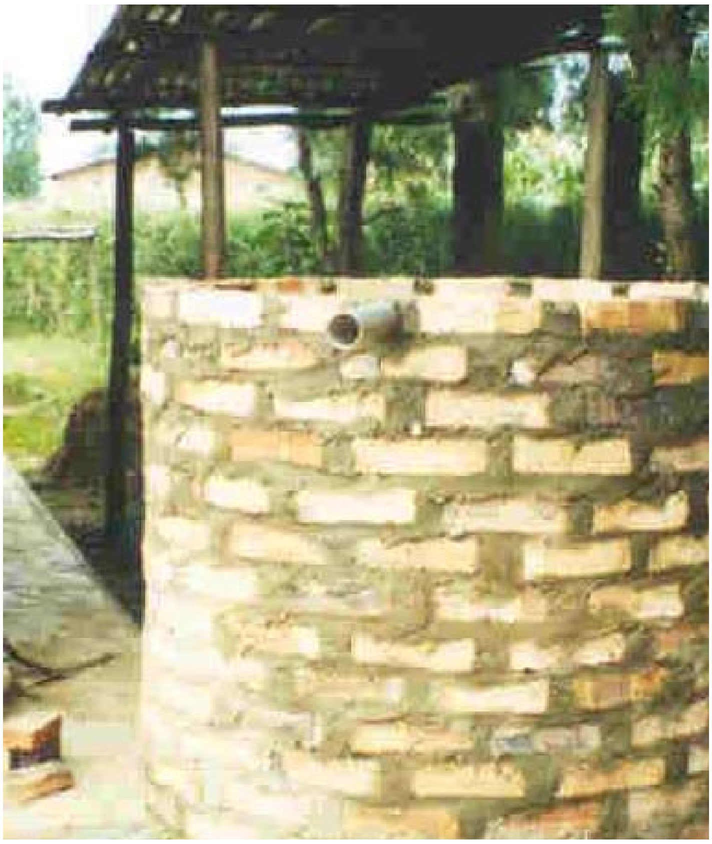

Figure 4 Full height of the brickwork clearly showing the position of the overflow

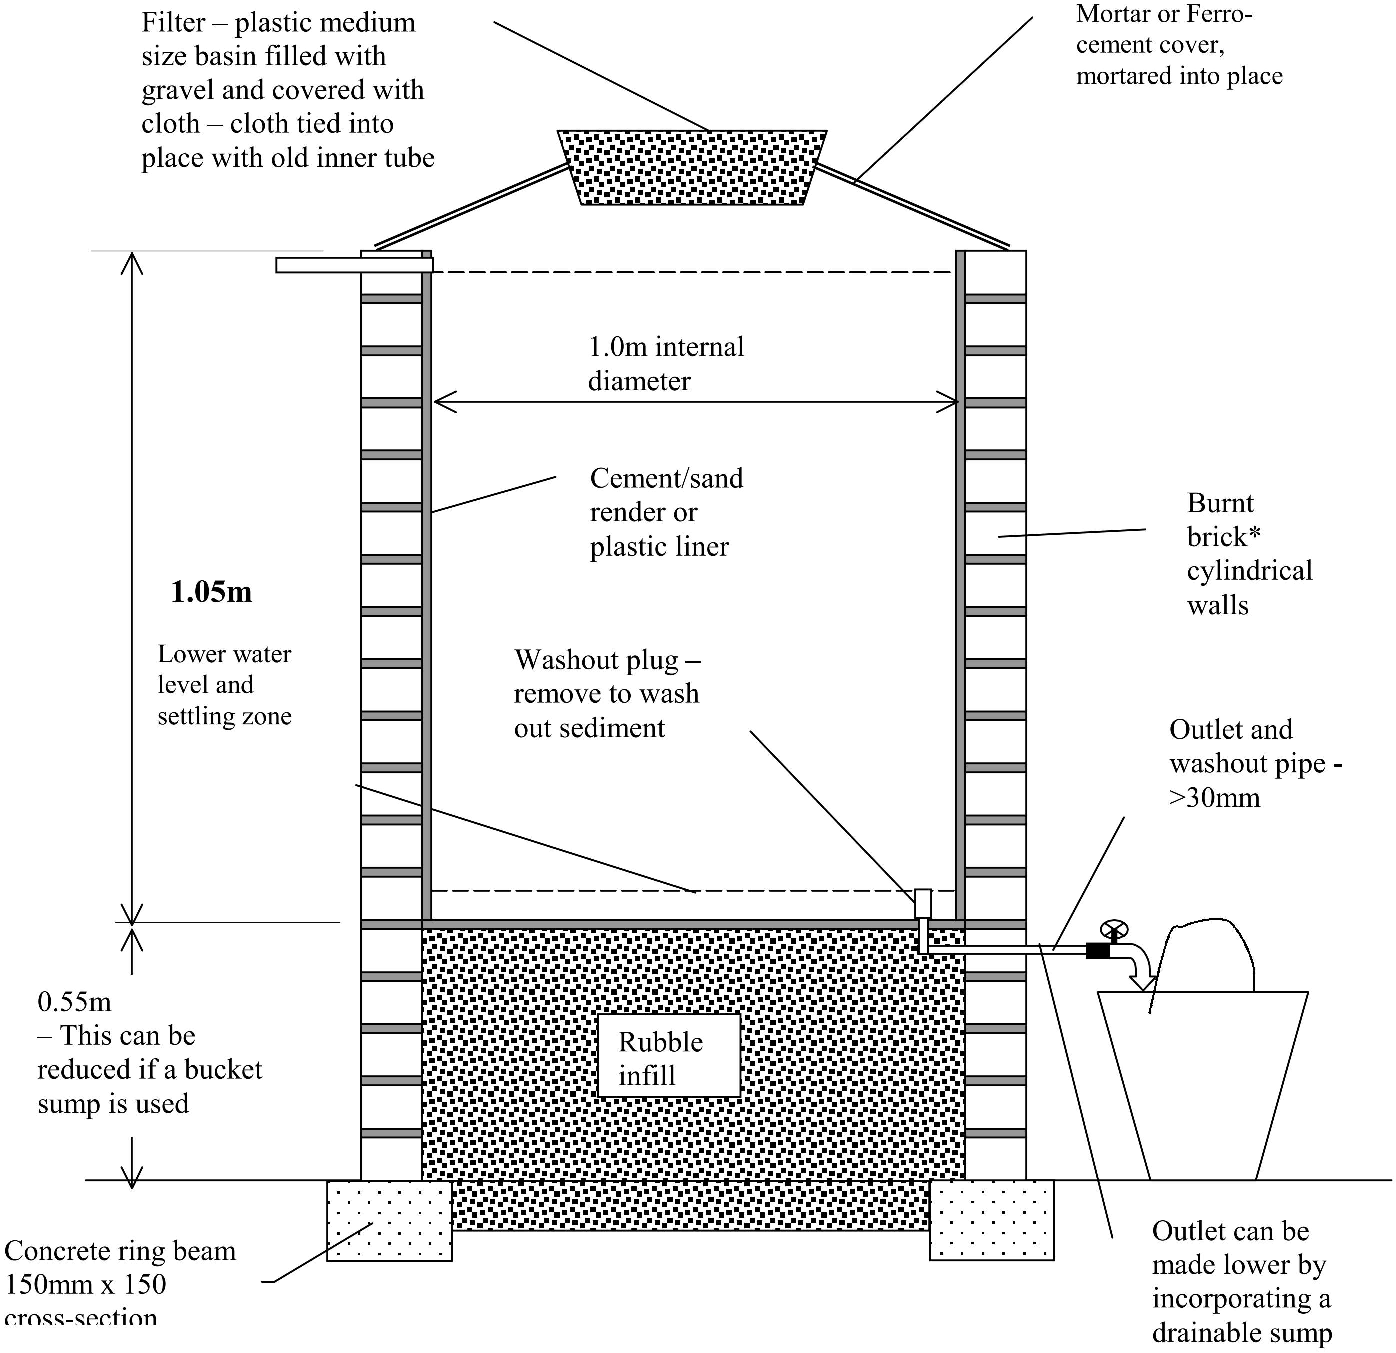
- Apply a mortar mix with a waterproof additive on to the walls and base (quantity as per manufacturers instructions) to a depth of 1cm. Cover and leave this for about twelve hours then pour in about 20 litres of water as this will help prevent cracking and shrinking (make sure the tap is turned off!), this should now be left for a further 24 hours.
- On the top course of bricks apply a layer of mortar and carefully lift on to this the shell cover, make a smooth radius around the base of the cover and the jar wall.
- Make a series of about twenty holes in the bottom of the basin using a hot nail or a drill (Ø6mm) for the rain to enter the jar. Fill the basin with aggregate (about 20mm) to about one third full.

- Cut out a square section of clean cloth that will cover the basin and have sufficient to overhang down the sides, then tie around the sides of the basin with string or rubber inner tube strip to hold the cloth in place.
- Lower the basin in to the jar.
- Fix the appropriate gutter to the roof and place the downpipe directly on to the cloth.

8. Care of the jar on completion

Once the jar is finished fill with 125mm of water each day so that the structure is gradually loaded rather than all at once.
It may be noticed that the jar will leak slightly somewhere around the sides, it is best if this is left for at least a week, as quite often the jar will eventually seal itself if the hole is small (this has come from masons personal experience in Uganda). However, if it shows no sign of sealing or the hole is quite visible, empty the contents and make the repair with a nil mix (i.e. purely a cement and water mix) from the inside of the jar.
It is important that there are no gaps around the filter and cover, or around the filter where light can enter as this will not only encourage the growth of algae but may be an entry point for mosquitoes both of which should be avoided.

9. Brick jar diagram



NB: for this tank the following brick details were:
* Burnt brick size – 225 x 100 x 75mm
1. Number of courses – 21*
2. Number of bricks per course - 14

Total number of bricks - 294

Diagram of Brick Jar construction

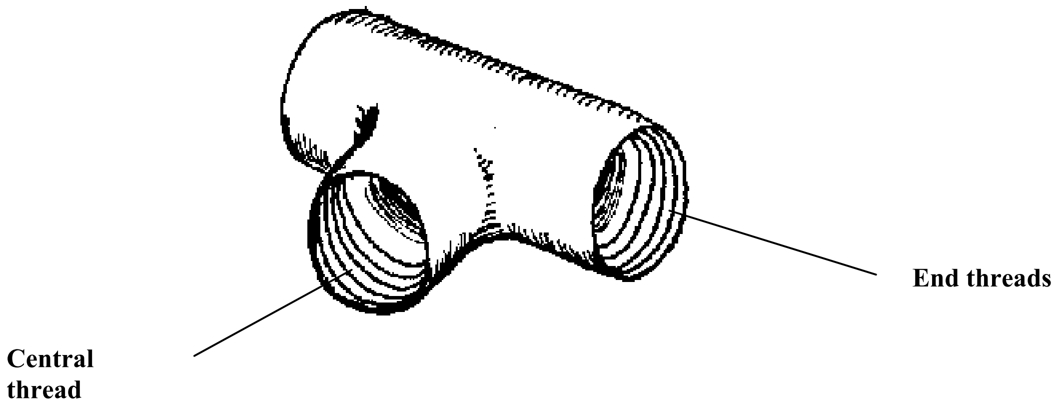
Appendix 1: Low cost threading of PVC pipes using a standard galvanised iron (GI) pipe fitting

There are many occasions were threads are required on PVC pipes so that other fittings can added to the pipe. This often involves the use of expensive threading equipment, which is not always available when needed and the charge for this service can become expensive when it is done repeatedly.
The method described here was tried out in Uganda after finding the problems mentioned above and was found to be a useful and successful solution that was very low cost. Though it requires some tools, a little bit of skill and some patience, once it has been made it will last for many threading operations and re-sharpening is simple to do.
The following example is for a ∅½” PVC pipe but the same procedure is carried out for other sizes:

Tools required:

One hacksaw blade (preferably with 24 teeth per inch)
A small (6”long) triangular file (the width across the faces should preferably be no more than about 3/16”or 4mm)
Pipe grips or a vice.
10” rough flat file.

The reliability of the threads for higher pressure applications has not been checked and care will be needed when trying this out.



10. Take a normal GI ∅½” Tee fitting as shown in Figure 1 and make three equally spaced saw cuts with the hacksaw blade in the central part of the Tee to just beyond the roots of the thread as shown in Figure 2.

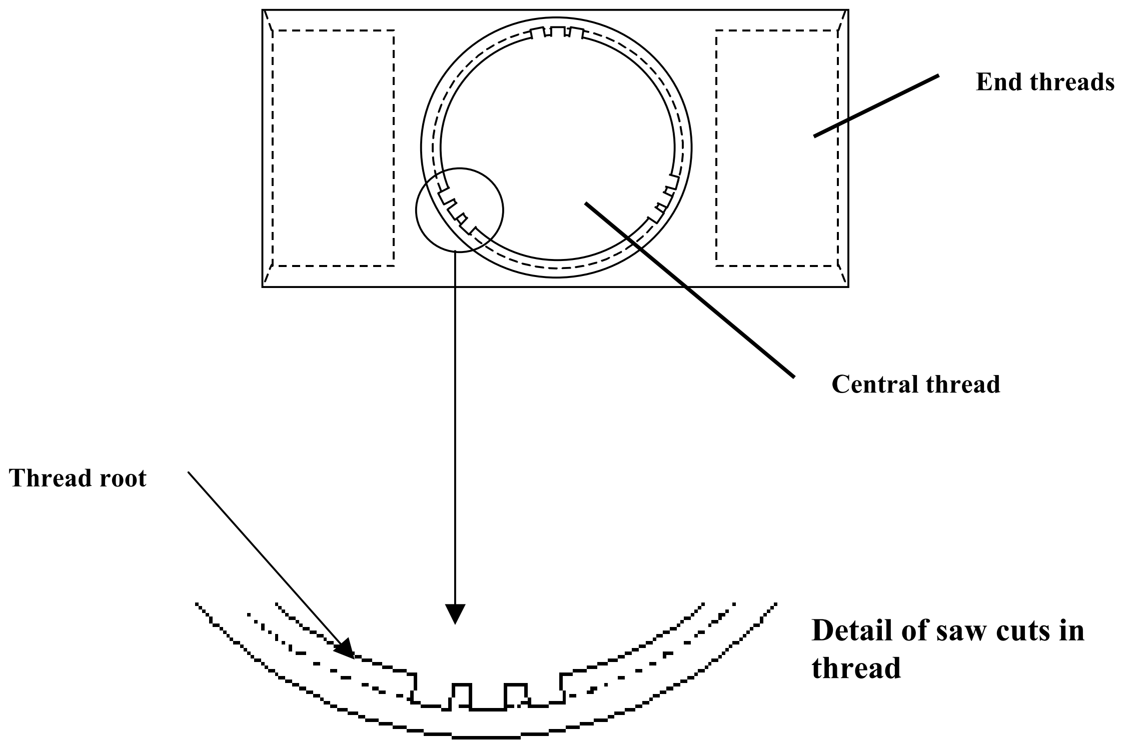


Figure 2 The GI Tee with the saw cuts equally spaced round the central thread

11. Make additional saw cuts as close as is practically possible to the first thread so that it is slightly wider than one of the faces of the triangular file, this is to ease the burden of filing.
12. Proceed to file each of the saw cuts so that the roots of the thread can no longer be seen.
13. File the left-hand side of the slot, as this will be the cutting edge, so that the profile is the same angle as the file i.e. 60° as shown in Figure 3.

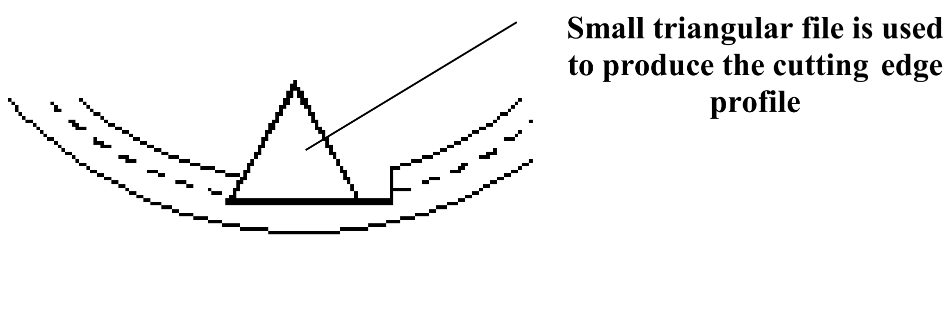

Figure 3 The GI Tee with detail of the cutting edge profile on thread

14. Using a rough file chamfer the end of the pipe to be threaded to the dimensions shown in Figure 4.

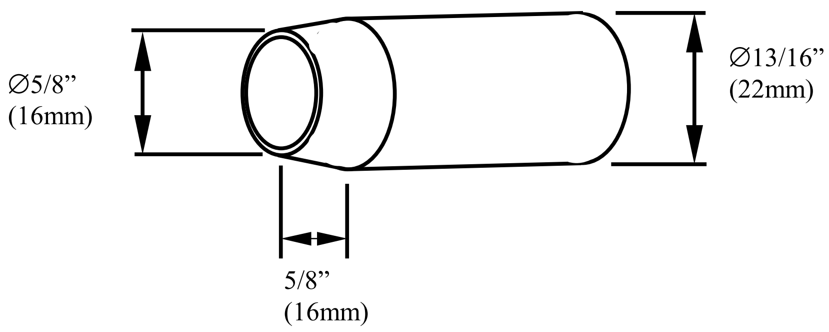

Figure 4 Chamfer dimensions for the ∅1/2” PVC pipe

15. Hold the pipe firmly in an upright position (using a vice or pipe grips) and apply a generous amount of grease or Vaseline to the thread cutter or to the pipe end. This will reduce the friction while thread cutting.
16. Place the thread cutter on top of the pipe and gently start to turn/thread it on to the prepared pipe, making sure that the top of the GI fitting is level as shown in Figure 5.

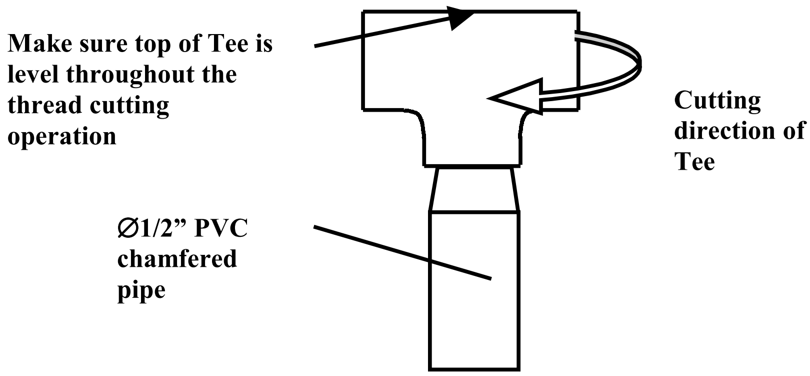

Figure 5 Starting the thread cutting

17. Turn several times (by inserting a screwdriver or steel rod through the Tee) then remove and clean out the thread of any plastic that has built up. For every revolution of the thread cutter turn back again half a revolution, this will break off the material being cut and avoid clogging of the cutting edge space.
18. Repeat the operation until a sufficient length of thread has been cut.

Re-sharpening the cutter is simply done by filing the cutting edge with the small triangular file until the blunt edge has been removed.
Polythene bags cut in to thin strips and wrapped round the thread is a good low cost substitute for PTFE tape.
Please note that it may take several attempts before a satisfactory thread has been made so practice on spare pieces of material until confidence and the quality is built up.

Contents

Introduction

Following the work of building some partially below ground tanks at Kyera Farm, Mbarara, Uganda for the collection of rainwater, there was a need to extract water from the tanks simply and effectively without incurring a large expense or relying on materials and spares being brought from overseas. During July and August 2000 a few designs and ideas were tried which caused sufficient interest from several NGO's to hold a training workshop at Kyera Farm. This manual is a direct result of that interest, it contains sufficient information for someone with access to a set of basic tools and a reasonable amount of practical skill to manufacture the handpumps without too much difficulty. Within this manual there are details of four types of direct action handpumps for use with domestic roof water harvesting (DRWH) tanks.

The main objective in the design of these hand pumps was to produce low cost handpumps, which can be manufactured and maintained with locally available materials and locally available skills.

It must be mentioned that these pumps are not intended for community use and are for household use only as community pumps require a much more robust design. All these pumps have been used at depths between 2.5 to 3m but may be used at beyond this subject to practical limitations. There may be situations where these pumps may be used for purposes other than with DRWH tanks, for example in irrigation, you are encouraged to apply them wherever there may be a use for them.

The following designs and parts list may be adapted or exchanged to suit the availability of materials or personal preferences, e.g. choice of foot valve or exchanging the handle from one pump to another.
I apologise for using both imperial and metric units in this manual, many items purchased in Uganda were found to use both units, please use the nearest equivalents wherever possible.

I would be grateful for any feed back you may have on any aspect of these pumps whether this is criticism or possible improvements.

2 List of tools required for handpump manufacture

This list is a good guide of what tools are required for the handpumps but it may be found that other tools may make manufacture easier or more cost effective. It may depend on what tools are available.

1 Hacksaw and blade

2 Hammer

3 Pliers

4 Pipe wrench

5 Hand drill

6 Set of drills (2mm, 3mm, 4mm, 5mm, 6mm, 7mm, 8mm,)

7 Screwdriver

8 Set of files (150mm triangular, 250mm half-round, 250mm rough)

9 Scissors

10 Tape measure

11 Stove (or some adequate heat source)

12 Sandpaper

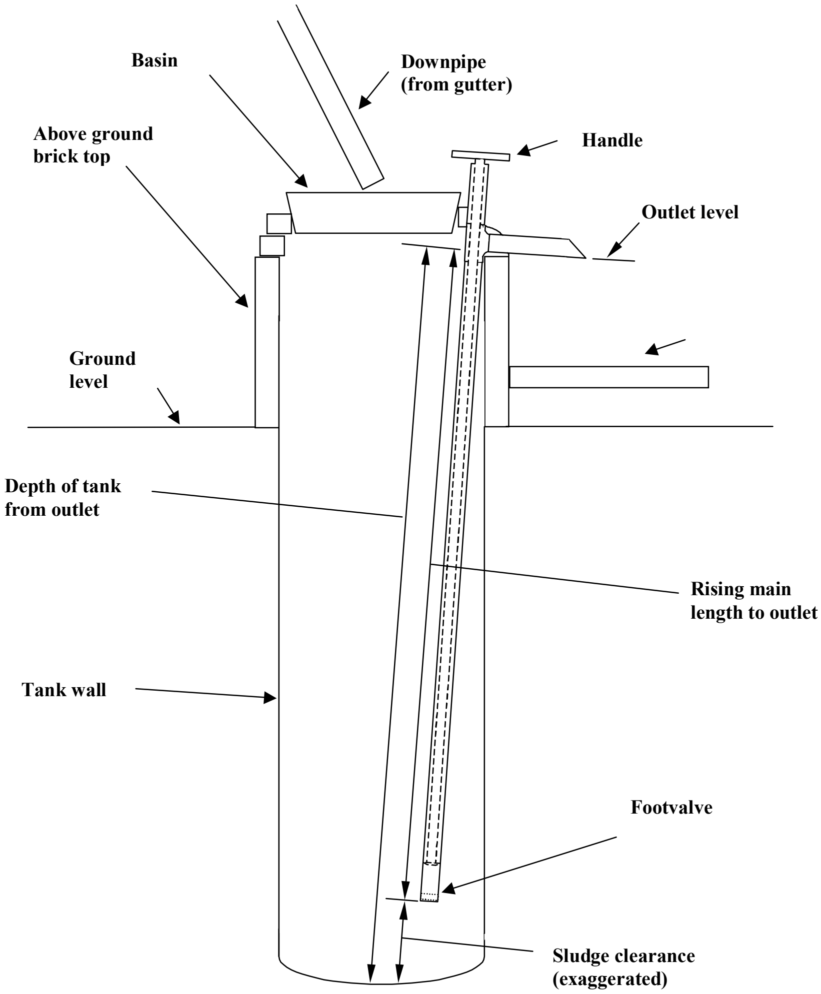

Figure 1 Principle components of domestic rainwater harvesting tank

A typical domestic rainwater harvest (DRWH) tank is shown in Figure 1 illustrating some of the major components and showing the handpump in position. It is important to note with the handpump that the footvalve must not come in to contact with the base of the tank and should ideally have sufficient clearance for any build up of sludge.

At the top of the tank the handpump protrudes through a small gap in the brickwork and is held rigidly with a small amount of sand and cement. This is placed around the Tee to restrain any movement from forces generated during operation. On larger tanks the handpump may protrude through a small hole in the cover, a mound of mortar is built up around the Tee to securely hold this in position. When maintenance is required the mortar can be carefully removed and the pump withdrawn.

Most containers used for collecting water in West Africa are plastic jerricans, so the distance from the handpump outlet to the stand should be about 25 to 50mm greater than the height of a 20 litre jerrican.

3 The DTU Handpump

The DTU Handpump is simple lift pump and uses a leather stirrup pump piston, which is available from most cycle shops. The principle of operation is as follows: As the handle is lifted the water above the leather washer is lifted with it, during this stage the footvalve is opened and the water fills the rising main below the leather piston. On the downstroke the footvalve is closed and the water in the lower section by passes the leather washer to the upper section, repeat operations transfers water to the outlet. It will be noticed during operation that water will pour from the outlet on both strokes, this is because the push rod displaces water within the rising main.

3.1 Manufacturing procedure.

- Measure depth of tank (from outlet level to bottom of tank) and subtract some small amount to ensure that the footvalve is not touching bottom of tank. This is to stop sediment from being drawn up in to the handpump (This may be around 250 - 300mm)

- Select a straight piece of Ø1 ½" PVC pipe with a smooth internal bore (This will cause less wear on the leather piston) and cut to required lengths as indicated in the following assembly drawing. Also cut the top tube and the outlet.

- Make sure the internal surface of the tee is clear of any obstructions, as this will interfere with inserting/removing the leather piston, file any obstructions until the leather piston passes through the tee.

- Make up the DTU or low cost valve (as shown in Appendix 1) and fix to the bottom of rising main.

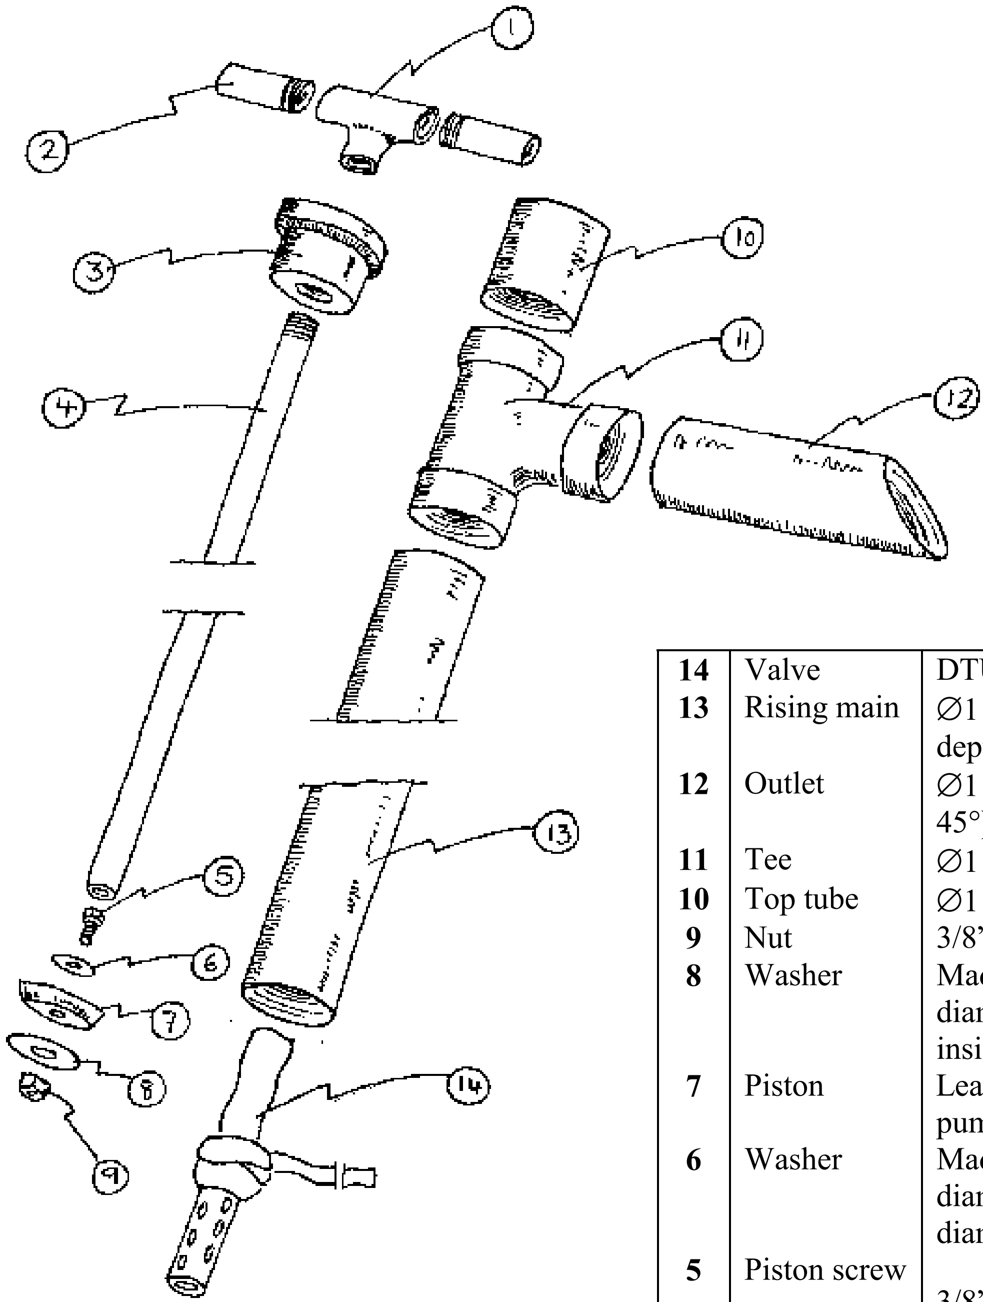
- Push top tube and tee on to rising main and measure or calculate the total distance from the top of the top tube to the top of the footvalve. From this subtract approximately 50mm and cut the pull rod to this measurement, this will ensure that the piston will not hit the footvalve at the bottom of the pull rod stroke.

- Thread the top end (details on threading PVC pipe is shown in Appendix 2) of the and pull rod and fit a Ø½ " PVC/GI Tee, also fit the two threaded handles and slide on the wooden support bush.

- Securely fix the 3/8" BSW (or an M8) screw in to bottom of pull rod. This can be done by heating the end of the pipe and pushing the PVC material in to the thread to stop the head of the screw from coming out of the pipe. A series of four saw cuts can be cut in to the end of the pipe to a depth equal to the saw blade (about 12mm) this will help when pushing the hot PVC material on top the thread.

- Place on the screw the washer, leather, second washer and the 3/8" BSW Nut on to the 3/8" BSW screw alternatively use a M8 screw and nut.
- Grease the leather washer (make sure that it will not taint or contaminate the water.
- Fit on the outlet tube on to the tee.
- Insert the pull rod into the rising main.
- Test operation of the handpump.
- If the handpump operates satisfactorily use PVC cement on the three joints of the PVC tee.

3.2 DTU Handpump assembly drawing



14	Valve	DTU type (see Appendix1)
13	Rising main	∅1 1/2” PVC (length to suit depth of tank)
12	Outlet	∅1 1/2” x 8” (200mm) (end at 45°)
11	Tee	∅1 1/2” PVC
10	Top tube	∅1 1/2” x 8” (200mm)
9	Nut	3/8” BSW or M8
8	Washer	Made from PVC pipe, outside diameter = 1 1/4” (30mm), inside diameter = 3/8” (8mm)
7	Piston	Leather washer from stirrup pump
6	Washer	Made from PVC pipe, outside diameter = 1” (25mm), inside diameter = 3/8” (8mm)
5	Piston screw	3/8” BSW x 3/4” (M8 x 20mm)
4	Pull rod	1/2” PVC pipe (length to suit rising main)
3	Pull rod bush	To suit pipe (see Appendix 3)
2	Handles	1/2” PVC pipe x 4” (100mm) (2 pieces)
1	Tee	1/2” PVC or GI

3.3 Cost example for 2.5m long DTU Hand pump

PART No.	NAME	UNIT	SIZE/ LENGTH	COST PER MATERIAL LENGTH (UGS)	COST/PUMP (UGS)	COST/PUMP US Dollar ($1= UGS1775)[1]
1	Tee	Inch	Ø½" GI (or PVC)	500	500	0.28
2	Handles	Inch	Ø½"PVC x 4" (100mm) 2 pieces	7,500 per 20ft	250	0.14
3	Pull Rod Bush	No	1	260	260	0.14
4	Pull Rod	Inch	Ø½"PVC x 80" (2000mm)	7,500 per 20ft	2,500	1.39
5	Screw	No	3/8" BSW X 1" or M8 x 25mm	500	500	0.28
6	Washer	No	3/8" (8mm)	100	100	0.06
7	Piston	No	Ø1 ½" leather	500	500	0.28
8	Washer	No	3/8" (8mm)	100	100	0.06
9	Nut	Inch	3/8" (or M8)	-	-	0.00
10	Top tube	Inch	Ø1 ½" PVC x 8" (200mm)	12,500 per 20ft	420	0.23
11	Tee	Inch	Ø1 ½ " PVC	2,500	2,500	1.39
12	Outlet	Inch	Ø1 ½" PVC x 8" (200mm)	12,500 per 20ft	420	0.23
13	Rising Main	Inch	Ø1 ½" PVC x 86" (2150mm)	12,500 per 20ft	4,480	2.50
14	Foot Valve (DTU)	No	1	675	675	0.38
					UGS13,205	**$7.36**

Material cost (UGS) = 13,205
(Labour Cost/day = 2,500)
Labour cost for 4 hrs = 1,250
Total cost = 14,455 ($8.14)

DTU VALVE COST:

¾" PVC pipe x 8" @ 10,000/20ft = 333
Inner tube x 4" = 90
2ft of inner tube strip = 250
Total cost = 673 ($0.38)

4 The Tamana Hand Pump

This slightly modified version of the Tamana handpump, which is used as suction pump, relies on a seal from the piston/valve and the bore of the PVC cylinder.

During operation and on the upstroke, the piston/valves lays flat on the PVC supports, this creates a lower pressure below the piston/valves which draws water in to the cylinder through the footvalve. As the push rod is depressed the piston/valves are slightly raised from their piston supports and water flows through the holes of these into the cylinder above the piston/valves. On each stroke water is discharged through the outlet, this is because on the downstroke the volume of the pull rod displaces water as with the previous handpump.

Labyrinth seals (a series of seals) can improve the time between seal replacements, this version uses only two as a demonstration but more could be added. A suitable length of ½ " PVC pipe is connected to the reducer which leads in to the DRWH tank and a floating valve is used for the intake (see Appendix 4 for details of the floating valve). The PVC pipe can either be threaded (as described in Appendix 2) and fitted with elbows to reach down in to the tank or it can be bent by heat application. The latter can be done by putting a wood stopper at one end of the pipe and pouring sufficient sand inside the pipe a few inches beyond where the bend is to be. Heat gently and evenly around the bend area and bend slowly until the desired angle is achieved. Cold water can be poured on to the pipe to set it quickly.

4.1 Manufacturing procedure

- Select a piece of Ø1 ½" PVC pipe (with a swaged end) with as smooth as bore as is possible and cut to 450mm long. Chamfer the swaged end and thread (using the method described in Appendix 2).

- Cut the top tube and outlet to length, to the dimensions shown in the following table).

- Cut three lengths of Ø3/4" PVC pipe and split each one lengthways. Their faces must be square with the bore.

- For the PVC supports: mark out two concentric diameters on a flattened piece of PVC pipe, the larger diameter is 1/8" smaller than bore of Ø1 ½" PVC pipe and the smaller diameter is the same as the outside diameter of the pull rod. Cut out the central hole out first, as this is easier. Then mark out 8 equally spaced holes and drill them 5mm diameter. Finally cut out the outside diameter and file smooth. N.B. The piston supports are made from PVC pipe by splitting, heating and flattening a suitable piece of pipe.

- Cut out two rubber piston/valves using the piston/valve cutter shown in Appendix 5.

- Assemble together as shown in following drawing, making sure that top and bottom piston stops are pushed up towards each other trapping the piston/valves in place, screw top & bottom piston stops in this position.

- Cut a 250mm piece of Ø3/4" PVC pipe for the handle, make a hole in the centre for the pull rod to pass through.

- Place a wood support bush on to pullrod and fix handle in place.

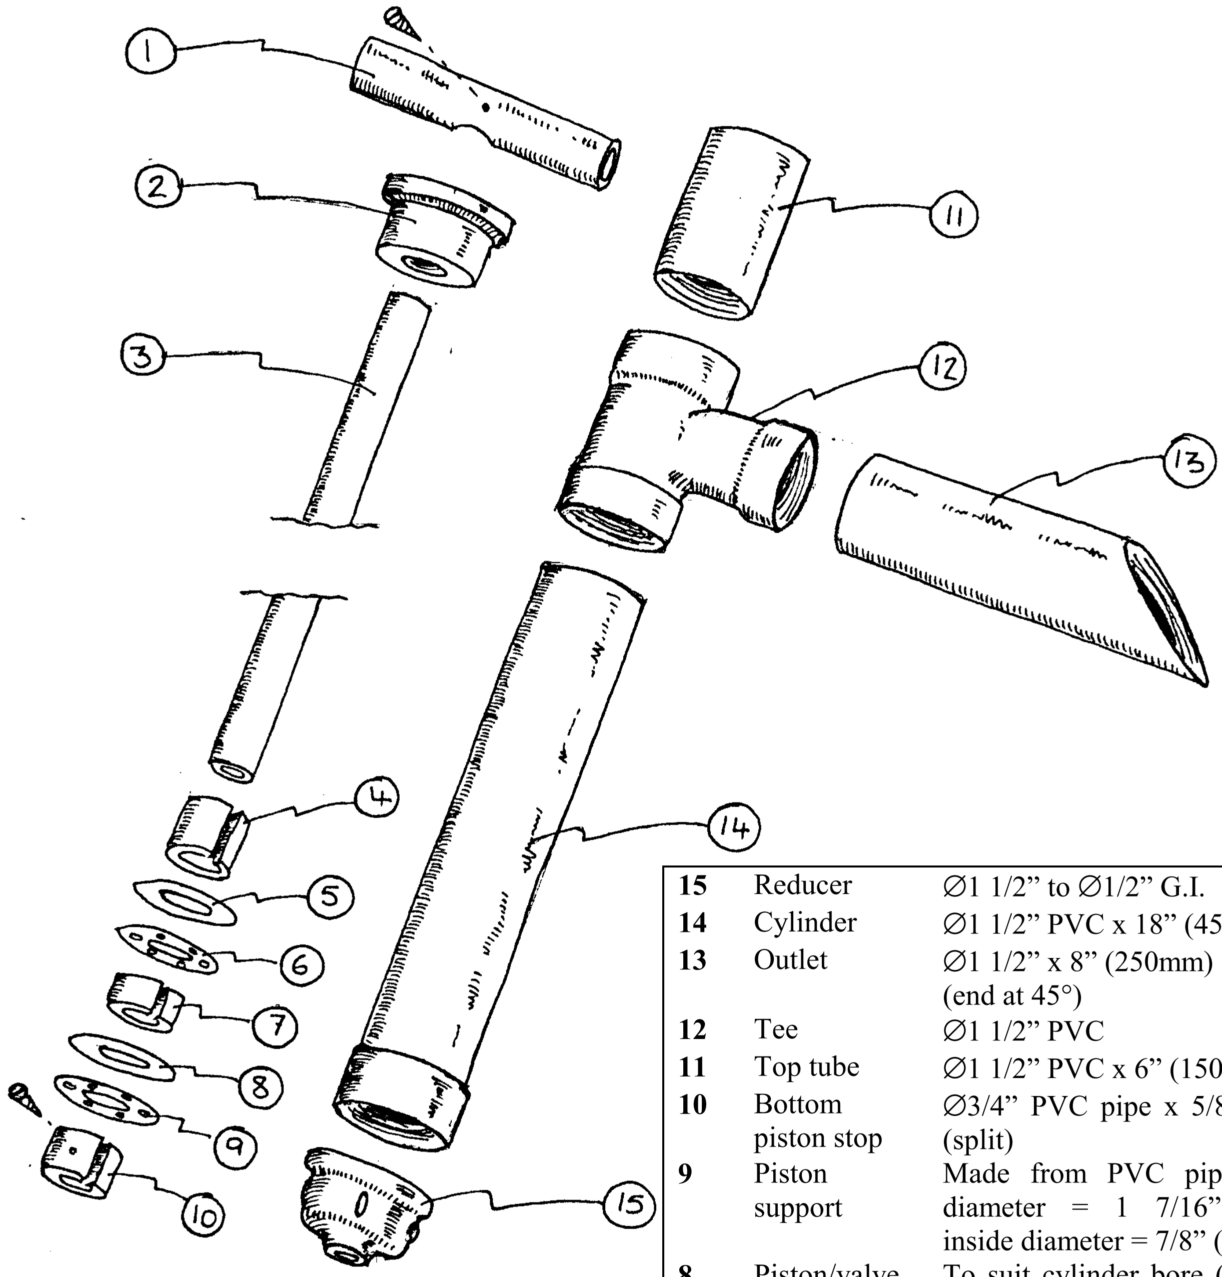
- Cut a small disc of PVC to 22mm diameter and cement this to the top of Ø½" PVC pullrod.

- Check that the piston assembly passes through the Ø1 ½" Tee, file any obstruction till this is achieved.

- Assemble and test.

- If pump works satisfactorily, cement the three joints around the Ø1½" Tee ensuring that pipes are in line with each other.

4.2 Tamana handpump assembly drawing



15	Reducer	∅1 1/2” to ∅1/2” G.I.
14	Cylinder	∅1 1/2” PVC x 18” (450mm)
13	Outlet	∅1 1/2” x 8” (250mm) (end at 45°)
12	Tee	∅1 1/2” PVC
11	Top tube	∅1 1/2” PVC x 6” (150mm)
10	Bottom piston stop	∅3/4” PVC pipe x 5/8” (16mm) (split)
9	Piston support	Made from PVC pipe, outside diameter = 1 7/16” (36mm), inside diameter = 7/8” (22mm)
8	Piston/valve	To suit cylinder bore (use piston cutter shown in Appendix 5)
7	Centre piston stop	∅3/4” PVC pipe x 5/8” (16mm) (split)
6	Piston support	Made from PVC pipe, outside diameter = 1 7/16” (36mm), inside diameter = 7/8” (22mm)
5	Piston/valve	To suit cylinder bore (use piston cutter as shown in Appendix 5)
4	Top piston stop	∅3/4” PVC pipe x 5/8” (16mm) (split)
3	Pull rod	∅1/2” PVC x 25” (625mm)
2	Pull rod bush	To suit pipe (see Appendix3)
1	Handle	∅3/4” PVC x 8 “ (250mm)

4.3 Cost example for 450mm long Tamana handpump

PART No.	NAME	UNIT	SIZE/ LENGTH	COST PER MATERIAL LENGTH (UGS)	COST/ PUMP (UGS)	COST/PUMP US Dollar ($1= UGS1775)[2]
1	Handle	Inch	Ø½"PVC x 8" (250mm)	10,000 per 20ft	335	0.19
2	Pull rod bush	No.	1	2000	260	0.14
3	Pull rod	Inch	**Ø½"PVC x 25" (625mm)**	**7500per 20ft.**	780	0.43

5 The “Harold” handpump

This is another lift pump, though it does not rely on having a seal or a flexible membrane within the rising main. The piston as such is a moulded plastic cup which is slightly smaller than the bore of the rising main, this is shaped in such a way that it has greater resistance on the up stroke and water is lifted by the cup. A small amount of water will leak past the gap around the cup. During the upstroke the footvalve opens allowing water into the rising main. On the down stroke the foot valve closes, and the water within the rising main flows around and above the cup. Repeated operation lifts water to the outlet and very little is displaced on the return stroke because of the small volume of the pull rod.

Despite the gap around the moulded cup the pump discharges a surprising amount of water per stroke.

5.1 Manufacturing procedure

- Measure the depth of the tank from the outlet to the bottom of the tank and subtract some small amount to ensure that the footvalve is not touching bottom of tank. (This may be around 200 to 250mm)

- Select a straight section of Ø1 ½" PVC pipe and cut to the required length.

- Cut the top tube and outlet to the right length as shown in the following table.

- Push these sections together with the Tee, and fit a footvalve to the bottom of the rising main (see Appendix 1 for footvalve assembly)

- Measure the distance from the top of the top tube to the top of the foot valve, subtract 1" from this and cut a section of 3/8” or 8mm steel rod to this length.

- Slit one and with a hacksaw to a depth of 16mm and the other end to a depth of 30mm (if a hand vice is unavailable see Appendix 6).

- Cut an 8" long piece of Ø½” PVC pipe for the handle and drill a 3/8” or 8mm diameter hole at the midpoint. Insert the handle on the pull rod, so the handle is level with the bottom of the 30mm slit.

- Prize open the two halves of the rod with a screwdriver and gradually push and hammer back the steel around the handle until the handle is firmly held in place.

- Slide on the wood support bush towards the handle.

- At the other end insert a piece of copper wire through the slit and wind round several times, push the washer up to the wire, then fit on the moulded cup (see Appendix 7) and bottom washer. Wrap the remaining copper wire around the rod above the washer to retain it. Push a screwdriver blade into slot and gently prize open the two halves so that the assembly is held firm.

- Check that there is no obstruction in the 1 ½” Tee, making sure that the pull rod assembly will pass through the Tee, file clear if needed.
- Push the assembled pull rod down into the rising main and test operation.
- If the pump works okay cement the three joints around the Tee making sure the pipes are all in line with each other

6 The Enhanced inertia handpump

The Enhanced inertia Pump is a lift pump, which again does not rely on a seal within the rising main but uses a central tube to lift the water, which overflows in to the rising main. On the upstroke the central foot valve is closed and the main footvalve is opened letting water in to the rising main. As the handle is depressed the central tube footvalve is opened letting water in to the central tube, meanwhile the main footvalve is closed. Repeat operations gradually brings water up the central tube, this then flows through the holes in the central tube in to the rising main and is eventually discharged at the outlet. A good commercial example is manufactured by made by the "New Zealand Pump Company"
This handpump seems to operate best when short strokes are used. The flow is steady on both strokes of operation again because of the high displacement from the central tube full of water on the downstroke.

6.1 Manufacturing procedure

- Measure the depth of the tank from the outlet to the bottom of the tank and subtract some small amount to ensure that the footvalve is not touching bottom of tank. (This may be around 8” - 10”)

- Select a straight piece of Ø1 ½" PVC pipe and cut to the required length.

- Cut to top tube and outlet from Ø1 ½" PVC pipe (see following table for dimensions)

- Make up the low cost valve or DTU valve and fit to bottom of Ø1 ½" PVC pipe. Make sure that it is a good tight fit, though once it is wet it will expand.
- Push together top tube, Tee and outlet and measure the distance to top of footvalve, from this subtract approx. 2" and cut a piece of Ø1 ¼" PVC pipe to this length. Use the swaged end for the top of the central tube as this seals the two tubes when the handpump is not being used.

- Cut a series of holes approximately 8mm diameter, which starts about 250mm below the top of central tube to around 200mm in length. The number of holes is not too important so long as there are sufficient holes for water to escape through and not too many that it weakens the tube.

- Cut a hole in top of central tube 7/8” or 22mm diameter for the handle.

- Cut the handle from a piece of Ø½" PVC x 200mm long and PVC cement it in to the hole in the central tube.

- Cut a PVC disc to fit in top of central tube and cement in place.

- Make up a foot valve and fit to the bottom of central tube. Note that the wood inlet needs to be a good tight fit inside the tube.

- Fit together and test.

- If test is okay, cement the three joints of the Tee ensuring that pipes and Tee are all in line with each other.

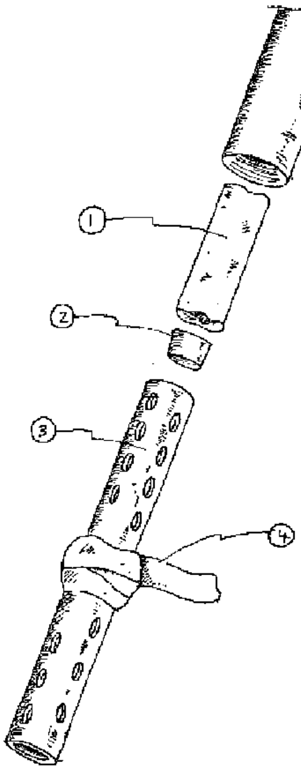
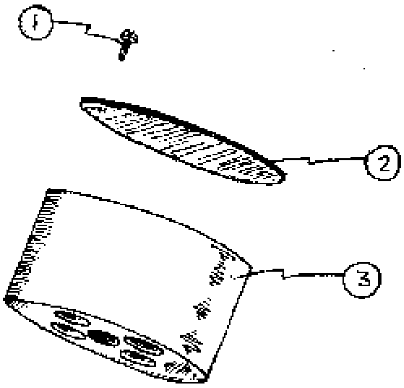
Appendix 1Footvalves



The DTU valve is a simple one way valve, which has only four key components. The manufacturing procedure is as follows:

- Cut off a length of Ø ¾ ” PVC pipe 8” long
- Drill a number of Ø 3/8” holes at the top and bottom sections, leaving a gap in the middle of about 2 ½”
- Make up a wood plug and wedge this in at the top of the PVC pipe.
- Slide a 4” length of cycle inner tube over the PVC pipe and start wrapping the rubber strip round the centre of the pipe and trapping the bottom of the inner tube sleeve.
- Make sure that when wrapping the rubber strip round that it is very tight. Wrap sufficiently round so that it is a good tight fit inside the bore of the rising main.
- Continue to wrap the remainder of the rubber strip round the pipe to seal the valve and rising main together.



The low cost valve needs little explanation, as it is self-explanatory. The important point is that the inlet needs to be a good tight fit inside the bore of the rising main as the forces generated during operation could dislodge it.
It may be preferable to make the inlets on a wood lathe but if there is no access to one then careful selection of a suitable piece of wood and some filing will suffice. Dimensional details of the inlets are given in Appendix 3.

1	Screw
2	Rubber inner tube disc
3	Wood inlet

Appendix 2 How to cut a thread in PVC pipe

There are many occasions where threads are required on PVC pipes so that other fittings can be fitted to the pipe. This often involves the use of expensive equipment, which is not always available when needed and the charge for this service can be expensive.

The method described here was tried out in Uganda after finding the above mentioned problems and was found to be a useful and successful solution that was very low cost. Though it requires some tools, a little bit of skill and some patience, once it has been made it will last for many threading operations and re-sharpening is simple to do.
The following example is for a Ø1/2" PVC pipe, but the same procedure is used for other sizes.

Tools required:

One hacksaw blade (preferably 24 teeth per inch)
A small 6" (150mm) long triangular file (the width across the face should preferably be no more than 3/16" or 4mm)
Pipe grips or a vice.
10" (250mm) flat file

The reliability of the threads for higher-pressure applications has not been checked and care will be needed if this is tried.

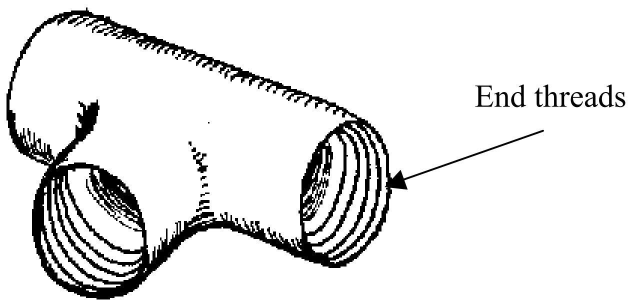


Figure 4 Galvanised Iron tee

Take a standard GI Ø1/2" tee as shown in Figure 4 and make three equally spaced saw cuts

- Take a normal GI Ø½" Tee fitting as shown in Figure 4 and make three equally spaced saw cuts with the hacksaw blade in the central part of the Tee to just beyond the roots of the thread as shown in Figure 5.

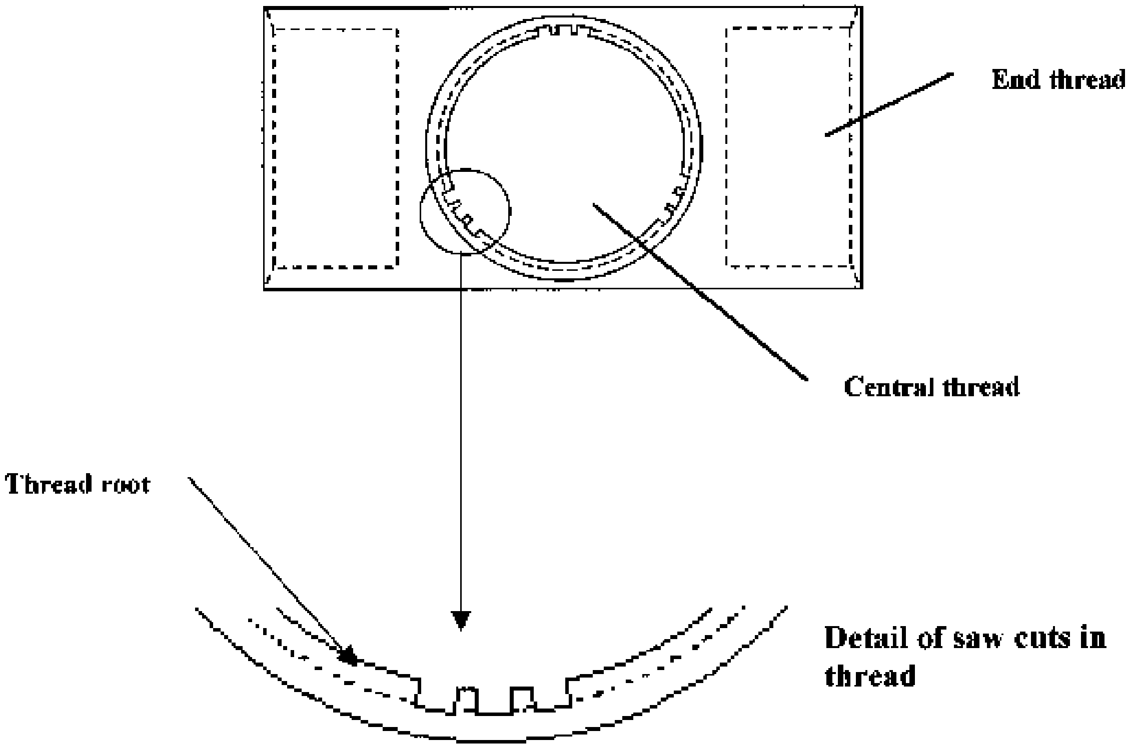

Figure 5 The GI Tee with the saw cuts equally spaced round the central thread

- Make additional saw cuts as close as is practically possible to the first thread so that it is slightly wider than one of the faces of the triangular file, this is to ease the burden of filing.
- Proceed to file each of the saw cuts so that the roots of the thread can no longer be seen.
- File the left-hand side of the slot, as this will be the cutting edge, so that the profile is the same angle as the file i.e. 60° as shown in Figure 6.

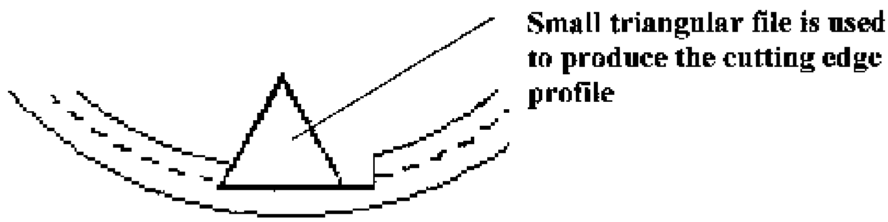

Figure 6 The GI Tee with detail of the cutting edge profile on thread

- Using a rough file chamfer the end of the pipe to be threaded to the dimensions shown in Figure 7.

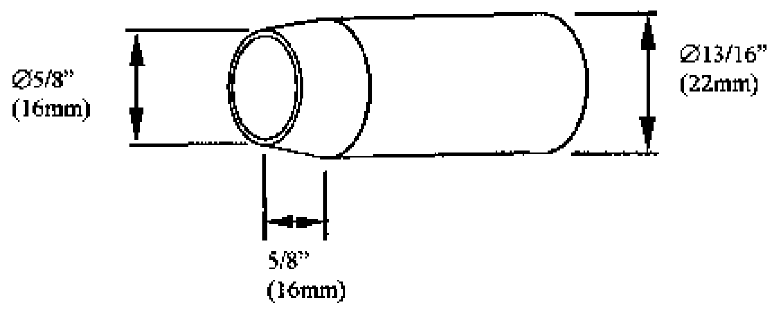

Figure 7 Chamfer dimensions for the Ø1/2" PVC pipe

- Hold the pipe firmly in an upright position (using a vice or pipe grips) and apply a generous amount of grease or Vaseline to the thread cutter or to the pipe end. This will reduce the friction while thread cutting.
- Place the thread cutter on top of the pipe and gently start to turn/thread it on to the prepared pipe, making sure that the top of the GI fitting is level as shown in Figure 8.

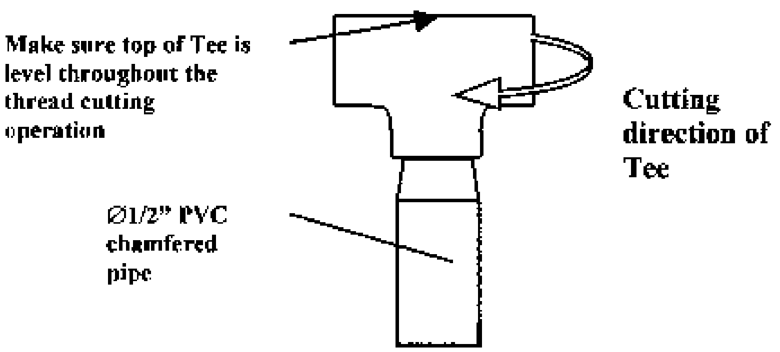

Figure 8 Starting the thread cutting

- Turn several times (by inserting a screwdriver or steel rod through the Tee) then remove and clean out the thread of any plastic that has built up. For every revolution of the thread cutter turn back again half a revolution, this will break off the material being cut and avoid clogging of the cutting edge space.
- Repeat the operation until a sufficient length of thread (no more than the length of thread inside the Tee) has been cut.

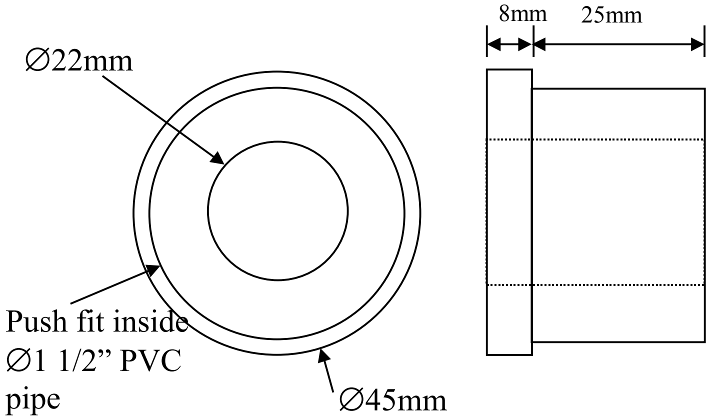
Re-sharpening the cutter is simply done by filing the cutting edge with the small triangular file until the blunt edge has been removed.
Polythene bags cut in to thin strips and wrapped round the thread is a good low cost substitute for PTFE tape.

Please note that it may take several attempts before a satisfactory thread has been made so practice on spare pieces of material until confidence and the quality is built up.

Appendix 3 Pull rod bushes and inlet details

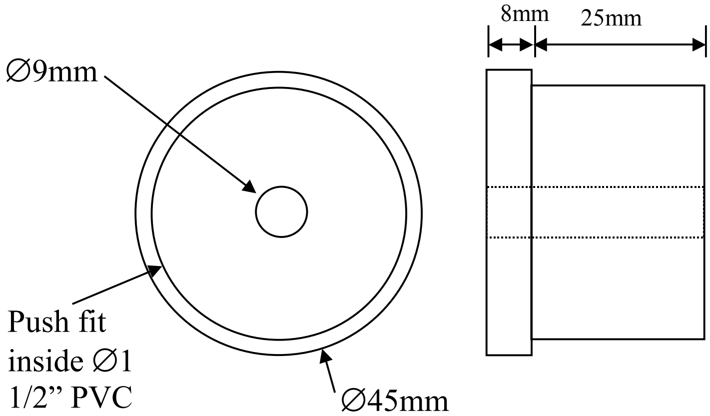
Pull rod bush for DTU and Tamana handpumps

Material: Hardwood



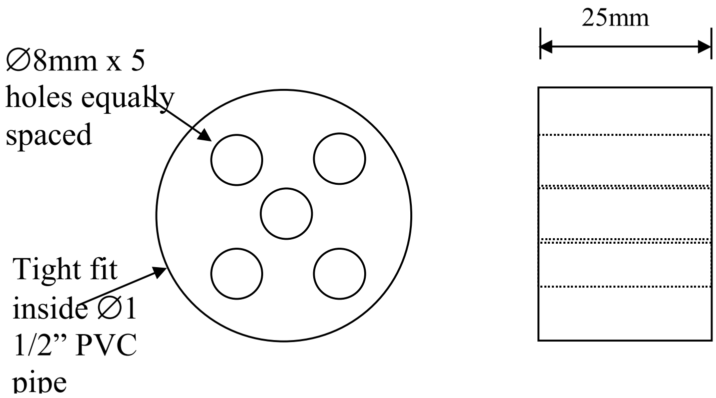
Pull rod bush for Harold handpump

Material: Hardwood

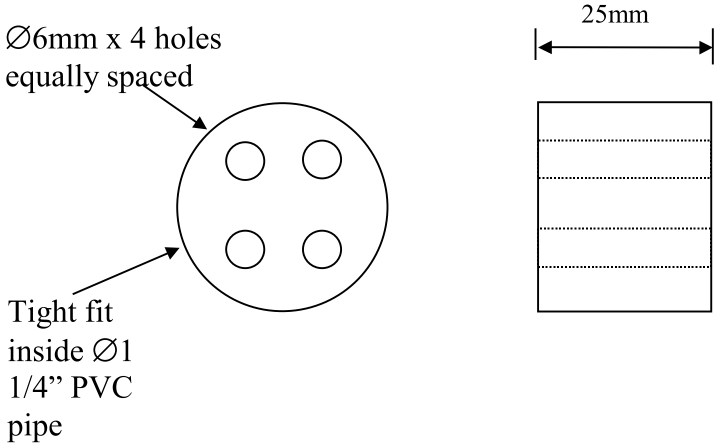


Inlet for ∅1 1/2” PVC pipe, Harold and Enhanced inertia handpumps

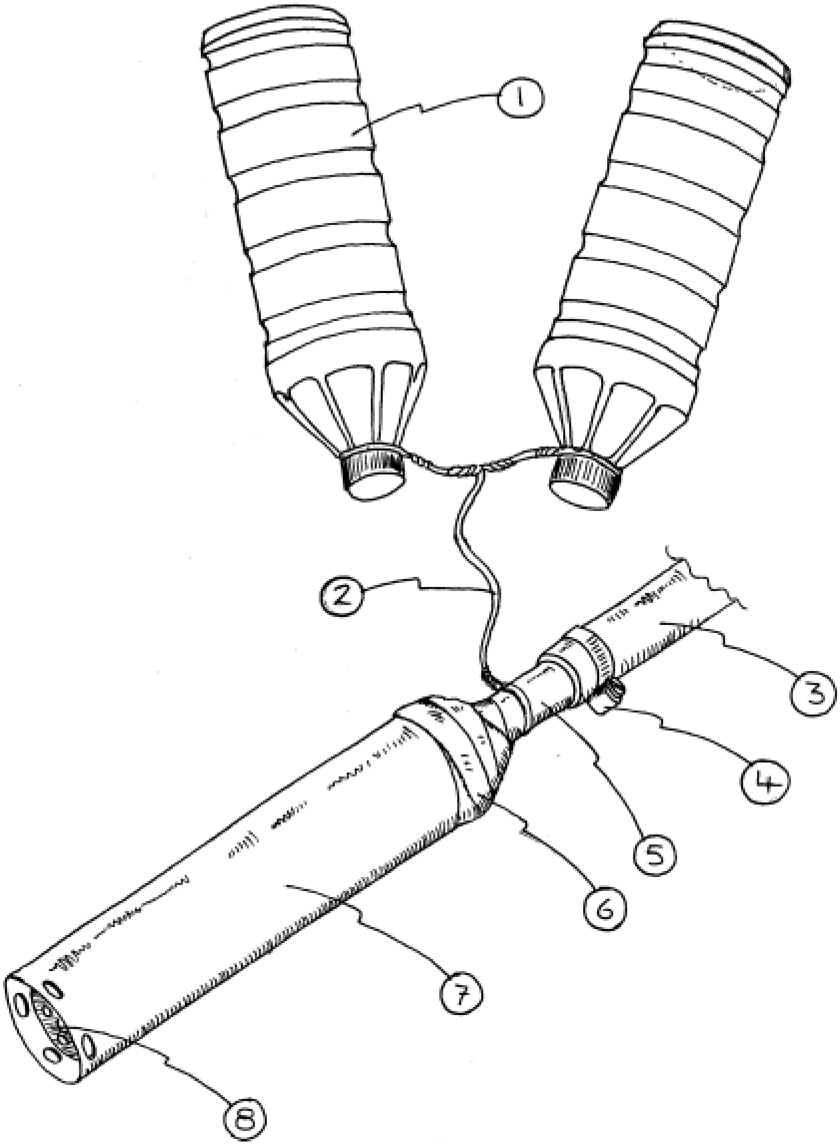
Material: Hardwood



Inlet for ∅1 1/4” PVC pipe, Enhanced inertia handpump

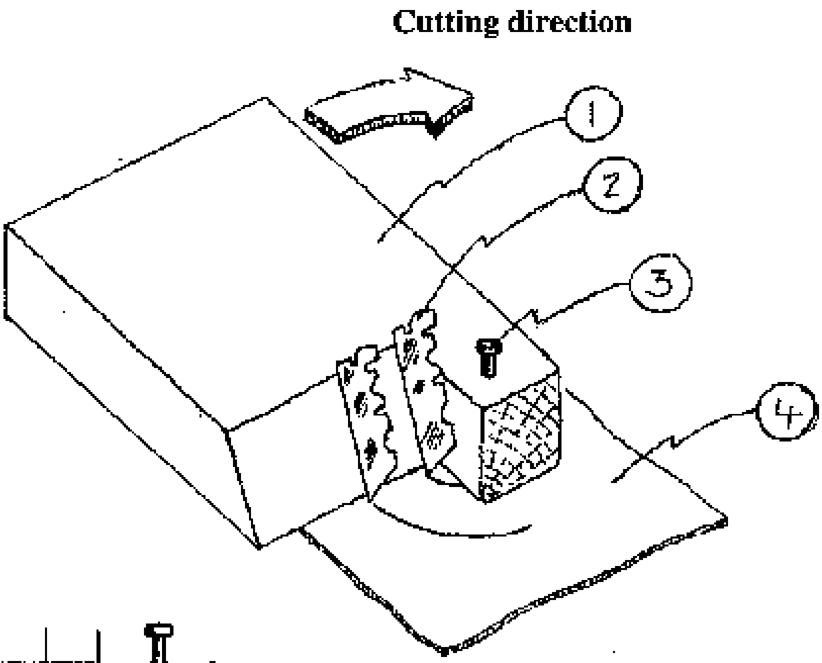


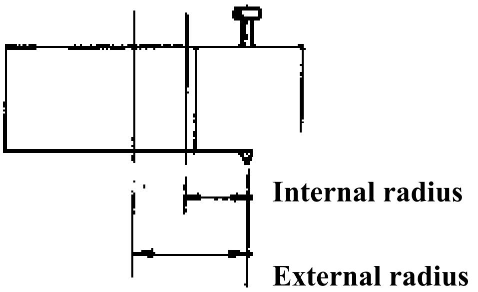
Appendix 4 The floating valve



1	Plastic bottles
2	Insulated copper wire
3	Flexible hose
4	Hose clip
5	Ø1/2" PVC pipe (approx. 150mm long)
6	Rubber inner-tube strip
7	Ø1 1/2" PVC pipe (approx. 200mm long)
8	Wood inlet valve (see appendix 1)

Appendix 5 The piston/valve seal cutter





1	Wood block
2	Razor blade sections
3	Pivot (nail)
4	Rubber being cut

The Tamana seal cutter is made from a suitable piece of wood with dimensions of 50mm x 12mm x 75mm.
The angle of the cut out is at 45° cut sufficiently far back so that the pivot pin and razor blades are all in line with each other.
A razor blade is broken in half and one end of each is broken again to give the acute cutting edge as shown.
After hammering a nail in for the pivot mark off as accurately as possible the internal and external radii taken from the outside diameter of the pull rod and the bore of the rising main respectively on to the wood. The razor blades are then pushed in at these marks making sure the bottom of the blades are at the same height as the pivot point.

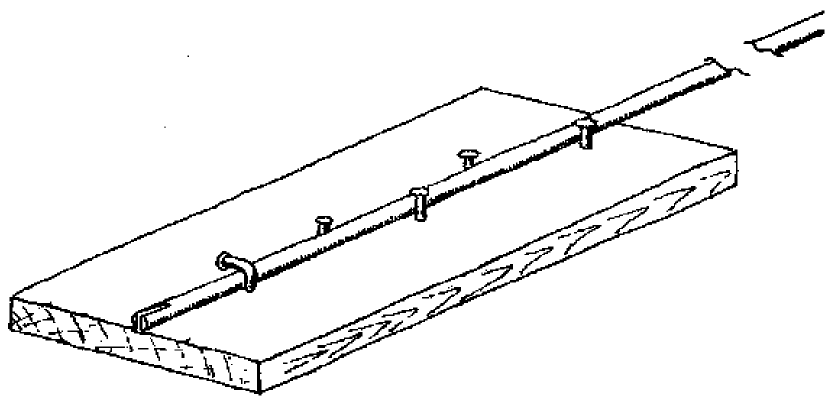
Cut out a small square of rubber inner tube slightly larger than the finished diameter and put the pivot in the centre of the square. Hold this with one finger while rotating the block in a clockwise direction as shown until the disc is cut through.

Appendix 6 Fixture for slitting Harold pump pull rod

The difficulty in obtaining a low cost vice has led to the development of this simple method of work holding. It uses parts and tools that are easily available and will hold a rod firmly enough to saw a slot in the ends.

It uses a series of nails that are staggered down the length of the rod as shown in the figure below. These are hammered into place on alternate sides whilst it is laid flat on a piece of wood. This traps in to position. The nail nearest the end to be sawn is bent over the bar so that it stops the rod from lifting upwards and sideways while sawing, and is turned sideways when removing the pull rod after sawing.

When starting the cut keep the saw at an angle of around 25 degrees and keep it at this angle until the right length of the saw cut is achieved. Then twist the rod round 180 degrees and saw to the same length. Once this is done gradually lift the saw up while sawing until it is 90 degrees to the pull rod. After sawing the rod can be removed by rotating the bent nail out of the way and the bar can be slid out.



Appendix 7 How to make the Harold pump moulded cup

Using the diagrams shown on the following page the procedures are:-

1 Cut a length of Ø1 ½" PVC pipe to 50mm long
2 Cut lengthways.
3 Heat gently and open at split
4 Heat again to produce a flat strip by pressing on a flat surface.
5 While not and pliable, use the wooden form to press into a short length of Ø1 ½" PVC pipe and hold till set (approx. 1 minute).
6 Mark off the centre of the cup and drill to suit the pull rod diameter (8mm).
7 Cut off cup so that target diameter is about 2mm less than inside diameter of 1 ½" PVC pipe.
8 Remove sharp edges with sandpaper.

How to make a wooden form for moulded cup.

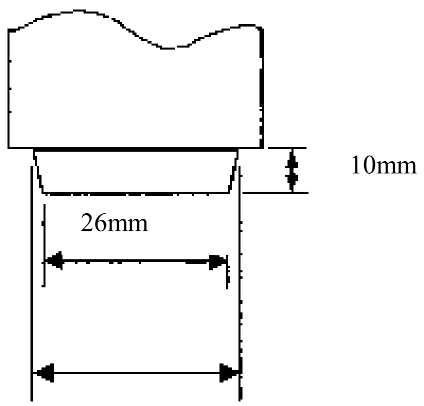
Cut a length of Ø1 ½" PVC pipe off at about 25mm long.

Using the inside diameter and mark off with a pen onto the end of a suitable piece of wood.

Mark off a second diameter of Ø26mm (this will give an angle of approximately 12°)

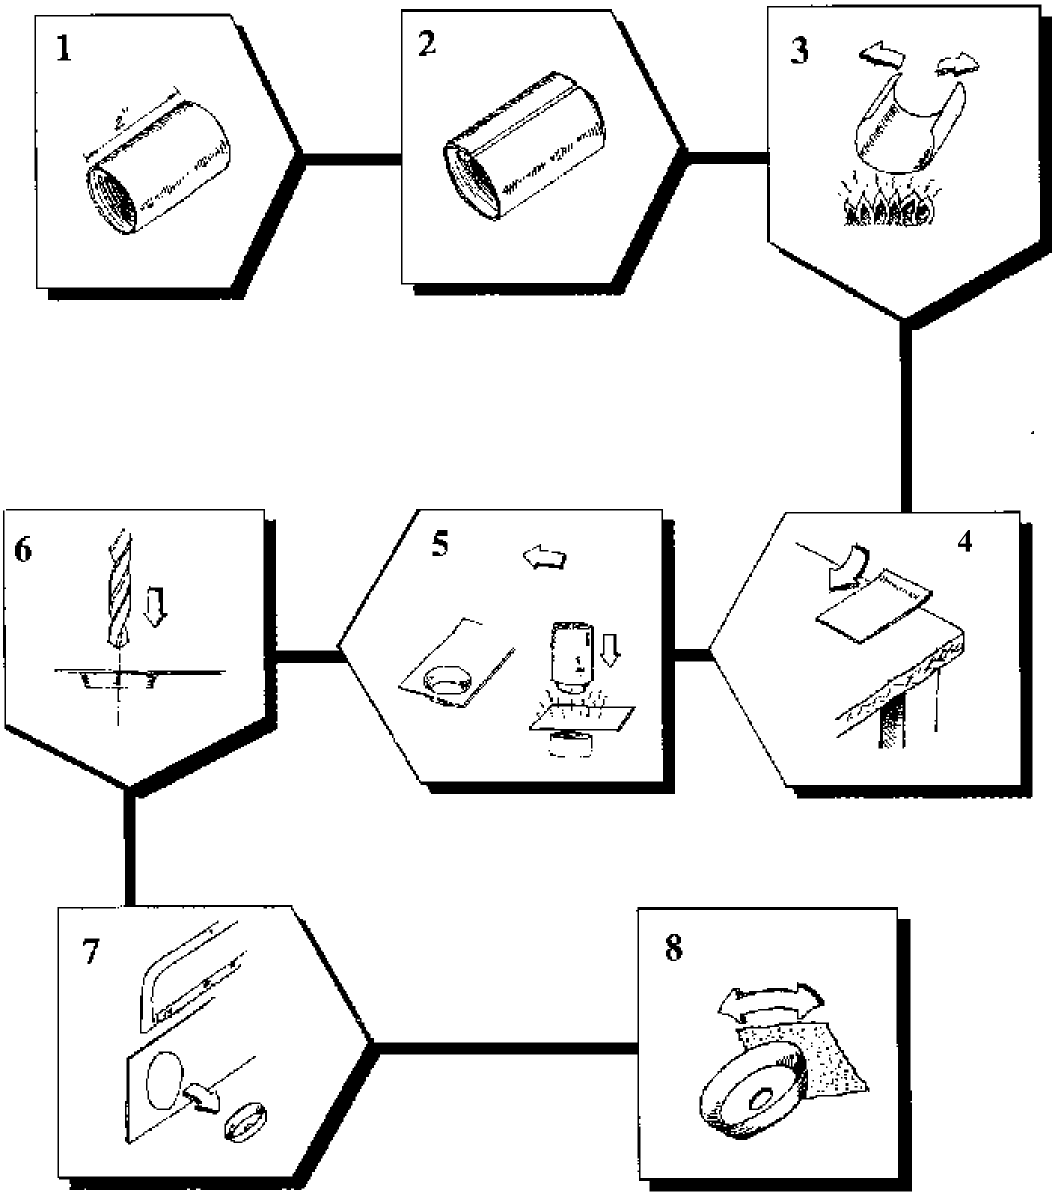
Mark off length of form to 12mm long.

File the taper to shape (or alternatively use a wood lathe)



To suit inside diameter of
pipe minus 2 x wall thickness

Sketches of manufacturing the moulded cup



TR-RWH 10 RAIN-JAR HANDBOOK

PRODUCTION AND USE OF MORTAR RAINWATER JARS

This Handbook was written with special reference to Uganda, whose climate is favourable to roofwater harvesting. It is based on 2-years immediate research in Uganda and several years Ugandan experience of jar production (however general Ugandan DRWH practice is based on other, and more expensive, forms of water storage). Unreinforced mortar jars are sometimes called ‘Thai Jars’ as they have been extensively used in Khon Kaen Province of Thailand since 1985 and are also common in Cambodia and Vietnam. In these countries, concrete rather than wooden moulds (as described below) are preferred: however trials of three type of mould when making 8 jars in Mbarara in 2005 indicated that wooden moulds are easier to use.

Costs are given in Ugandan shillings – USh.2000 = €1.0; USh.3000 = £1.0

Acknowledgment We acknowledge with thanks the financial support (in 2006) and encouragement of WaterAid Uganda that enabled the completion of mortar rain-jar development and testing, and the writing of this Handbook.

Contents

1 Why collect roofwater

Rainwater running off a roof is a very convenient source of household water, because you don't have to walk far to fetch it. If roofwater harvesting is done carefully, the quality of the water is similar to that of water fetched from boreholes or protected springs.

Roofwater harvesting needs

- A water store such as a jar, tank or underground cistern.
- A suitable roof (normally of mabati or tile – collection from thatch is rarely worthwhile)
- A guttering system to intercept the run-off and lead it to the water store

Normally roofwater harvesting is only considered for houses that already have a suitable roof, in which case, the water store is the main expense. This Handbook is about how to make a 1600 litre mortar jar (with little or no metal reinforcement). Such rain-jars provide one of the cheapest and most flexible forms of water storage – costs can be as low as USh.50 per litre of storage capacity (= €25 per cubic meter). The technology of manufacture is fairly simple, does not require an electricity supply and is suitable for a micro-enterprise in a village.

2 How much roof do you need; how much water can you harvest?

Most of Uganda gets a good rainfall (1000 to 1500 mm a year) spread over two rainy seasons. In all but the far North it is uncommon to have more than 8 weeks with no rain. In the 'Cattle Corridor' rainfall is less – 800 to 1000 mm a year – but adequate for harvesting. Only in NE Uganda is rainfall so low (under 800 mm a year) that roofwater harvesting is not rewarding. Appendix A lists Ugandan Districts and their rainfall status.

Roofing is a bigger problem, since although over 60% of houses have some 'hard' roofing, there are parts of the country where the fraction is much lower (whereas other parts have over 90% hard roofing). However for many reasons, metal roofing is steadily growing in popularity and the fraction of roofs suitably for roofwater harvesting will probably rise to over 80% within ten years. In extreme cases it is worth

Of the rain that falls on weven a hard roof, a fraction is lost as splash or evaporation. The rest can be led to a water store, but sometimes that store is already full so the new water is wasted as 'overflow' A small store overflows more than a big store. Using the water jars described in this handbook, you may assume that 15% of the rainfall on the roof does not reach the jar and another 25% overflows the jar, leaving 60% of the rainfall to be drawn from the store.

Table of expected yields from a roofwater harvesting system

The **bold** figure is thousands of litres per year; the figure in brackets **( )** is yield in litres per day for 8 months a year (during the remaining 4 months the yield is only half this figure)

District Rainfall (see Appendix A)	High	Medium	Low	Suggested number of jars
Large roof (100 m^2)	**78** (250)	**66** (220)	**54** (180)	4 - 6
Medium roof (60 m^2)	**47** (150)	**40** (130)	**32** (100)	3 - 4
Small roof both sides (40 m^2)	**31** (100)	**26** (85)	**22** (70)	2 - 3
Small roof one side (20 m^2)	**15** (50)	**13** (45)	**11** (35)	1 - 2

The table above is based upon a particular way of managing the stored water. It would be possible to draw 40% more water in the wet months if none were saved for the dry months.

3 Where to place rain-jars round a house

Most Ugandan houses are rectangular and longer (along the roof ridge) than they are wide. For this shape of building, the best place to put rain-jars would be near the centre of each long wall – at the front and the back. This arrangement is shown in Figure 1 and will work with small gutters (for example 2" wide ones). However many householders would not want to place a jar in front of their house but prefer it at the end of the house as in Figure 2 -

which will require bigger (say 3”) guttering. With jars it is **not** normally sensible to lead the water from both front roof and back roof to the same jar since the long piping will be ugly and too expensive for the benefit obtainable.

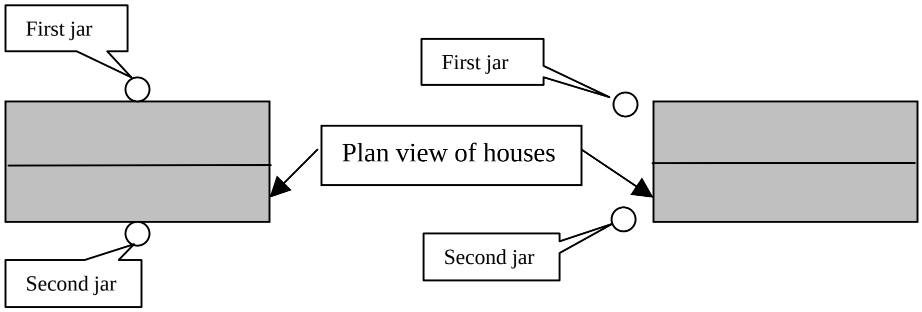


Figure 1 **Figure 2**

If the roof is single-sided – as is the case with many trading centre shops – the jars can be set side by side.

The same arrangement usually applies where more than 2 jars are used, as shown in Figure 3.

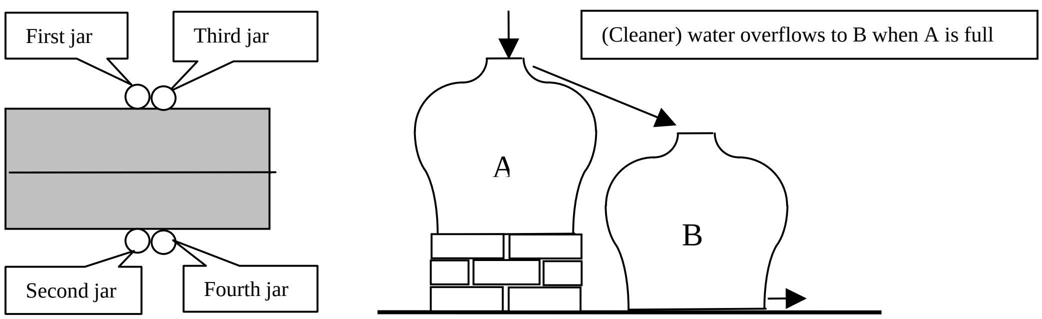

Figure 3

4 *Why mortar jars rather than other forms of water storage*

For storing very large quantities of water the ground itself is the cheapest store: thus wells draw from a reservoir of groundwater that is replenished during each rainy season. Artificial ponds (‘valley dams’) are another way of storing hundreds of thousands of litres of water. However neither the ground nor a pond is suitable for cleanly storing roofwater, for which we always install a jar, tank or cistern.

The main options for a roofwater store are as follows

Pottery jar	30 litres	v small & difficult to keep water clean	USh.100 per litre
Oil drum	180 L	if open-topped then water gets polluted	USh.170 per litre
Plastic drum	1000-12000 L	clean and light but expensive	USh.250 per litre
GI Tank	2000-10000 L	shortened life due to rusting	USh.70 per litre
Ferrocement tank	6000 L	built on site	USh.80 per litre
Partly below ground	6000-12000 L	needs a handpump and good ground	USh.65 per litre
Mortar Rain-Jar	**1500 L**	**built in workshop**	**USh.50 per litre**

5 *Making a jar – preparing for the two stages of production*

Each jar has a base and a shell (body). Both of these are made of un-reinforced ‘mortar’ (sand + cement) which once formed into shape needs to be cured for 7 days. So the main stages of production are (A) making the base disc, (B) making the shell and (C) curing.

Before starting work we need to establish a suitable working space (workshop) that has enough shaded space, tools for making mortar, somewhere to keep tools and materials secure at night and the special equipment needed for jar manufacture.

Space requirement Each jar needs about 5 square meters of floor-space. It needs to be both made and cured under shade from the sun. However production includes applying a layer of mud and then letting it dry, which may be difficult on wet days. A completely indoor workshop is perhaps too expensive and cannot use the sun to dry the mud quickly, however it offers the best security against damage to newly plastered jars and against theft of water. An outdoor workshop with shade matting cannot be used during rain. The ideal would be to build each jar on a trolley that could be moved in and out of the workshop door.

The number of jars in the workshop at any one time depends on how quickly they are sold once they are ready for sale. Jars are not safe to be moved until they have been cured for 7 days. So a workshop making 4 jars per week needs to be *at least* 20 square meters of shaded, hard and level space with 2.4 meters headroom, plus 'outside' space for jars awaiting collection. The workshop door must allow entry of the special jar-lifting cart, which is approx 2 meters high and 2.2 meters wide.

Tools A minimum tool-kit is
- Wheelbarrow for fetching and holding mud
- Spade
- Trowel
- 'Floats' (wooden for main plastering, metal for finishing)
- Level
- Container for measuring out sand and cement
- Blankets or grass to completely cover each jar during curing
- Polythene (such as DPC) for putting on the floor under the base disc and for covering jar during curing

Special equipment
- Two sets of wooden moulds (or more if production is to exceed 4 jars per week). For details of the moulds see Appendix B. There are other sorts of moulds such as filled-bag moulds and concrete ones. Each has disadvantages and we recommend wooden moulds.
- Jar-transporting hand-cart (both for delivery and to move jars from workshop to sales area). For details of the cart see Appendix C.
- Frame to allow each jar to be entered by a man/woman (in order to remove the wooden moulds in it 1.5 to 2 days after plastering.) without their touching the still-weak top of the jar.

Materials

The materials involved in constructing jars are cement, sand, mud, water and steel (rod and pipe). The cement is standard 'ordinary portland' cement (experiments substituting pozzolanic cement for Portland cement have not been done, so we recommend you **don't** use pozzolanic cement). To the cement, which should be bought from a reliable source, a waterproofing agent ('leak-seal') should be added and well mixed. The usual mix is 1kg of waterproofing agent to 50 kg cement.

Sand is a subject of much discussion in Uganda. 'Lake sand' is claimed to be the best for concrete and mortar, but it is often expensive to transport to the production site and we try to use local sand wherever possible. A local sand is 'suitable' for making mortar if
- It contains less than 10% 'fines' (as measured by the bottle test described below)
- Not more than 65%, and not less than 15%, of the sand is so small it will pass through a 0.4mm sieve (see the sieve test described below).
- It does not feel sticky when wet
- There is no organic material in it and it does not smell of vegetation

If the available local sand is too fine to satisfy this specification, it may be mixed 50:50 with a coarser sand, or with stone dust, brought from elsewhere.

Mud is required (1 – 2 wheelbarrows-full) for covering the wooden moulds as a release agent. This should be sticky enough to hold onto the wood, but not so sticky (so much clay) that it dries very hard. The producer may need to try out different sandy soils to make the mud from. See section 15 about possible problems relating to mud.

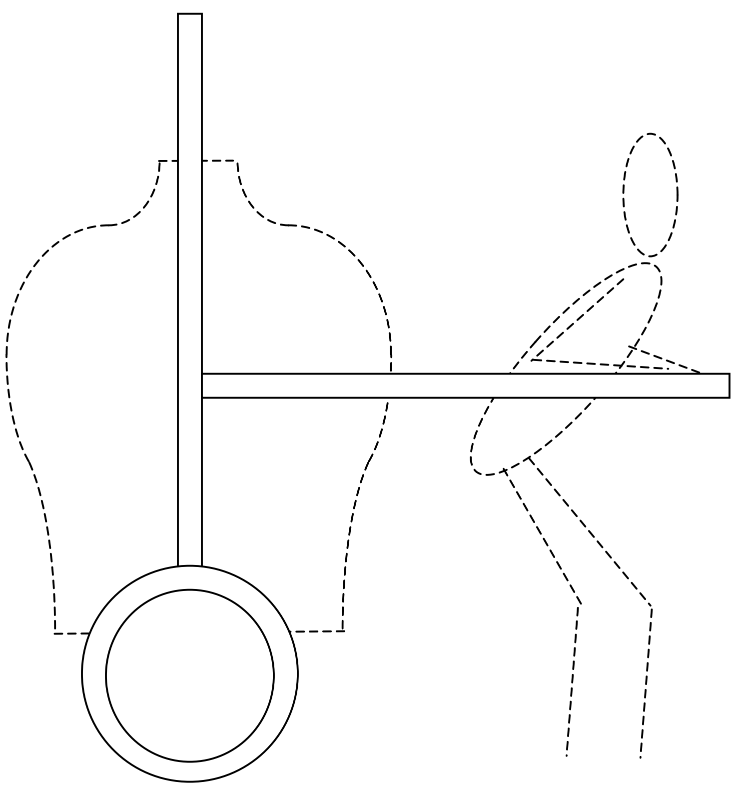

Fig 5 Special handcart (or donkey cart) for lifting, transporting and placing jars

Two Tests For Selecting Mortaring Sand

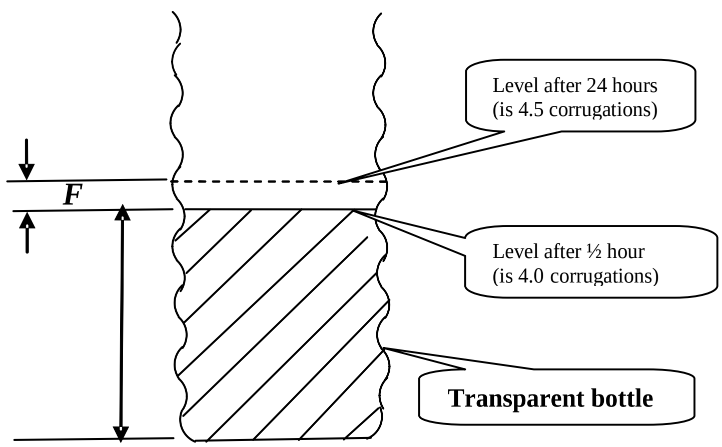
Bottle Test for seeing what fraction of a soil is 'fines'

Take the 'sand' you would like to use and break up any lumps with a mortar and pestle (or with the back of a spoon in a saucepan). Pass the soil through a very coarse kitchen sieve or through coffee-tray mesh. With what passes through the sieve, 1/3 fill a transparent bottle such as a ribbed plastic spring-water bottle and add clean water to nearly fill the bottle. (If you use chlorinated tap water, let it stand in an open pan for some hours to get rid of the chlorine.) Let the soil soak for 10 minutes, then shake it hard for ½ minute. At the end of shaking, immediately put the bottle on a flat surface in good light and start timing.

After ½ minute all the sand will have fallen to the bottom and will form a layer whose height *H* you should measure. (Sometimes you can use the corrugations of the bottle itself to measure height).

After 24 hours the 'fines', namely the silt and clay, will have fallen down to form a layer on top of the sand. The height of this extra layer we can call *F*.

For good mortar work *F* should not be more than 1/10 of *H.*



Sieve test to check the grading of the sand

You will need two sieves, a coarse one (with 1.2 to 2 mm holes) and a fine one (such as a household sieve for tea) with 0.4mm holes.

First sieve some soil through the coarse sieve and weigh out 100 grams (on a Post Office scale?).

Now sieve this 100 grams through the 0.4 mm fine sieve and weigh what goes through. Not more than 65% (or at worst 70%) should go through.

6 Stage A – Making the base disc

The base disc is a simple component of mortar (3:1 sand:cement), but it must be made before the tank shell and properly cured (= kept covered and moist). It is essentially a mortar disc (115cm in diameter x 25mm thick) in which other components are embedded. These components are

- a water outlet pipe (essential)
- a washout pipe (usually omitted)
- lifting handles (optional)
- a strip of steel mesh (optional)

The disc is cast onto a flattened surface covered with polythene and inside a metal strip 25mm thick bent into a circle and joined by adhesive tape to maintain its inside diameter as 115 cm. The mortar must be tamped so that it completely fills the space inside the strip – the mix being made **just** moist enough to do this reliably but still rather dry and stiff. After 2 hours, the metal strip can be removed (unwrapped). The top of the disc, for 5cm in from its edge, is made rougher by heavily pitting it with a trowel or spike or by cutting. In addition a 7 cm strip of (3-4mm) mesh may be buried in the part of the disc where the shell will sit on it, leaving about 4 cm protruding. The disc is next covered and kept moist for at least 6 (and preferably 24) hours to cure.

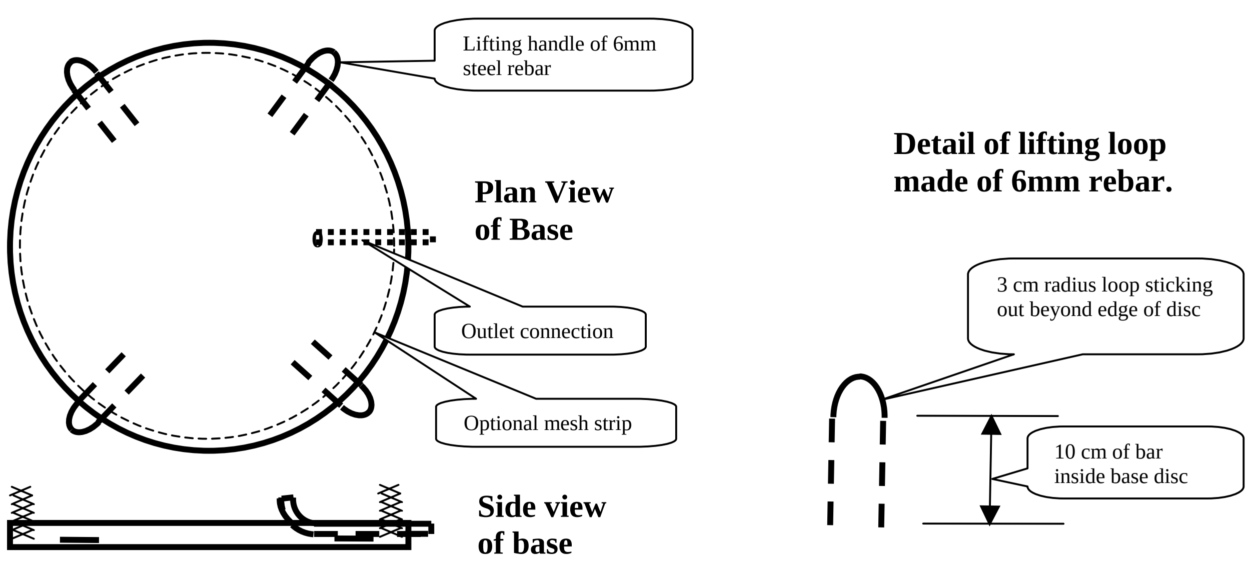
The outlet connection is set into the base disc as soon as the mortar there has set enough to cut a slot for it. The outlet (3/4" metal pipe + elbow or pipe and bent-up length of hose) is placed in the slot and mortared over. The inside end of the outlet (elbow or hose) should stand at least 2 cm above the surface of the base disc. This is so that outflowing dirty water is not drawn from the very bottom of the jar. The entry to this outlet should be plugged with wood or cloth to prevent mortar falling into it during later stages of construction.

The reason why a washout pipe is usually omitted is that an inlet filter should be used that prevents much debris ever entering the jar so that it doesn't need annual cleaning. Moreover the base disc is not thick enough to allow a washout pipe of useful diameter (over 25 mm bore). Cleaning a jar itself introduces further likelihood of contamination so is best avoided, however these jars are small enough that some accumulated mud can be removed without a person actually entering the jar.

Lifting handles can be incorporated in the base as an alternative to lifting the jar with a chain wrapped round its circumference below its widest point. (That is the method employed when the jar is lifted onto the Delivery Handcart described in Appendix C).

The base is now ready for moulds to be placed onto it as the first stage in shell construction.

Figure 5 The base of the jar



7 *Stage B – Making the jar shell*

The shell is made in 4 or 5 steps once the base has been cast and allowed to set (for at least 3 hours). These steps are

a) Assemble wooden moulds on the base and cover them with mud to roughly form shape of jar.

b) Let the mud dry then plaster over it with mortar.

c) Cover and cure for at least 48 hours, then remove the wooden moulds and mud and add 'nil' layer.

d) Cover and cure for 2 more days then (optionally test with water.

e) Cure for 3 more days.

Step	a)	b)	c)	d)	e)
Activity	Mud onto moulds	Plaster with mortar	Remove moulds, add 'nil'	Test with water (optional)	Completed, ready for delivery
		Cure under moist cover (see box titled 'Curing' below)			
Days	1	2	4	6	9

Notice that each jar occupies workshop space for 7-8 days and the wooden moulds are in use for 3-4 days. Thus each set of moulds can be used to produce, at most, 2 jars per week.

The steps above are now described in more detail.

a) Mould assembly and mud application on Day 1

The 5 layers of mould boxes (A to E) and the 4 layers of planks (F to I) are assembled on the base, using mud to fix them in position and to space one above each other. A spirit level can be used to ensure each layer is level. A basin (at least 45 cm diameter), weighted with stones, is placed at the top. A wooden bar may be used to support it, as shown below.

Figure 7 Joint between shell wall and base

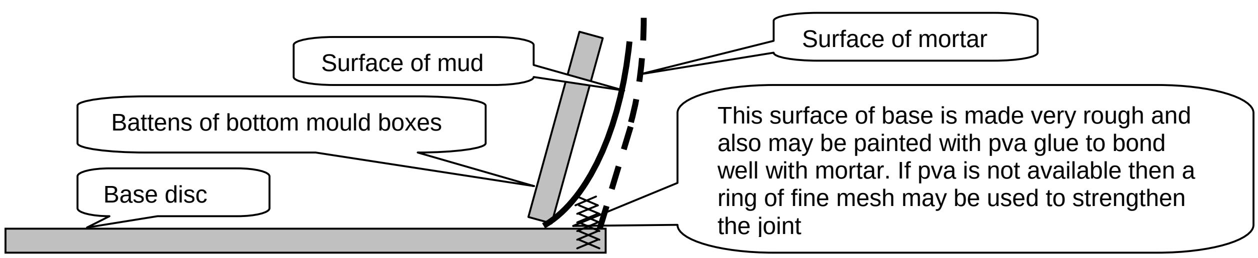


Figure 8 Applying mud to top of moulds

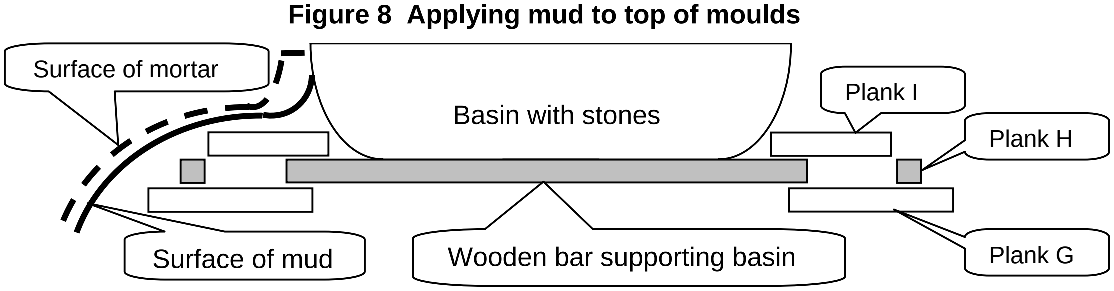

The moulds are then covered with a fairly thin layer of mud shaped to make the desired shape of the jar. The mud should be moist enough to stick to the battens on the outside of the moulds when thrown at them in the manner of a plasterer. The shaping can be with a wooden or metal plasterer's float. The edge 5 cm of the base disc and the protruding mesh (if used) should be kept clear of mud.

Curing

Unlike mud bricks or lime, cement needs to be kept as dry as possible during mixing and as wet as possible during the next week (the 'curing' period). As we are applying mortar by plastering, the water content of the mix has to be suitable for the plaster to stick to a vertical surface. However after a couple of hours, when the mortar has 'gone off' (hardened a little) we want to put it into a moist atmosphere to stop it losing water by evaporation. Experiments have shown that well-cured cement is much stronger than cement left out in the sun.

In practice we do three things:
- shade the jar from the sun
- put some water inside the jar and close its top opening
- cover the jar with wet grass or wet cloth and covering that with polythene sheet to keep the moisture in.

Curing for a long time means the workshop must be large enough to hold many jars. In practice 7 days curing should be enough. When the jar is transported to site it may experience bigger forces than after it has been placed in its final position. For this reason it is unwise to move it after only 3 or 4 days.

Because it must be applied and removed many times, it is worth making a polythene cover which can be slipped over the top of a jar and then tied together round the bottom of the jar. Under the polythene can be wet grass or wet blankets. Grass is probably easier to moisten and then keep moist. Blankets should be sewn together to make a jacket that can easily be put on and taken off a jar. They should be dried out after use on each jar to stop them rotting. Production workers are always reluctant to replace the exterior grass/blankets once they are removed, so it is recommended that only the material covering the top aperture is removed to allow access for demoulding on Day 4.

b) Let mud dry, then plaster over it with mortar on Day 2

When the mud is semi-dry, with a wet float fill over any large cracks that have formed and to give it an even surface. (If the cracks are more than 5 mm wide, the mud has shrunk a lot and therefore contains too much clay: this will cause problems during demoulding [step c)] – a sandier mud should be used for the next jar.)

The whole jar shell should be mortared, over the mud, to a uniform thickness of 10-12 mm with 3:1 well-mixed sand-cement. The cement contains 2% leak-sealing compound. The water content of the mortar should be that which allows good dense plastering – if it is too wet the final mortar will be weaker, if it is too dry the plastering will be rough and contain voids. On completion of applying the mortar, it should be re-trowelled with a well-moistened metal float to give a dense smooth surface. Later, see step c), the inside of the jar below the widest point will be given another 2 mm of 'nil' (cement + water slurry).

The top collar of the jar should be formed using the basin as a mould and (for best appearance) a scraper resting on the basin to ensure the collar is uniform thickness (say 25 mm), circular. The top should be flat or sloping slightly down to the outside.

The joint between shell wall and base is an important one and is shown in the figure above. The base must be very rough (pitted or grooved), clean and wetted where the wall meets it. If available (not in Uganda), pva glue, neat or diluted 1:1 with water, should be applied to the base and allowed to go sticky before applying the mortar. Where pva is not available and there is any uncertainty about the quality of the joint between base and wall, a strip of mesh will have been set in the base with 4 cm protruding. Bend this mesh outwards to allow mortar to be placed behind it, then bent it back upright, press it into the mortar and cover it with further mortar.

Some water should be put in the jar as soon as the mortar has hardened to ensure the atmosphere inside the jar is moist and the mud does not dry out further (thereby getting too hard and also perhaps stealing moisture from the mortar it touches).

c) Cover and cure, then remove both wooden moulds & mud, add 'nil' layer on Day 4

Cure for 48 hours (see Section 8 below). Now carefully remove basin and moulds without cracking the shell. This takes some skill and it may be prudent to start with mould removal on day 5 and change to day 4 once skill has been built up. To remove planks or boxes the mud holding them in place must be loosened with a knife or stick. Only the planks can be taken out from above. All the boxes are loosened and passed out by a person *inside* the jar. However to enter and leave the jar no force must be put on the jar's collar: instead the person enters and leaves using the framework shown in Figure 4.

After removing the moulds they should be inspected for any damage (like loose battens) and repaired if necessary.

All loose mud is scraped or brushed from the inside of the jar and taken out. The jar inside is then washed and the plug blocking the outlet pipe is removed. Do not leave much mud in the shallow pool at the bottom of the jar.

A slurry is made of cement and water using about 10 kg of cement. This is brushed onto the *inside* of the jar from its widest point downwards to the base to form a waterproofing layer 1 to 2 mm thick.

d) Cover and cure for 2 more days then (optionally) test with water on Day 6

Cure for 48 more hours. Now a strength test can be applied by filling the jar with water. As it is 4 days since the mortar was applied, the strength of the jar should have reached 50% of its final value. The different test options are described in Section 10 of this Handbook. The outlet hosepipe should be tied up the side of the jar to a wooden stick marked with heights (10cm, 20cm etc) so that the level of water in the jar can be monitored. If water is available it certainly a good idea to at least half-fill the jar (say up to 65 cm deep). this has two purposes:

- to make sure the jar has no serious defects low down (damp patches may form on the surface but these will disappear after 24 hours as the leak-seal compound reacts with the seeping water). If however there is leakage from a point defect, fine sand can be sprinkled onto the inside water surface immediately above the defect so that the sand is drawn into the leak to block it.
- to help it cure completely.

e) Continue curing until Day 9

Day 9 is 7 days after the mortar was made. Curing well (moistly) for 7 days should have developed most of the jar's strength so that it is ready for transport to site.

8 *Inlet, outlet and overflow arrangements*

The purpose of an **inlet filter** is to let in water but to prevent organic debris *or light* from entering the jar. The inlet to a jar is usually a basin that fits snugly into the top collar (e.g. the same basin that was used for forming the collar, whose diameter of 45-50cm was big enough to allow entry of the demoulder to the jar). Basins are slightly tapered and this taper improves the fit. The bottom of the basin should be pierced with many holes (for example using a heated nail) to let the water flow through it. The basin is next 2/3 filled with gravel sufficiently large that it does not slip through the holes. Finally the basin is covered with a cloth that allows water to flow through it. If the cloth is given an elasticated edge, it can easily be removed, washed and replaced. A stick can be used to raise the centre of the cloth so that some of the debris (twigs, leaves) that it catches will slide off it. However if the stick is too long (and the cloth-cone too steep-sided) some water will be lost too.

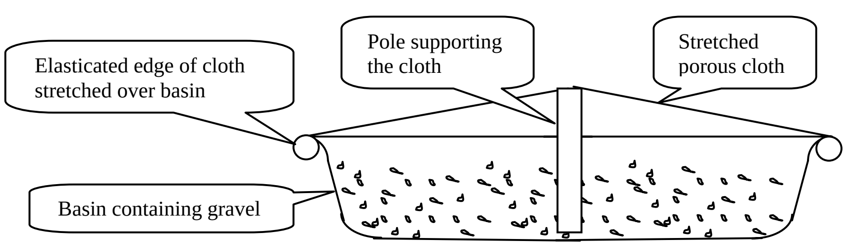

Figure 9 Basin used as inlet filter

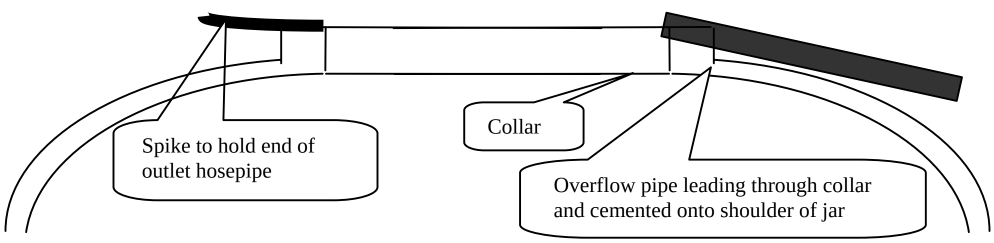
If the bowl is directly under the end of a gutter, or (even better) under the ends of two gutters discharging towards each other) then no down-pipe may be needed. If the water overshoots the basin during intense rainfall, a chain can be hung from gutter-end to basin to guide the run-off flow.

Some systems, especially those near dusty roads, have an arrangement called ‘first-lush diversion’ whereby water falling from the gutter can be temporarily diverted so that it misses the basin. This diversion is put into place during a dry season so that when the first rains come, the very dirty ‘first flush’ runoff doesn’t go into the jar. After 10 minutes of good rain, the runoff should become cleaner and it is time to remove the diverter.

The combination of a cloth-and-gravel inlet filter and the diversion of the silt-laden ‘first flush’ will ensure that the jar very rarely needs cleaning – perhaps once in 3 years. Frequent cleaning is not a good practice for rainjars as it introduces contamination and removes any slime layer on the walls that are digesting bacteria.

An **overflow** is needed so that when the jar is completely full any new roof-runoff water has somewhere to go. The simplest arrangement is to allow water to emerge around the rim of the basin and run down the outside of the jar. However it is often better to incorporate a 20-25mm bore pipe in the collar of the jar that leads out as far as the shoulder of the jar, so that overflow water can be directed in a chosen direction or taken to a second jar as shown in Figure 3 (in Section 3 above). Overflow water is generally a little cleaner than the water already in the jar, so the overflow jar should be used mainly as a source of drinking/cooking water.

An **Outlet** is obviously needed. We have shown the outlet pipe embedded in the base. This is because if the outlet pipe were just held by the thin jar wall, it would not be secure and big forces applied to it could break the jar. Where the pipe emerges from the base, at the bottom of the jar wall, it can be a simple metal tube onto which a hosepipe is fitted (and tied by rubber strap). The other end of the hosepipe should be hooked over a spike coming from the collar of the jar. Such a hosepipe outlet is cheap, easy to use to fill containers and can be easily replaced if broken or stolen.



However a hosepipe gives no protection against water being stolen or the tank contents being lost due to careless or malicious dropping of the pipe. So some users will prefer to have a tap which in turn requires a thread to be formed on the end of the tube emerging from the jar base.

Whether using a tap or a hosepipe, when the jar is nearly empty the water is available only at the level of the jar’s base. (The last 2-3 cm of water cannot be withdrawn – it is likely to be dirty with sediment). Thus to fill a jerrycan placed on the ground, the jar base must be on a plinth at least 30-40 cm high. Alternately the plinth can be lower and a pit dug next to it to accommodate the jerrycan. Such a pit may need a gravel base and a drain.

9 Testing the completed jar

A good jar is one of the right thickness (about 13mm at the bottom and 10mm at the top), good to look at, having no leaks and of course not breaking when filled with water.

We can roughly test the average thickness by noting how much cement we use. More than 1.6 bags and the jar is too thick; less than 1.2 bags and it is too thin.

The jar is made of mortar – a material that gets stronger over time. Mortar reaches almost its full strength 28 days after it was mixed, but at 7 days it has only developed 70% strength and at 4 days only 50%. So if we can half fill it at 4 days without it bursting, it is likely we could safely fill it completely at 28 days. Actually we want the jar to be more than ‘just’ strong enough so filling it completely on the 4th day shows it has a ‘safety factor’ of about 2. – a good value.

It is possible to apply an ‘over-pressure’ to the jar at 7 days or even 28 days after mixing the mortar. This is an interesting test to apply during research but too difficult to do during production, because it needs the inlet filter to be replaced by a special strong and watertight seal. Indeed all testing with water is a bit difficult because it requires a lot of water (75 jerrycans) to be available, to be put unto the jar and taken out again. The likely water tests are therefore

a) half-fill every jar at 4 days (with 750 litres of water) to confirm safety factor >1,
b) completely fill every jar at 4 days (with 1500 litres of water) to confirm safety factor >2,
c) completely fill at 4 days every 10th jar that is made to check that the production procedures are sound,
d) completely fill at 7 days every jar whose purchaser pays to have it so tested (say USh.5000/-)

Although passing test a) does not absolutely guarantee that a jar is sound, it requires less water than the other loading tests and it enables any low-down cracks to be identified. It is very difficult to effectively repair cracks, so a jar found to have vertical cracks over 50mm long should be abandoned.

Test b) is the most severe.

Passing tests d) shows a safety factor of at least 1.5.

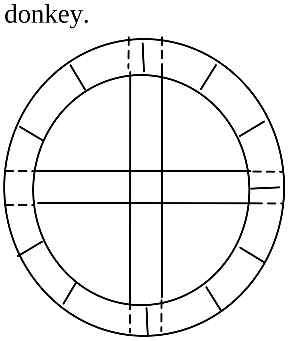
The overall requirement for test-water is reduced if water can be transferred from jar to jar. Half the water in a jar can be transferred to another jar by gravity (through a hosepipe connected from outlet to outlet), but the rest of the water will need raised by hand-pump or by lifting jerrycans.

When a jar is first filled with water its outside surface will become moist and remain so for a day or more until the waterproofing additive develops its power to seal off seepage.

10 Delivering and placing the completed jar

The jar, once made and purchased, needs to be delivered. It is heavy (say 270 kg) and not easy to grasp. The easiest way is to suspend it from two hooks by chains sleeved with hosepipe. One chain is fitted round the jar at about 40 cm above the ground: the chain is joined by a bolt with washers and a nut. Two more chains are bolted to this ring-chain to form loops that will connect to carrying poles or to a special transporter cart. The cart, sketched in Figure 5, has hooks about 1.8 meters off the ground which can be lowered to 1.55 meters when the cart is tilted back. So the jar chains are attached to these hooks in their low (tilted back) position and then – with the pull of several people – the cart is pulled upright, so lifting the jar 20-25 cm. The jar is then tied with ropes to the frame of the cart (at all points of contact a car tire is used to buffer the mortar jar from the steel frame) and the cart is pulled or pushed by 3 people or a donkey.

A jar can be carried on a pick-up truck (or even, in flat country, on a motorcycle trailer. However in both cases it is difficult to lift the heavy jar on and off the vehicle. Therefore for distances up to 6 km in a low-wage country, delivery by handcart is likely to be the best option, even though it needs a team of three people or one person and a donkey.



On arrival at site, where a plinth of 40 cm height has already been built, the jar must be lowered onto the plinth. This will require temporary ramps to be placed for the cart wheels to run up – for example planks supported by two bricks at one end. The arrangement is shown in Figure C2 of Appendix C. Once positioned above the plinth, the jar is lowered onto it. The plinth should be solid, given a level mortar top and then be surfaced with 1 cm of wet mortar just before the jar is placed on it. A suitable plinth would be built on a rammed foundation 15 cm below ground level and take the form of a circular wall with one or two interlocked diameter walls – as shown in the plan alongside.

11 Costing the jar production

The costs below are in Ugandan shillings in 2006 at which time the exchange rate to one Euro was about USh2000/-

There are three main costs associated with jar production (up to the point a jar is ready for delivery) namely:

- Materials and components
- Labour
- Use ('rental') of capital equipment.

Materials and components

Each jar requires		
Cement (opc) 65-75kg		USh.24000/-
Sand (assumed local sand 'balanced' by up to ½ 'Lake sand' brought from afar) 200 kg		USh. 2000/-
'Leak-seal' waterproofing agent, 1 kg		USh. 1500/-
Basin and outlet pipe/hose		USh. 6000/-
[optionally 3m x 8cm mesh		USh. 1000/-]
	Total materials	*USh.34000/-*
Labour		
Assuming a production rate of 4 jars per week from a team comprising 1 mason and 1 labourer		
Labour cost per jar is USh.(60000+20000) / 4		*USh.20000/-*
Use of capital equipment		
Wooden moulds costing USh.150000 and assumed to last for 30 jars		USh. 5000/-
Premises – 6 m^2-wk per jar @ USh.700/m^2/month		USh. 1000/-
Hand tools and frame - USh.100000 divided over 6 months production		USh. 1000/-
Water for testing, assume some recovery so 300 L per jar @ USh.5000 / m^3		USh. 1500/-
	Total rentables per jar	*USh. 8500/-*
On site cost		
A plinth of height 400mm and diameter 1100mm needs to be built at the site for each jar and the jar mortared to it after delivery		*USh. 6000/-*
Total without delivery		***USh.68,500/-***
Delivery by handcart over 3km (cart rental & unskilled labour)		*USh. 8000/-*
So the cost per delivered jar (with no profit to the producer) would be		***USh.76,000/-***

The investment required to set up jar production at a rate of 4 per week is		
Moulds (2 off) x USh.150000		USh.300000/-
Tooling		USh.100000/-
Handcart		USh.350000/-
Work in progress (4 jars not delivered)		USh.270000/-
	Total investment excluding premises	**USh.1,020,000/-**

12 "On-site' and 'factory' production of jars compared

There are two ways of making mortar jars for use at a household. Under 'on-site' construction the jar is made in its final position alongside the house; under 'factory' construction the jar is made in a workshop and then carried to its final site. With large above-ground tanks and with all underground tanks, there is no choice – they have to be made 'on site'. With the mortar jars described in this Handbook, which weigh about 270 kg, there is the possibility of carrying them to site and hence the option of making them in a small workshop 'factory'.

The advantages of ‘factory’ production are

- a higher level of production quality control can be maintained, hence allowing thinner jar walls and the use of less cement,
- suitable sand can be found and used,
- A permanent shading structure can be created and used rather than having to be created anew for each jar,
- the bulky moulds (occupying 1.5 m^3) do not need to be carried to the customer’s house,
- the jar can be made and displayed prior to purchase – the householder does not have the uncertainty about timing or quality that comes with having to commission a mason to visit their home to construct jars,
- if each (or every say 5^{th}) jar is to be water-tested, which requires 1500 litres of water, this water can be held at the workshop and used for testing many jars,
- the jar-builder does not have to visit the site three times (for moulding, for plastering after the mud has dried and for demoulding) or stay on site for 3 days.

The advantages of ‘on-site’ production are

- the jar does not have to be transported or lifted onto its plinth,
- some materials and perhaps a little labour can be provided by the householder,
- the location of any jar subsidised by some aid programme can be guaranteed.

13 What can go wrong in jar manufacture

Making jars takes some skill. The first jar made by a new producer is likely to have faults and will probably need to be discarded.

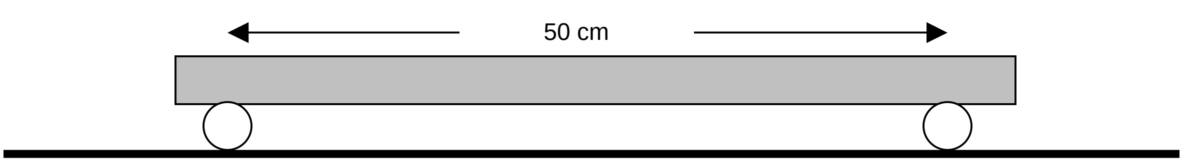
A badly made jar may fail either by leaking or by actually bursting when filled with water. It may also look mis-shapen or ugly. Here is a list of what could go wrong:

- the cement and/or sand is of poor quality
- the jar develops cracks when the moulds are being taken out
- the jar leaks where the shell joins the base
- the jar shell is too thin in places
- the jar was not cured properly
- the jar looks irregular.

(a) Poor cement and/or sand

Cement quality is often a problem in Uganda. The cement is of variable quality before it reaches the market and often deteriorates due to bad storage thereafter. Occasionally cement is adulterated with ash etc. There have been several recent building collapses in Kampala that may be due to poor cement. It is not practical to thoroughly test cement but a test for really poor cement is as follows:

Mix sand:cement in proportions 3:1 and cast three mortar bars (inside a wooden mould) each 5cm x 5cm x 60cm. Make sure the mortar is not too wet and tamp it well into the corners of the mould. Cure it well – 7 days under moist conditions. Now put it on two round poles resting on flat ground and placed 5 cm from each end of a bar as shown. Put a load of 10 kg onto the centre of each bar. If all bars break the cement is quite unsuitable; if only 1 bar breaks it is barely suitable (the jars should be made thicker than normal). If all the bars survive the “10 kg test” the cement-sand combination is acceptable.



In the **materials** paragraph of section 5 of this Handbook, there is advice on selecting sand.

(b) The jar develops cracks when the moulds are being taken out

When a jar contains water, its walls are subject to tension so that any crack will tend to open up slightly: cracks cannot carry any tension. Vertical cracks more than 5cm long make the jar much weaker, and it may fail by bursting when filled. If the crack is 10 cm long and is found anywhere except near the top of the jar, the jar will almost certainly fail. The main cause of cracks is too much force being applied when taking out the moulds. This may be due to wrong practice (esp. to not scraping away enough mud before taking out each mould box) or due to the mud being too strong when dry (containing too much clay). So inspect the jar for cracks before and after taking out the moulds to see if demoulding has produced new cracks. If it has, try to be more careful next time, or wait longer (more than the two days listed in Section 7 of this Handbook), or make the mud more sandy.

(c) The jar leaks where the shell joins the base

The shell is made about 2 days after the base, so the joint between the two is a joint between 'new' and 'old' mortar. This is not ideal but it cannot be avoided. So to make a good joint we want the part of the base under the shell (wall) to be very rough – pitted with a chisel or grooved, completely cleaned/washed of mud and at least 4cm thick. If there is significant leakage under the bottom of the wall, for the next jar pay more attention to roughening and cleaning. If PVA adhesive is available, paint the edge of the base with a 1:1 mix of that before mortaring the shell wall onto it. Alternatively introduce mesh into the joint, as described in Section 6 as an option.

(d) The jar shell is too thin in places

It is almost impossible to measure the wall thickness of a jar (unless it breaks) so the main check on thickness has to be during plastering. Remember the lower part of the jar (below its widest diameter) needs to be about 2 mm thicker than the upper part. Using too little cement (under 1.25 bag) in the 3:1 mortar is an indication the walls are *on average* too thin. However if a jar fails it will probably be where it is thinnest. So if a jar does fail during water testing, examine the pieces to see whether any are thinner than 12mm (lower part) or 10mm (upper part).

(e) The jar was not cured properly

It is hard to persuade masons to take moist curing seriously, as many believe that cement is like mud and has to dry out. There is no test you can apply to test whether curing was good, so you cannot ever be sure poor strength is due to inadequate curing. Thus good practice has to be enforced during production and it is especially important that the jar is not exposed to the sun during its curing period, that 'wet covers' are replaced after demoulding and that as soon as possible some water is put inside the jar.

(f) The wall-base joint leaks after the jar is delivered although it did not leak earlier when tested.

The cause of this is inadequate support from the plinth. The plinth must meet the base disc all the way round and also not be made of such soft material that the disc can sink perceptibly under the weight of the water in it (1.5 tonnes). Inadequate foundations for the plinth may also allow the jar to gradually lean over after some months of use.

(g) The jar looks irregular

The good shape of the jar mainly depends on the skill of the plasterer when applying the mud and therefore should improve with experience. Jars produced in Thailand over the last 20 years look very smart and 'machine-made' although they use only hand-plastering. It would be possible to make a shaped piece of plywood to place across the whole top of the jar to check its symmetry after mudding, but this is not really necessary. However such a guide could be more useful in making sure the top collar (round the basin) has a level top, is of uniform thickness and looks a clean circle.

The surface of the jar can be made smoother by painting it with a thin layer of weak 'nil' (= cement plus water) or with whitewash/lime.

14 Instructions for using rain-jars

[These instructions need to be passed on from the jar-maker to the jar user by word of mouth or by some sort of document.]

How much water should you draw from each jar?

A rainjar accepts water on wet days so that you can use it later on dry days. However you need to ‘manage’ the stored water to get the greatest benefit from having the jar. The method of management is to decide how much water to draw from the jar each day – an amount that may vary from one season to another.

Sometimes a jar overflows because there isn’t room in it to accept more rainfall: overflow water is wasted. If you draw more water from the jar each day, that creates more space for new water to enter and so reduces overflow. Up to a certain point, the more water you draw in the wet season, the more water you get.

However if you draw too much water in the wet months there won’t be much left at the beginning of the next dry season.

We recommend the following way of balancing wet and dry season use, by varying what you try to draw from the jar according to how much water is still left in it.

The jar is marked with three bands:

Band 1 (coloured red) is 0-600 litres. If the water level is in this band, you haven’t much left and we recommend you draw ***not more than 2 jerricans a day*** from each rainjar. If there is no more rainfall, the water will last for 15 days. To make it last a month without rainfall, reduce the demand to ***not more than 1 jerrican a day***.

Band 2 (coloured yellow) is 600-1000 litres. If the water level is in this band, we recommend you draw ***not more than 3*** jerricans a day from each rainjar.

Band 3 (coloured green) is 1000-1500 litres. If the water level is in this band, we recommend you draw ***not more than 5*** jerricans a day from each rainjar.

How can you ensure high water quality?

Properly used, roofwater is safe to drink and cook with. For this to be so you should:

Clean out your gutters twice a year – more often if your roof is under trees.

Make sure the filter bowl is always in position, that it is full of gravel or very coarse sand and its cloth cover is in position. Wash that cover whenever it gets clogged with leaves or mud and replace it when it gets torn or decayed. This inlet filter stops vegetation, lizards, rats and insects from entering the jar.

The first rains of a new wet season will wash much dust off the roof, making the run-off water very cloudy. So for two days after such ‘new rains’ boil the water from the jar before drinking it. Some people also divert the roofwater away from entering the jar during the first half hour of such new rains. If you live by a dusty road it is also worth sweeping down your roof at the end of the dry season (but not leaving the sweepings in the gutter!)

It should NOT be necessary to regularly clean out your jar: such cleaning may do more harm than good. In any case do not let anyone enter the jar – if you want to clean out a jar, do so from above using a cup on the end of a stick.

Mosquitoes

Although adult mosquitoes and their eggs can easily get into a rainjar, new mosquitoes will not breed in it provided organic matter like leaves is not allowed to enter and the water in the jar is kept DARK. (Light enables microscopic plants to grow and indirectly to feed the mosquito larvae.)

16 General conclusions

1500 litre mortar jars can be made in a simple workshop at a “workshop-door” cost of around USh.70,000, including testing with water on Day 4. After adding the cost of small gutters, a plinth, transport to site and some producer profit, the price might rise to USh.100,000. This is cheaper per litre than other roofwater storage technologies available in Uganda, and such capacity can be installed in easy steps up to say 6000 litres (USh.350,000/-).

However successful jar production requires skills and an attention to detail unlikely to be obtained from a casual employee or self-help householder. Therefore the technology is only suitable for serial production by an artisan who carries the consequences of poor quality control.

Capital of about USh.1 million is needed to set up each workshop.

APPENDICES

Appendix A Classification of Ugandan districts by rainfall

The table below (for all Ugandan Districts created by end 2004 but not those created since) categorises each District according to its annual rainfall (averaged over the whole District). In some large Districts there is such variation *within* the district that some parts may be wetter and other parts drier than as shown in the table.

The four rainfall categories are
High H (over 1200mm); **Medium** M (1000-1200mm); **Low** L (800-1000mm) and
Very low U (under 800mm and therefore unsuitable for roofwater harvesting).

District	R	District	R	District	R	District	R
NW Region		*E Region*		*Central Region*		*SW Region*	
Adjumani	M	Bugiri	H	Kalangala	H	Bushenyi	H
Arua	H	Busia	H	Kampala	H	Kabale	M
Moyo	H	Iganga	H	Kayunga	M	Kanungu	M
Yumbe	H	Jinja	H	Kiboga	M	Kisoro	H
N Region		Kaberamaido	H	Luweero	M	Mbarara	L
Apac	H	Kamuli	M	Masaka	M	Ntungamo	L

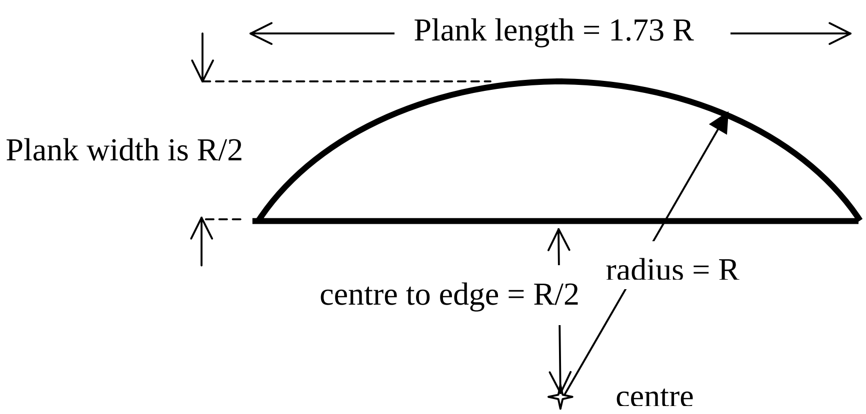
Appendix B Instructions for making a wooden mould-set (for a 1500 litre Rainjar)

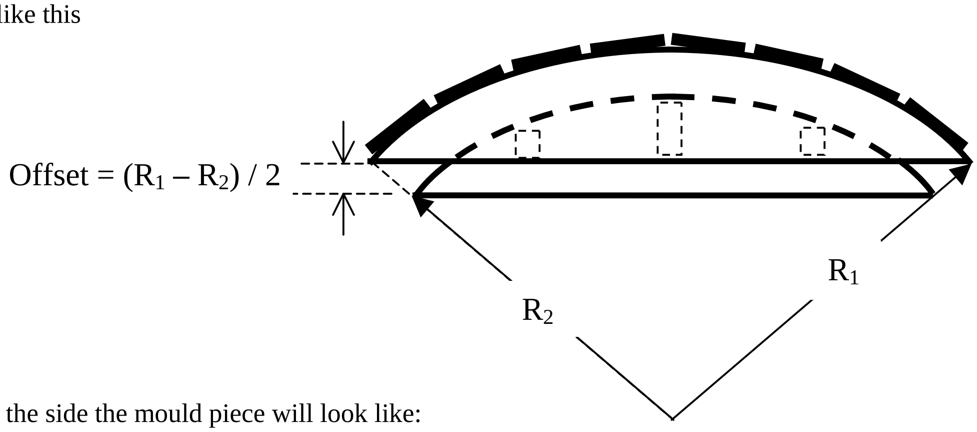
A mould set consists of 5 layers of open wooden boxes (A to E) and 4 layers of plain planks. Each mould box consists of

- A top plate
- A bottom plate
- Spacers to keep the two plates the right distance apart
- Battens connected the curved edges of the two plates together.

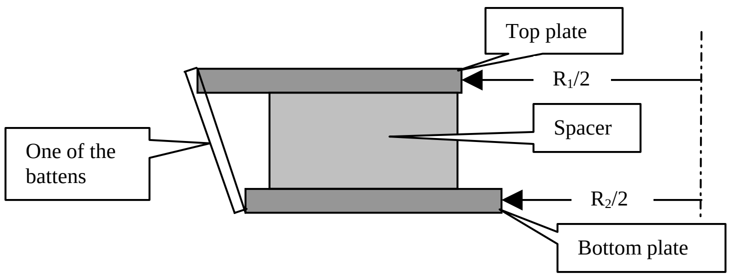
A typical full plate has the shape below. Its curved edge makes exactly 1/3 of a circle.



A typical mould piece uses two plates with different radii (R1 and R2) but the same centre and from *above* might look like this



From the side the mould piece will look like:



The height *H* of the mould piece is the measurement from top face to bottom face,
Make *H* = 230mm.

The plates are made of wood 20-25mm thick, so make the spacers 190mm high.

The battens should also be made 240 mm long.

Table of dimensions for Mould pieces

Layer (200mm)	Plate	Radius, mm	Width, mm	Offset, mm	Length, mm
A (bottom box)	Bottom (a)	480	240	12	830
	Top (b)	505	253		874
B	Bottom (b)	505	253	25	874
	Top (c)	555	278		960
C	Bottom (c)	555	278	28	960
	Top (d)	612	306		1059
D	Bottom (d)	612	306	14	1059
	Top (e)	640	320		1107
E (top box)	Bottom (e)	640	320	-85	1107
	Top (f)	470	235		813
F (first plank)		430	126		608
G		380	111		537
H		320	95		455
I		250	73		354
Extra planks D-E		*640*	*320*		*1107*

Wood required

We need two qualities of wood: fairly good and well-dried (for the top and bottom plates of the boxes and for the top planks) and rough unplanned wood for the outside battens.

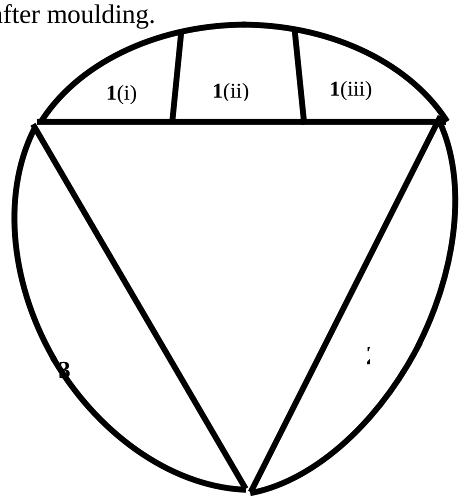
Good quality wood (the individual plates can be cut so that they overlap a little along the plank and hence there is a little saving on total length) comprises:

- Planks F, G, H and I need 6” wide wood of total length about 7.5 meters
- Plates (a), (b) and (f) need 10” wide wood of total length about 10 meters
- Plates (c), (d) and (e) need 12” wide wood of total length about 16 meters
- Plates (e) need an extra strip attached to their inside edge to make them wide enough.

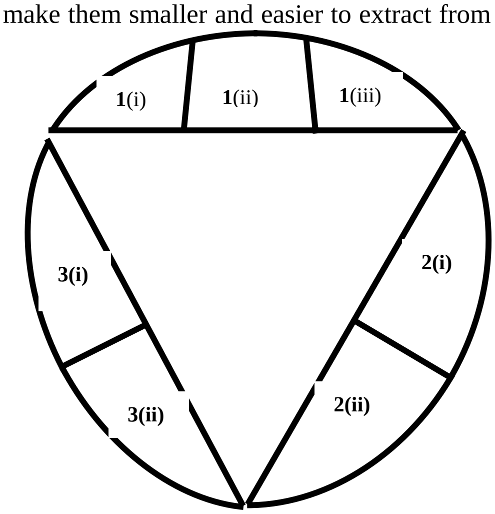
Such good wood costs USh.6000 to USh.12000 per plank of length 3 to 3.5 m.

Production

Each box layer is divided into several mould pieces. First three ‘full-size’ pieces are made for each layer (A to E), then one of them is cut into three parts as shown below **1**(i), **1**(ii) and **1**(iii), so that it is easy to extract them first [starting with **1**(ii)] when taking the moulds out, after the mortar has cured for 2 days. For the top two layers (D and E) it is a good idea to also cut pieces **2** and **3** into two parts, to make them smaller and easier to extract from the jar after moulding.



Lower layers
A, B and C, 5 pieces



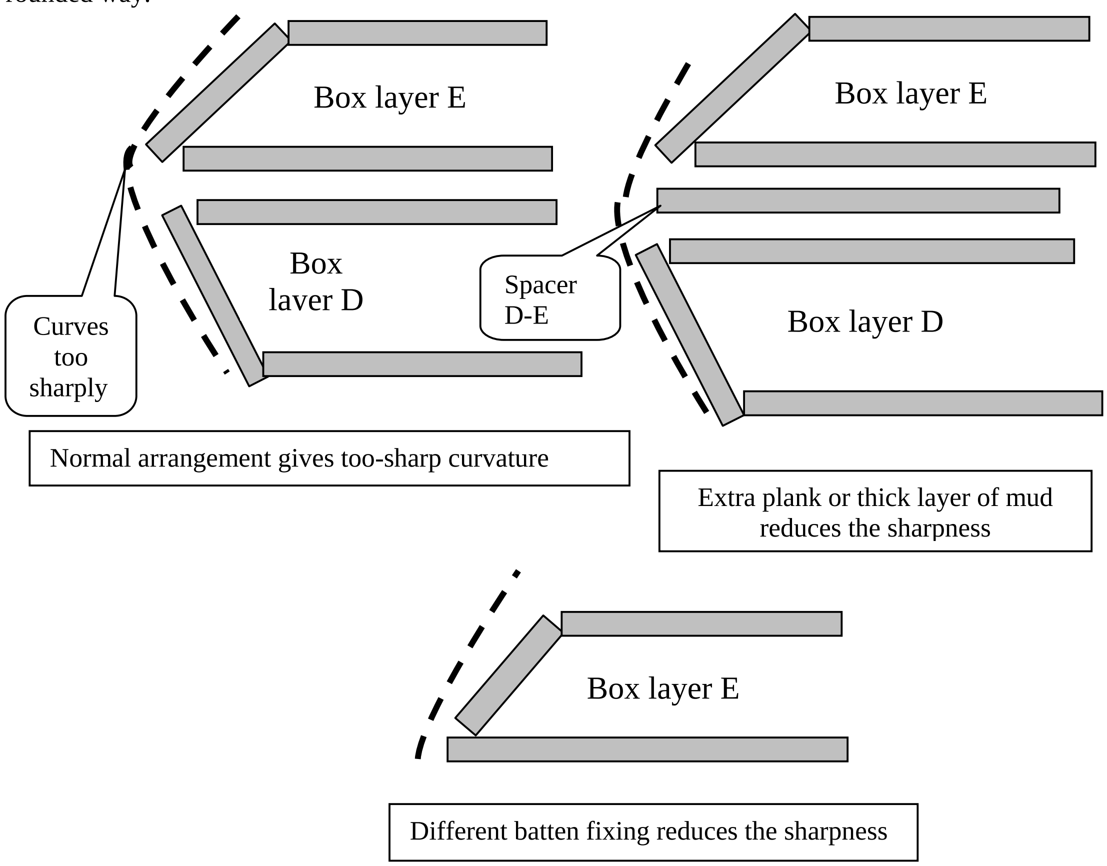
Upper Layers,
D and E, 7 pieces

The actual shaping of the planks can be done quickly and cheaply with a panga by a skilled woodworker, can be cut with a saw or can be machined in a mechanised carpentry shop. It is helpful to first mark out the shape of each piece onto thin (1/8") plywood and cut out a set of patterns. Only one pattern is needed for each of the plates (a) to (e) and planks F to I. These easily transportable patterns are used to mark out the 1" planks.

After cutting (and perhaps transporting), the 1" thick plates and spacers need to be nailed together in the right relative positions (with correct offsets) and then the battens are nailed onto the outsides. 2" (=50 mm) nails should be used.

Making the jar without too-sharp corners

Because layers D and E meet at a sharp angle, the finished jar will also have such a sharp angle, which does not look good. This can be avoided by adding an extra plank layer (called *D-E* in the table).Other alternatives are to use a lot of mud between layers D and E, or to shape the edge battens on boxes D and E so that they meet in a more gently rounded way.



Normal arrangement gives too-sharp curvature

Extra plank or thick layer of mud reduces the sharpness

Different batten fixing reduces the sharpness

Top pieces

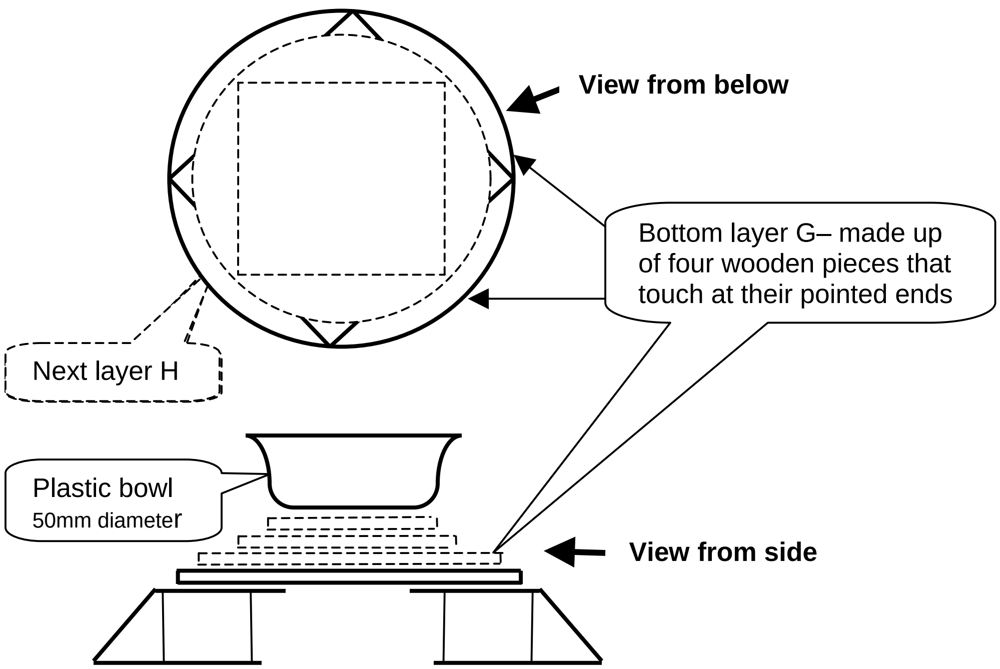
To complete the top of the tank there needs to be several layers of thinner wood. This is because the neck of the tank decreases in size fairly rapidly. The top pieces are not hollow boxes but planks (with no battens attached to their rims) laid directly onto each other.

There should be four layers (F, G, H and I) each of thickness 25mm (separated with a layer of mud), with four pieces per layer. The layers will be placed on top of each other so that they overlap. A plastic bowl is placed on the top layer to act as mould for the neck of the final jar. Removing these planks should be quite easy, as they will slide out and can then be extracted through the top of the partly-cured mortar jar.

The drawing below shows two of four layers on top of each other (as viewed from below). The radii will decrease from each layer to the next. Suggested radii for 4 layers (x 25mm) are given in the table above.

The plastic bowl is not just a part of the mould as it will later be the inflow screen. Its diameter needs to be enough (at least 45mm) for a man to climb through. The bowl edge should be rounded (as shown) and not folded over.

Assembly of top pieces (F to I) and bowl on top of boxes E



Appendix C Instructions for making a jar-delivery cart

Jars are 140 cm wide and 140 cm high and weigh over 250 kg: they are therefore very difficult to lift onto a motor vehicle for transport from workshop to house. Therefore a handcart (which can also be a donkey-cart) has been developed specifically to lift jars, transport them and lower them into place. Such a cart can also be used to move jars round the workshop.

The main parts of such a cart are

2 wheels,

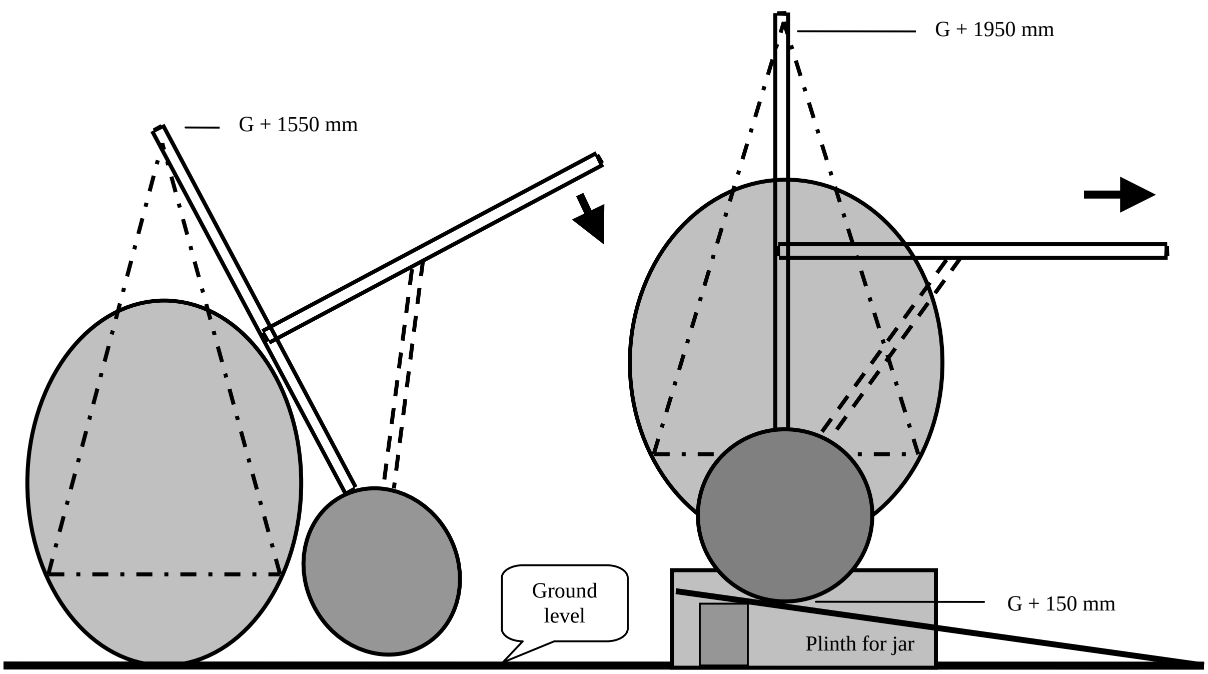
2 wheel bearings but *no* axle crossing from side to side,

A frame with hooks from which a cart may be suspended by chains,

One or two forward shafts (one shaft for 2 donkeys, two shafts for one donkey)

A suitable cart that uses motor-vehicle inflated wheels is described in Technical Release TR56 “Water tank delivery cart for two donkeys” that can be downloaded from web site www.eng.warwick.ac.uk/dtu/pubs However the drawings in this TR56 are in fact for a one-donkey cart (two shafts). Moreover the TR shows a winch above the cart frame for lifting the jar. Most users will omit this feature and instead use tilting the cart frame as their way of lifting the jar off the ground.

Figure C1 Tilted cart, jar on ground Figure C2 Upright cart on ramp, jar 400mm above ground



In Figure C1, the tilted cart has just been attached to the jar by chains (15-20mm steel chain, sheathed in plastic piping and joined together by bolts and nuts).

Before transport the cart must be pulled upright, so that the shafts are horizontal and the jar is clear of the ground. The jar is then secured to the frame by ropes. A cushion such as a car tyre is placed between jar and frame to protect the jar from damage.

During transport it is pulled (and pushed from behind) with the shafts horizontal and hence the load balanced.

After transport, on arrival at the site, the cart is run up onto two planks as shown in Figure C2 so that it is high enough to clear the plinth built to receive it. The cart can now be tipped a little to lower the jar onto the plinth.

The cart described in TR56 is built of heavy hollow, square-section, rolled steel (RHS) 50 x 50 x 3 mm. This thick section is only available in Kampala. One alternative is to make such a section by welding together pairs of angle iron (each 50 x 50 x 3 mm), but this is expensive. Another alternative is to use a thin but widely available section (50 x 50 x 1.2 mm) and add extra members to the frame such as that shown dashed in Figure C1. The bottom ends of the two frame uprights (where the wheels bearings are to be welded on) can be stiffened by forcing a short length of 1½“ water pipe up inside them.

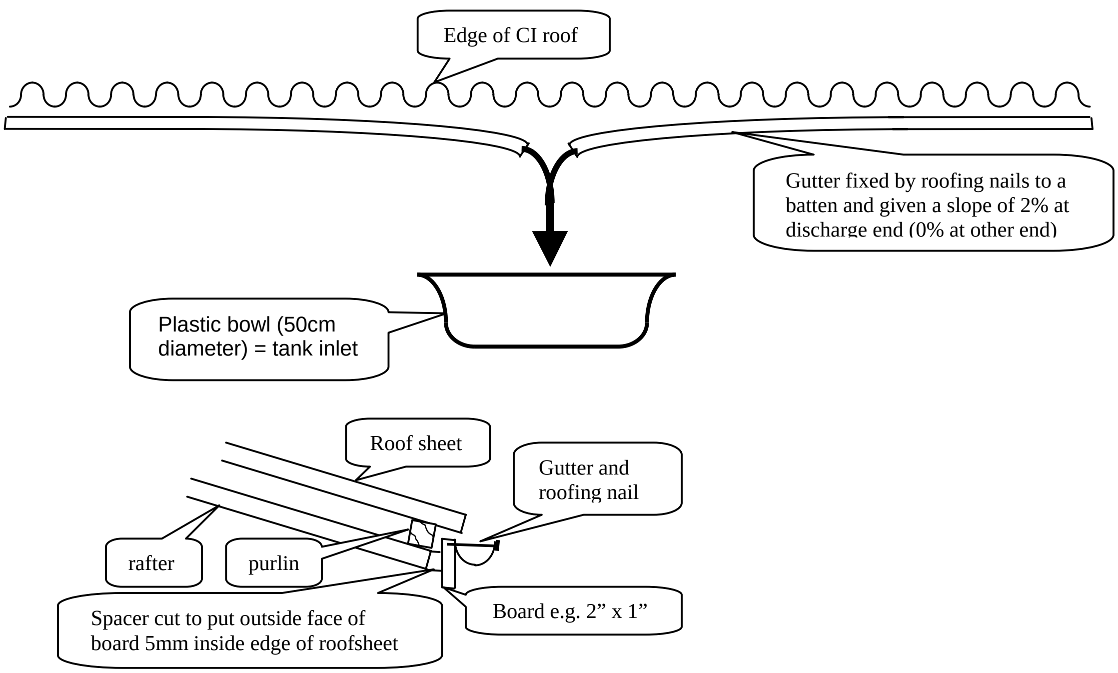
Having made the steel frame, choose suitable scrap car wheels (rim + tyre); no good tread is required. A 14” rim with 4 bolt holes is suitable. (If a pipe-in-pipe bearing is used – see below – then the hole in the wheel centre should be large enough to pass over a 2” water pipe.

Either find a scrap front-wheel car bearing that fits the wheel (usually available in Kampala) and weld it onto the frame (with or without the brake disc still attached)

Or make a pipe-in-pipe bearing, which is a 2” water pipe rotating round a 1½” water pipe. The space between the pipes is filled with grease and with a spiral of 1mm thick plastic cut from a pvc pipe. The outer pipe attaches to the wheel. The inner pipe is welded to the frame. Further details are given in TR28.

Appendix D Guttering

There are many demonstrations in Uganda of guttering that is ineffective or unnecessarily expensive. Gutter slopes are often wrong, large guttering is commonly used where small gutters would suffice, joints leak etc. The PVC guttering widely used in other countries is not yet available in Uganda. With jars, long gutters are not required and it is not necessary to lead water from one side of a house to the other. Ideally each jar should be fed from its own 8–15 m^2 of roofing via its own guttering. If the jar is fed from both sides by short (e.g. 3m) length of guttering, then these gutters can be as small as 50mm width – for example a medium-gauge 2" pvc pipe sawn in half. The 'non-discharge' end of the gutter needs to be blocked with wood or by using heat to fuse the two sides of the gutter together.



If the jar can be placed right under the gutters, no further connection is needed. However the jar is 140 cm diameter and usually needs to be placed a little further out than the roof edge. In this case a short length of sloping larger gutter (say 4") needs to be placed perpendicular to the roof edge to bring the runoff out to the tank inlet bowl.

Appendix E Labelling demonstration and normal jars

If information is painted onto jars by a signwriter, then the jar 'explains' itself. The following 4 boxes show possible patterns of information.

Yellow box

This Rain-jar holds 75 jerrycans (1500 litres) of water.
It was made on *[Date]* using 1.1/4 bag (70kg) cement and no steel reinforcement.
With one rain-jar + 6 m of gutter you can harvest 60 litres of water a day in the wet months. With 4 rain-jars + 16 m of gutter you can harvest 100 L a day in wet months, 60 L per day in dry months.

Green box	**Orange box**	**Red box**
1500 litres	**1000 litres**	**600 litres**
When the water level is in this band, draw up to 5 jerrycans per day.	When the water level is in this band, draw not more than 3 jerrycans per day.	When the water level is in this band, draw not more than 2 jerrycans per day.

The green band is at the top of the jar, the orange band in the middle and the red band at the bottom.

DTU

Ram pump programme

Computerised ram pump calculators
A short user guide

TECHNICAL
10
RELEASE

DTU Ram Pump Programme

Computerised calculator programmes

Hardware requirements

The minimum hardware requirement for these programmes is an IBM compatible PC with an 8088 processor. If you have the minimum requirement, only the DOS programme DOSPUMP will run. Although all three programmes should work on an IBM compatible machine with an 80286 processor running Windows 3, we recommend that the Windows programmes are used on an IBM compatible machine with at least an 80386 SX processor and four megabytes of RAM that is using Microsoft Windows 3.1 (or later versions).

Contents

1. Calculator Installation

There are three programmes on the 720k 3.5" disk inside the cover of this book. Two of them must be installed on a hard disk and run under Microsoft Windows®. The third programme runs under DOS and can be run from the floppy disk drive or installed onto a hard disk.

The two Windows programmes are:

WINPUMP
PUMPDATA

The DOS programme is:

DOSPUMP

You will not need to use both the Windows and the DOS programmes because they do the same thing. If you have a version of Microsoft Windows® on your computer, do not bother to install DOSPUMP as well as the other programmes.

1.1 Installing the Windows ram pump programmes

To install the ram pump programmes that run under Microsoft Windows® insert the disk in the floppy disk drive, then type the letter identifying the drive, followed by a colon (:).

For example:

A:

Then press the [Return] key.

The [Return] key is also called the [Enter] key and often has an arrow on it, like this ↵.

Type **PWIN** followed by the letter identifying the hard disk drive being used, a colon (:) and a backslash (\), and the directory name **DTUPROGS**, which is where the programmes will be installed.

For example:

PWIN C:\DTUPROGS

Then press the [Return] key.

When the programmes have been installed, a message appears advising you that installation is complete and telling you to press any key to continue.

Press the space bar.

The Windows programmes have now been copied to your hard disk, but Microsoft Windows® does not know this. The next stage of installation tells Microsoft Windows® that they are there and installs them as Icons at the Microsoft Windows® Programme Manager screen.

To do this, type the letter identifying the hard disk drive where the programmes have been copied, followed by a colon (:).

For example:

C:

Then press the [Return] key.

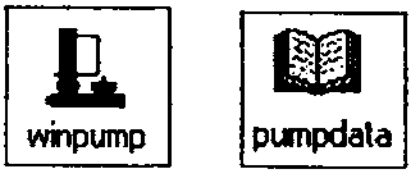
Type **CD\DTUPROGS** and press [Return] to change to that directory on your PC.

Type **SETUP** and press the [Return] key.

Microsoft Windows® starts and the DTU programme installation window appears. The DTU programme installation window has two buttons:- OK and EXIT.

Use the mouse to click on the OK button to start the installation.

The programmes are installed in a few seconds with progress being shown in the bar above the control buttons. A programme group called DTU programmes is created under Microsoft Windows' Programme Manager, and the DTU Windows programmes are installed there with these icons.



1.1.1 To run the Windows DTU calculator programmes — WINPUMP and PUMPDATA

Start Microsoft Windows® and click the mouse on the icon for the programme that you want. Click twice quickly (using the left mouse button) to run the chosen programme.

1.2 Installing the DOS DTU ram pump calculator programme — DOSPUMP

To install the ram pump calculator that runs under DOS, insert the disk in the floppy disk drive, then type the letter identifying the drive, followed by a colon (:).

For example:

A:

Then press the [Return] key.

Type **PDOS C:\DTUPROGS**

When the programmes have been installed, a message appears advising you that installation is complete and telling you to press any key to continue.

Press the space bar.

If you do not have a hard disk, the programme can be run from the floppy disk.

1.2.1 To run the DOS DTU calculator programme — DOSPUMP

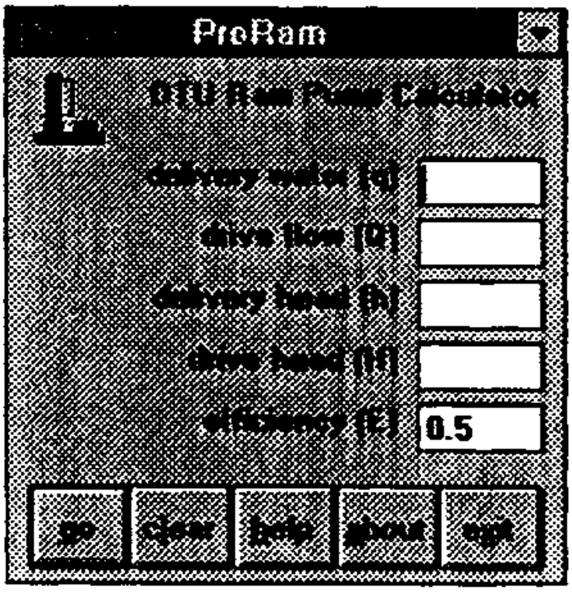
There are two ways to run this programme — from the hard disk or the floppy disk.

Running from the <u>hard disk</u>	Running from the <u>floppy disk</u>
Type the letter identifying the hard disk drive where the programmes have been copied, followed by a colon (:). For example: C: Then press the [Return] key. Type **CD\DTUPROGS** and press [Return] to change to that directory on your PC. Type **DOSPUMP** and press [Return] to start the programme.	Put the floppy disk into the drive, then type the letter identifying the floppy disk drive, followed by a colon (:). For example: A: Then press the [Return] key. Type **DOSPUMP** and press [Return] to start the programme.

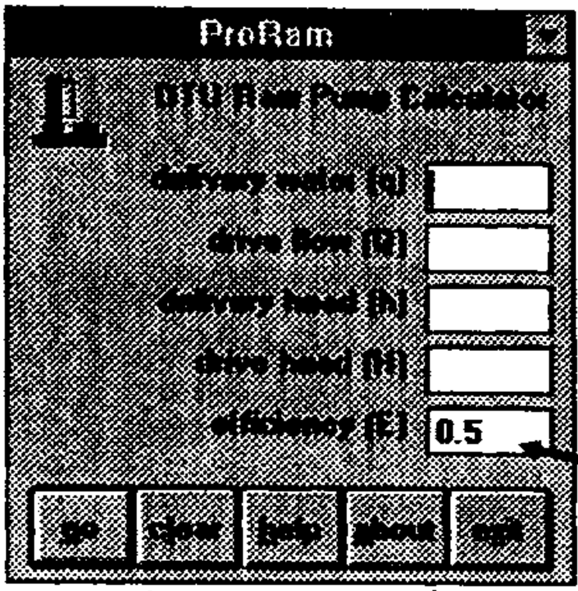
2. Using the DTU programme WINPUMP

When you click on WINPUMP the ProRam window opens. This window is used to enter variables to work out the equation: $E\ (Eta) = \frac{q\ h}{Q\ H}$.

This is the ProRam window:



Winpump is used by filling in any four of the variables for a ram pump system, (Q,q,H,h, and E) and clicking on the GO button. The missing variable is then provided for you.



Use this button to "minimise Winpump, but leave it running in the background behind other programmes.

When you have made an entry in one box, press the Tab key to move to the next box (or use the mouse to click on it.

You can change the value given for "efficiency" if you know that your pump has a higher or lower value. The value is expressed as a fraction of 1, so a 75% pump efficiency would be typed in as 0.75.

The buttons each have one letter underlined. Each button makes something happen, and it can be made to do this by either typing the underlined letter, or clicking on it with the mouse.

If you are using more than one pump, always remember to divide the drive flow between them before calculating.

When you have made one calculation and wish to make another, click on the "clear" button. All the values will disappear, except for 0.5, which is the default pump efficiency.

If you want to know the pump efficiency of an existing system, delete the entry for efficiency and fill in the other variables, then click on the GO button.

To leave WINPUMP, click on the "exit" button, of type the letter X.

WINPUMP's usefulness is limited, but it can be very handy for making quick calculations of the effect of changing parts of a system's design. For example, you can quickly find out what difference it would make to the delivery flow if you added a metre to the drive head or reduced the drive flow.

An example is when a system design is actually going to deliver more water than is needed and by varying the entries for drive head and delivery head we can see whether we could save money on the drive pipe, or deliver to a point high enough above the originally planned delivery tank for the excess to be usefully gravity fed to a garden plot.

DOS users will find that the DOSPUMP programme is a very similar calculator to WINPUMP. It looks different because it runs under DOS, but it does the same things.

3 Using the DTU programme PUMPDATA

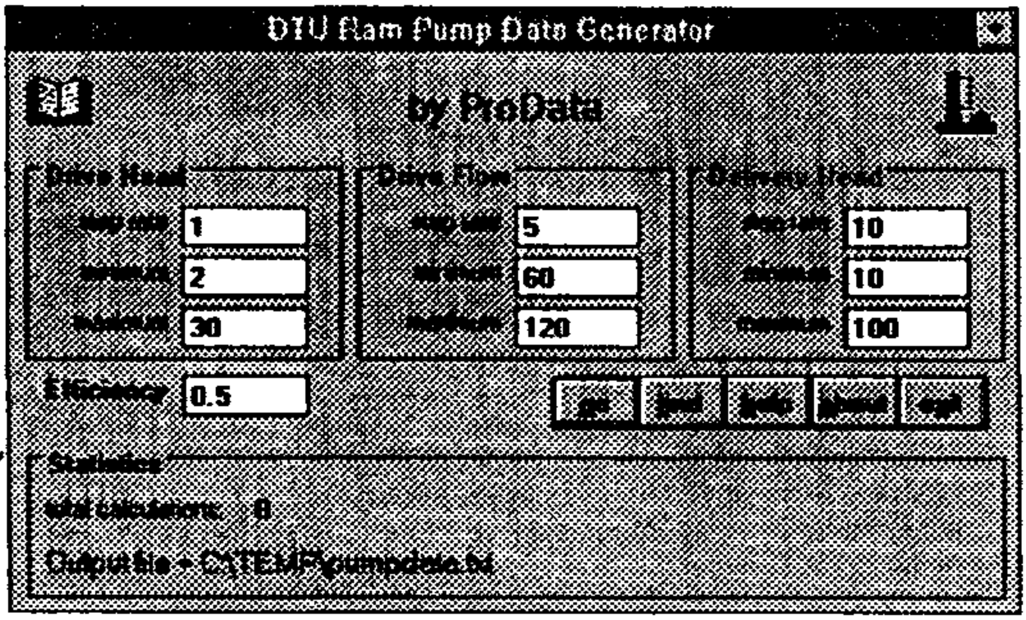
When you click on PUMPDATA the DTU Ram Pump Data Generator window opens. This window is used to enter variables to work out the equation

$$q = \frac{\eta Q H}{q h}$$

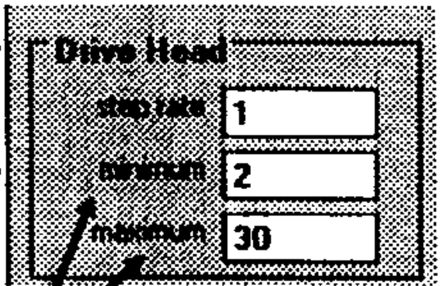
for a wide range of conditions. All possible answers within the ranges given are calculated. The range of results can then be sorted and printed.

This is the DTU Ram Pump Data Generator window:

A range of values for the Drive Head (H), Drive Flow (Q) and Delivery Head (h) are calculated for a particular pump efficiency. If you know the efficiency of the pump in use, begin by changing the efficiency value (which is given as 0.5 or 50% by default).



When the efficiency has been set, the "Drive Head" figures are entered (in Metres).

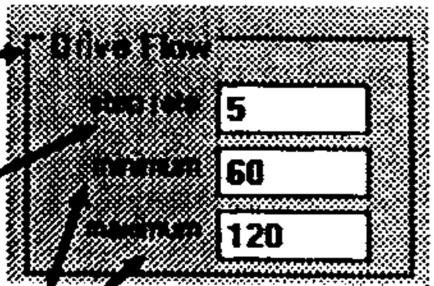


The "step rate" is the amount by which the value is advanced for each set of recalculations. For example, with a step rate of 1, the Drive Head will be calculated for every value between the minumum of 2 and the maximum of 30 (whole numbers only). If the step rate is changed to five, the minimum number will be advanced in fives to the maximum.

Change the step rate to a bigger figure to reduce the number of calculations carried out if your computer is very slow.

Change the minimum and maximum Drive Head to those available at the site being calculated.

When the "Drive Head" range has been set, the "Drive flow" figures are entered (in litres per minute).

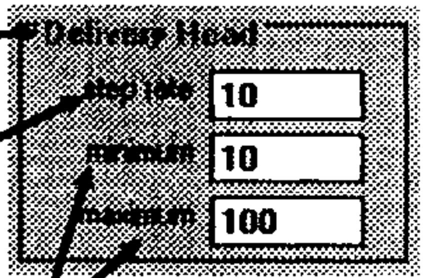


The "step rate" is the amount by which the value is advanced for each set of recalculations. For example, with a step rate of 5 as shown, the Drive flow will be calculated in fives from the minumum of 60 to the maximum of 120 litres per minute. If the step rate is changed to 10, the number will advance in tens from the minimum to the maximum.

Change the step rate to a bigger figure to reduce the number of calculations carried out.

Change the minimum and maximum Drive flow to those available at the site being calculated. If a single flow is known, type that flow into both the minimum and the maximum boxes.

When the "Drive flow" range has been set, the "Delivery Head" figures are entered (in metres).

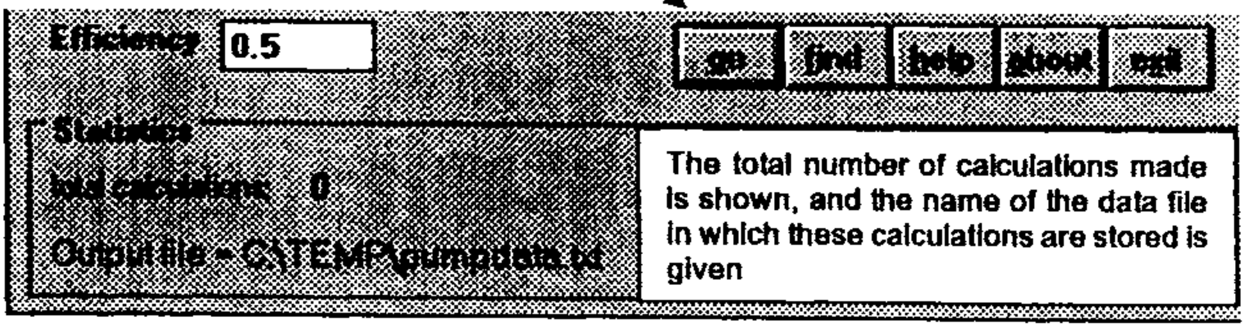


The "step rate" is the amount by which the value is advanced for each set of recalculations. For example, with a step rate of 10 as shown, the Delivery Head will be calculated in tens from the minumum of 10 to the maximum of 100 metres. If the step rate is changed to 20, the number will advance in twenties from the minimum to the maximum.

Change the step rate to a bigger figure to reduce the number of calculations carried out.

Change the minimum and maximum Delivery Head to those available at the site being calculated.

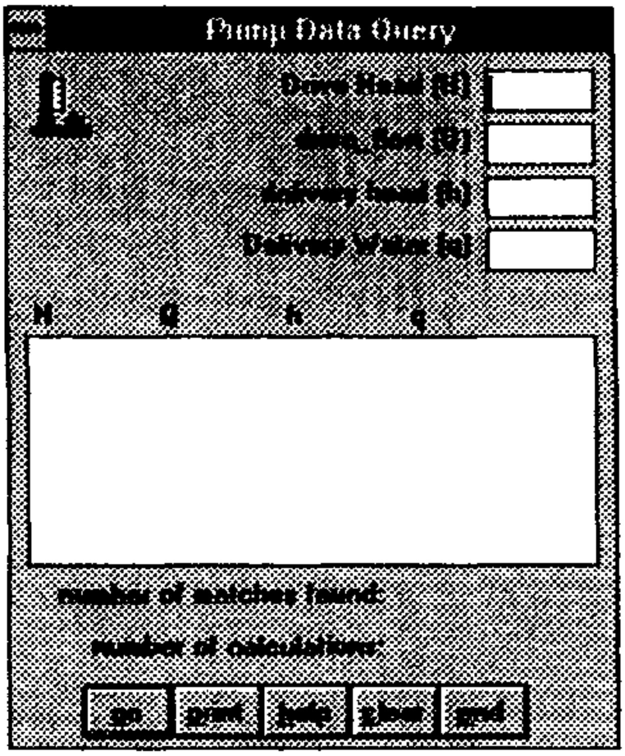
After setting the Step rates and the maximum and minimum entries for Drive Head (H), Drive Flow (Q) and Delivery Head (h) at a site, click on the "go" button to start making calculations.



The total number of calculations made is shown, and the name of the data file in which these calculations are stored is given

3.1 Looking at the results

When the calculations have been made, they are saved in the file called "pumpdata.txt" on your hard disk. You can look at this using a wordprocessor or other programme if you want to. To look at the calculations in this programme, and to select restricted ranges to look at, click on the "FIND" button to open the PUMP DATA QUERY window.



Asking the calculator a question

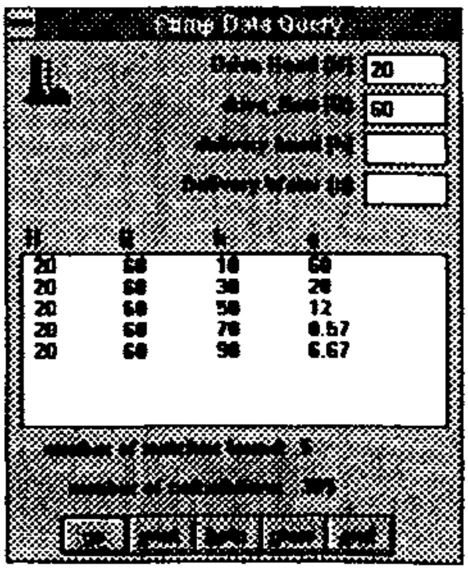
A Query is simply a question. You can ask to see the data for a restricted set of variables, or for all. To see all, just click on the GO button without putting anything in the boxes.

To see a restricted part of the calculations you have just made at the DTU Ram Pump Data Generator window, make at least one entry in the boxes alongside Drive Head, Drive Flow, Delivery Head and Delivery Flow.

For example, if you wanted to see how much drive flow would be needed at a site with a known drive head, delivery head and required delivery flow, type the known values in the boxes and click on the GO button.

EXAMPLE

In this example, a drive head of 20 metres was possible but the drive flow was restricted to 60 litres per minute. We wanted to know how much water could be pumped to a range of heights. The step rate for the delivery head had been given as 20 metres at the DTU Ram Pump Data Generator window, so only five calculations for delivery head were made for its range of between 10 and 100 metres.



Notice how it is possible to generate silly answers if you are not careful. The first calculation in the list shows a Drive Head of 20 metres and a Delivery Head of only 10 metres — gravity feed!

Printing the result

To print the information you have found, simply click on the PRINT button. Make sure that your printer is attached and turned on, with paper in it before trying to print anything.

It can be useful to print a range of calculations for a particular site before visiting it. For example, you might know that the site must deliver 10 litres a minute before the client will be interested, you might also know the efficiency of the pump to be installed, and the fact that there is plenty of drive water (120 litres a minute or more). You may also know that the delivery head is at least 50 metres. If you then find all possible combinations of drive Head and Delivery Heads of 50 metres or more that give a delivery flow of 10 litres a minute or more, this would be useful to have with you when assessing a site.

Asking another question

If you want to find the answer to another question, click on the CLEAR button to clear your first question and its answers from the window. Then type in the relevant values for your new question and click the mouse on the GO button.

Leaving the PUMPDATA programme

When you have finished making your calculations, click the mouse on the END button to close the DTU PUMPDATA programme.

4 Using the DTU programme DOSPUMP

Refer to section 1.2.1 To run the DOS DTU calculator programme - DOSPUMP to start the programme from your hard disk or from the floppy disk provided.

This is what appears on the DOSPUMP main screen.

```
DTU Ram Pump Calculator by ProData

Q=Drive Flow: q=Delivery Water: H=Drive Head: h=Delivery Head: E=Efficiency

Which variable to calculate: Q, q, H, h, E, ?=help, X to quit
```

Type which one of the five variables, Q, q, H, h, and E you want to calculate.

Be careful to type "Q","H" and "E" as upper case letters and "q" and "h" as lower case letters.

WINPUMP users will find that the DOSPUMP programme is a very similar calculator. Because it runs under DOS its appearance is different, but it does the same things as WINPUMP.

Whichever variable you select, a window will open asking you to enter a value for the other variables, one at a time. For example, if you type "q", the window shown below opens prompting you to give a value for E (the pump efficiency).

```
DTU Ram Pump Calculator by ProData

Q=Drive Flow: q=Delivery Water: H=Drive Head: h=Delivery Head: E=Efficiency

Which variable to calculate: Q, q, H, h, E, ?=help, X to quit

                    Delivery Water
                    enter value for E:
```

You are asked for each of the other four variables in turn, and when you have entered them (press [Return] after each entry), the programme displays the missing value lower on the screen. An example is shown below.

```
DTU Ram Pump Calculator by ProData

Q=Drive Flow: q=Delivery Water: H=Drive Head: h=Delivery Head: E=Efficiency

Which variable to calculate: Q, q, H, h, E, ?=help, X to quit

                    Delivery Water
                    enter value for E: 0.6
                    enter value for H: 5
                    enter value for Q: 90
                    enter value for h: 60

                    the value of q is  4.50

                      Again? (y)es or (n)o:
```

When you have entered all the variables, a window at the bottom of the screen a message prompts:

"Again? (y)es or (n)o:"

Type the letter Y to clear the screen and calculate a result for another set of variables.

Type the letter N to close DOSPUMP.

RELEASE

DTU Technical Release TR10 *1996*

Cardboard Calculators for Designing Ram Pump Systems

1 INTRODUCTION

In the Development Technology Unit we have for many years been designing water systems that use hydraulic ram pumps. We have also trained water specialists from over 10 countries how to make the pumps and design systems to put them in. To design a good system, you have to do some calculations. We have found that most people do not enjoy using formulas or doing maths, so we have developed special cardboard 'calculators' that can be used instead of formulas. They give the same answers as the formulas in books but are much easier and quicker to use.

When we design a water system using ram pumps, we like to be able to know *before* we build it how much water it will deliver. This is called the "delivery flow". The first DTU calculator is the *Ram Pump System Design Calculator* and is meant mainly for working out such delivery flows.

The second cardboard calculator is called the *Friction Headloss Calculator*. We use it to help select the right sizes for the different pipes in a ram pump system. It can also be used for choosing the pipe sizes in a gravity-feed water system.

In this Technical Release we describe how to make the two calculators and how to use them.

The last three pages of this Technical Release are single-sided master pages to be photo-copied each time you make a calculator. We suggest that the first photo-copy you make should be attached to this Release in case the copy masters get separated and lost.

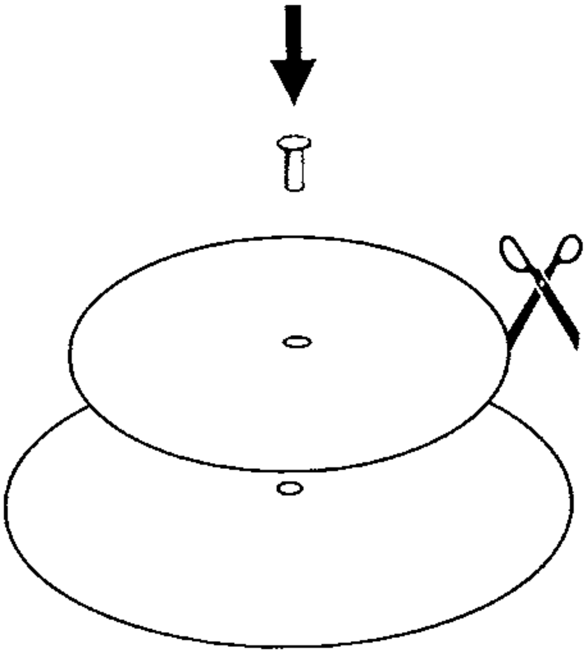
2 MAKING THE CALCULATORS

Start by photo-copying the calculator parts printed on the 3 pages at the end of this Release. The thicker the paper or card you can use for these copies, the better; card as thick as 180 gpm can be fed through some slow photo-copiers. The *Delivery Flow Calculator* has 2 parts, both on the same page. The *Friction Headloss Calculator* has 3 parts, spread over the two following pages.

Carefully cut out the parts of the *Delivery Flow Calculator.* You will be assembling them by pushing a rivet through the centre holes and turning the ends over, so the cut-out circles for these centre holes should be the same size as the rivet you will be using. It is important to make these holes round and put them in exactly the right place on the disc.



The rivet can be of plastic or soft metal. We have successfully made rivets from short strips cut from thick plastic piping, rolled on sandpaper to make them round and then turned over at the ends with a hot iron. You could also use a short plastic or steel bolt with washers and two nuts: the nuts have to be tightened against each other so that they hold the discs not quite tight.The holes can be reinforced with self adhesive "ring reinforcements" sold in some stationery shops to strengthen the holes on paper sheets held in ring-binders.

If the calculator is always to be used in one office, the 2 discs can be held by a drawing pin (through their exact centres) onto a notice board. The pin must be loose enough to allow the discs to rotate freely.

If the calculators are to be carried around or taken out of doors, they will soon get torn or dirty. If at all possible you should cover each one on both sides with transparent plastic. Clear adhesive plastic sheet is sometimes sold in stationery shops for use to protect schoolbooks. If you place any hole-strengthener under the plastic, this will help prevent it falling off. It also helps if you can make a waterproof pocket to carry the calculators in.

The *Friction Headloss Calculator* is made in the same way as the *Delivery Flow Calculator.* except that there are now 3 parts free to rotate on the same rivet or pin.

3 USING THE 'RAM PUMP SYSTEM DESIGN CALCULATOR'

The *Ram Pump System Design Calculator* has two discs and a swinging arm. It carries four scales

Feed head *H*	Range 1.5 to 30 meters
Delivery head *h*	Range 10 to 120 meters
Feed flow *Q*	Range 10 to 800 litres/minute
Delivery flow *q*	Range 0.5 to 80 litres/minute

Check that you can find each of these scales.

The last scale is in three parts called "efficiency = 50%", "efficiency = 60%" and "efficiency = 70%". If you do not know what your system efficiency might be, use the "60%" part. If you think it might be rather low, use the "50%" part and if it might be very good use the "70%" part.

The calculator is for calculating the flow from a complete *system*, not just from a single pump. If your system has several pumps working side by side, you should use as *Q* the feed flow to the whole system, not the drive flow to just one of the pumps. The calculator will then tell you the delivery flow from the whole system and not just the output of one pump. If your system does have only one pump in it, there is no problem; the feed flow you use will all go through that one pump.

To learn how to use the calculator we suggest you practice with the following example.

Suppose you have a system in which
feed head = 4 meters,
delivery head = 40 meters,
feed flow = 50 litres per minute,
efficiency is unknown so we use 60%,
then the calculator should show a delivery flow of 3 litres per minute.

Here are the two steps.

Step 1 Hold the outside disk and turn the inside disk until 50 litres per minute on scale *Q* is exactly in line with 4 meters on scale *H*.

Step 2 Pinch the two discs together with your fingers so that one cannot slip past the other and then turn both disks together until the *q* scale is at the top. Find 40 meters on scale *h* and read the flow above it on the "efficiency = 50%" part of scale *q*. You should get close to 3 litres per minute.

The calculator is not super-accurate. It will give you an answer that is "close enough". If you followed the example above and got an answer that was not close to 3 litres/min it might be that

- you let the disks slip past each other,
- you used the wrong scales,
- the holes in the middle of your disks have become badly worn and the disks are very loose.

4 USING THE 'FRICTION HEADLOSS CALCULATOR'

When water flows through a pipe there is some friction between the water and the pipe walls. This causes something called "friction headloss" which is measured in meters. A pipe with a small diameter has a bigger headloss than a larger pipe for the same flow of water. A big headloss usually means that the system delivers less water than it should.

The *Friction Headloss Calculator* has two disks and a swinging arm. It carries four scales which you might look for:

Length of pipe	Range 2 to 3000 meters
Flow through pipe	Range 1 to 500 litres per minute
Bore of pipe ("Bore" is the same as "Inside diameter")	Range 16mm to 200mm
Headloss	Range 10cm to 100 meters

and the two small arrows on the swinging arm called "steel" and "plastic". At the top of the swinging arm is a big arrow labelled "flow through pipe".

You can use this headloss calculator to help you choose the best size for the delivery pipe, the feed pipe and the drive pipes in a ram pump system. You can also use it for pipes in gravity feed systems. We will now describe each of these four uses.

Use 1: Delivery pipes

When you come to choose the size of a delivery pipe, you will usually already know how long it is, how high it rises and how much water is to flow through it.

Suppose for example you know that at a particular site:

pipe length = 500 meters,

flow through the pipe = 10 litres per minute and the pipe is plastic,

the delivery height h = 60 meters.

Standard pipe sizes (*outside* diameters) are 20 mm, 25 mm, 32 mm and 40 mm. For medium pressure pipes, their bores (their *inside* diameters) will be about 2 mm smaller - typically 18 mm, 23 mm, 30 mm and 37 mm. Your problem is to decide which size is right.

Suppose you think that the 30 mm bore pipe might be suitable. The calculator lets you find out if it is. The calculation goes as follows:

Step 1 Hold the outer disk and rotate the inner disk until 500 m on the Length scale is touching 30 mm on the Bore scale.

Step 2 Pinching the two disks together so that they do not slip, move the swinging arm until the big arrow at its top is touching 10 litres per minute on the Flow scale.

Step 3 Read the headloss scale underneath the "plastic" arrow. You should find about 1.6 m.

You now have to decide whether this headloss is OK. It should normally be between one fiftieth and one tenth of the delivery head h. If headloss is more than $h/10$ your system will be quite inefficient, so you should try a larger pipe. If it is less than $h/50$ you are using a delivery pipe that is too big: you could save money by trying a smaller pipe. In our example the headloss *is* between $h/50$ (1.2 m) and $h/10$ (6 m), so our pipe size of 30mm is OK.

Use 2: Feed pipes

Your ram pump system may have a feed pipe connecting a stream or spring to a drive tank from which drive pipes lead to each pump. The calculation for feed pipes is just like that for delivery pipes except that the flow is now the feed flow to the drive tank, and of course the length and diameter we use are those of the feed pipe. Feed pipes are usually plastic, so use the "plastic" arrow on the swinging arm. Common pipe sizes for feed pipes are 50 mm, 63mm, 75mm, 90 mm and 110mm outside diameter. The bores of these sizes for low-pressure pipe are about 47 mm, 59 mm, 72 mm, 86 mm and 105 mm. So first decide which bore you should try for the feedpipe, then use the calculator to work out its headloss.

When you have found the headloss, you should compare it with the *feed* head *H*). If it is over H/10, the feed pipe should be larger. If it less than *H*/50 the feed pipe could be smaller.

Use 3: Drive pipes

Each drive pipe carries the drive flow to a single pump: this is usually equal to the feed flow *Q* divided by the number of pumps running side by side. As the drive flow is not steady like the feed flow, but is constantly starting and stopping, the head loss in a drive pipe is higher than for other types of pipe. The *Friction Headloss Calculator* gives the right head loss for a steady flow. For a drive pipe with its unsteady flow we have to multiply the steady flow headloss by 2.

So choose a likely pipe size and for it calculate the steady flow headloss in the same way as for the delivery pipe, but using the length, bore, material and flow that belong to *one* drive pipe. Next multiply the calculator's answer by 2 to get the true headloss. Lastly check whether this true headloss lies between *H*/50 and *H*/10. If it lies outside this band, you should think of changing the drivepipe size. Notice that, as with the feed pipe headloss, we are comparing the drive pipe headloss with the *feed* head *H*.

Use 4: Pipes in gravity feed systems

In a gravity feed system, pipes are laid so that they slope downwards. The drop in height between where water enters a pipe and where it leaves it is what pulls the water through. For any one size of pipe, a bigger drop in height gives a bigger flow. We can use the *Friction Headloss Calculator* to work out what the flow will be. This is because in a gravity feed system, the friction headloss is exactly *equal* to the drop in height.

Let us take as an example a 1" galvanised iron pipe, whose length is 2 kilometres and which drops by 100 meters from one end to the other. We can now work out the flow through the pipe. The calculation goes as follows:

Step 1 Hold the outer disk still and turn the inner disk until 2 km on the length scale touches 26 mm on the bore scale. (A 1" GI pipe has a bore of about 26 mm)

Step 2 Keeping the two disks clamped together in your fingers, move the swinging arm until the "steel" arrow is touching 100 m on the Headloss scale.

Step 3 Read the flow opposite the big arrow on the Flow scale. You should get about litres/min.

If the flow is more than you wanted, try again with a smaller pipe. If the flow is too small, try a bigger pipe. Of course the flow through the pipe cannot be higher than the flow available at the entry to the pipe. So making the pipe bigger will only increase the flow if it is the pipe, and not the source, that is limiting it.

5 NOTE FOR ENGINEERS

The *Ram Pump System Design Calculator* is based on the simple formula:

delivery flow = efficiency x feed flow x feed head / delivery head ($q = Eff \times Q \times H/h$).

Most well-designed ram pump systems have an efficiency of between 0.5 and 0.7. Some pump manufacturers issue design tables based on the assumption that system efficiency is always 0.6. However you may meet systems that use undersize pipes or ram pumps operated at the very top of their drive-flow range or their delivery head range, where system efficiency is as low as 0.3.

The *Friction Headloss Calculator* is based on an approximate formula because a more exact formula would be too complex to convert into a slide rule (which is what these cardboard calculators are). The flow in pipes in practical water systems is always highly turbulent. In the range of flows of interest to system designers it is safe to use the approximate turbulent flow formula:

friction headloss = K x pipelength x flow $^{1.85}$ / internal diameter $^{4.9}$

If headloss and pipelength are measured in meters, diameter in mm and flow in litres per minute, then K = 650 for smooth plastic pipes and K = 800 for steel or GI pipes.

Headloss formulas are not very precise. The headloss may differ by +/-25% of the value predicted by the *Friction Headloss Calculator*. If you are using the calculator to predict flow in a pipe, you can expect to get within +/-10% of the actual value.

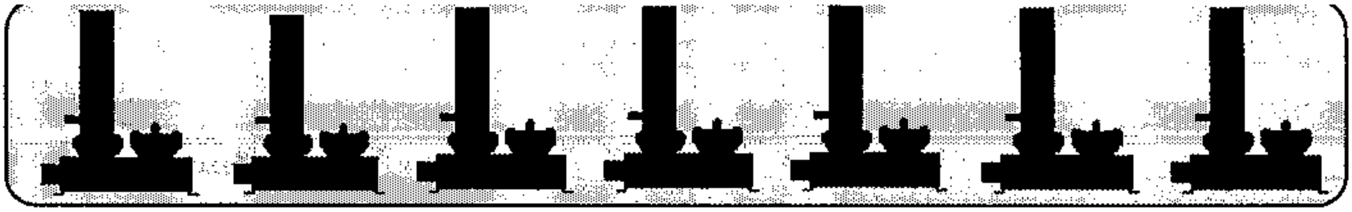
RELEASE

DTU S1 PUMP



DTU S1

hydraulic ram pump

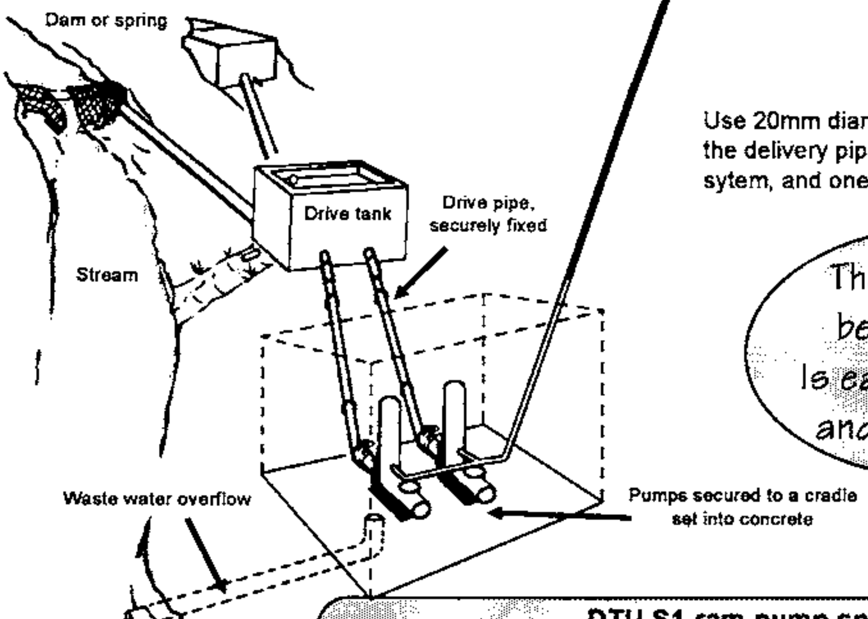
The name "S1" stands for a Steel pump with a drive pipe up to 1" in diameter.

A ram pump is powered by falling water. Water from a stream or spring is diverted and dropped through a drive pipe into the pump. The power of the falling water is used to pump some of the water where it is wanted. The amount of power in the falling water limits how high you can pump, and how much water you can pump. Generally, the more water you drop and the further you let it fall, the more power there will be.

The DTU S1 hydraulic ram pump is a steel machine, using a ¾" or 1" diameter galvanised drive pipe, that can lift water up to a height of 80 meters. It was designed for water supply to small groups of houses from minor sources of water such as springs and small streams. It is being used successfully in many African countries.
The pump has been designed to be made in small workshops with welding equipment and a pillar drill. A lathe can be useful but is not essential.
In areas where the water source flow varies greatly during the year, more than one pump can be installed, all sharing the same delivery pipe as shown in the drawing below.

Distribution system, for domestic use. A tank is always recommended.

Delivery pipe, rising all the way along its length (no ups and downs). The pipe should be buried where possible and protected if it has to be above ground.



Use 20mm diameter plastic pressure pipe for the delivery pipe if there is one pump in the sytem, and one size larger if there are two.

The DTU S1 can be locally made is easy to maintain and cheap to run!

DTU S1 ram pump specifications

The normal specifications of the DTU S1 ram pump are given here.
Sometimes you can operate pumps outside these limits, but they may not work well.

drive head range	—	2 to 15 meters
drive flow range	—	20 to 60 liters a minute
drive pipe material	—	Galvanised iron
drive pipe diameter	—	¾" for flows from 20 to 35 liters a minute
drive pipe diameter	—	1" for flows from 30 to 60 liters a minue
delivery head range	—	up to 80 meters
typical delivery range	—	0.5 to 10 liters a minute
delivery pipe diameter	—	20mm

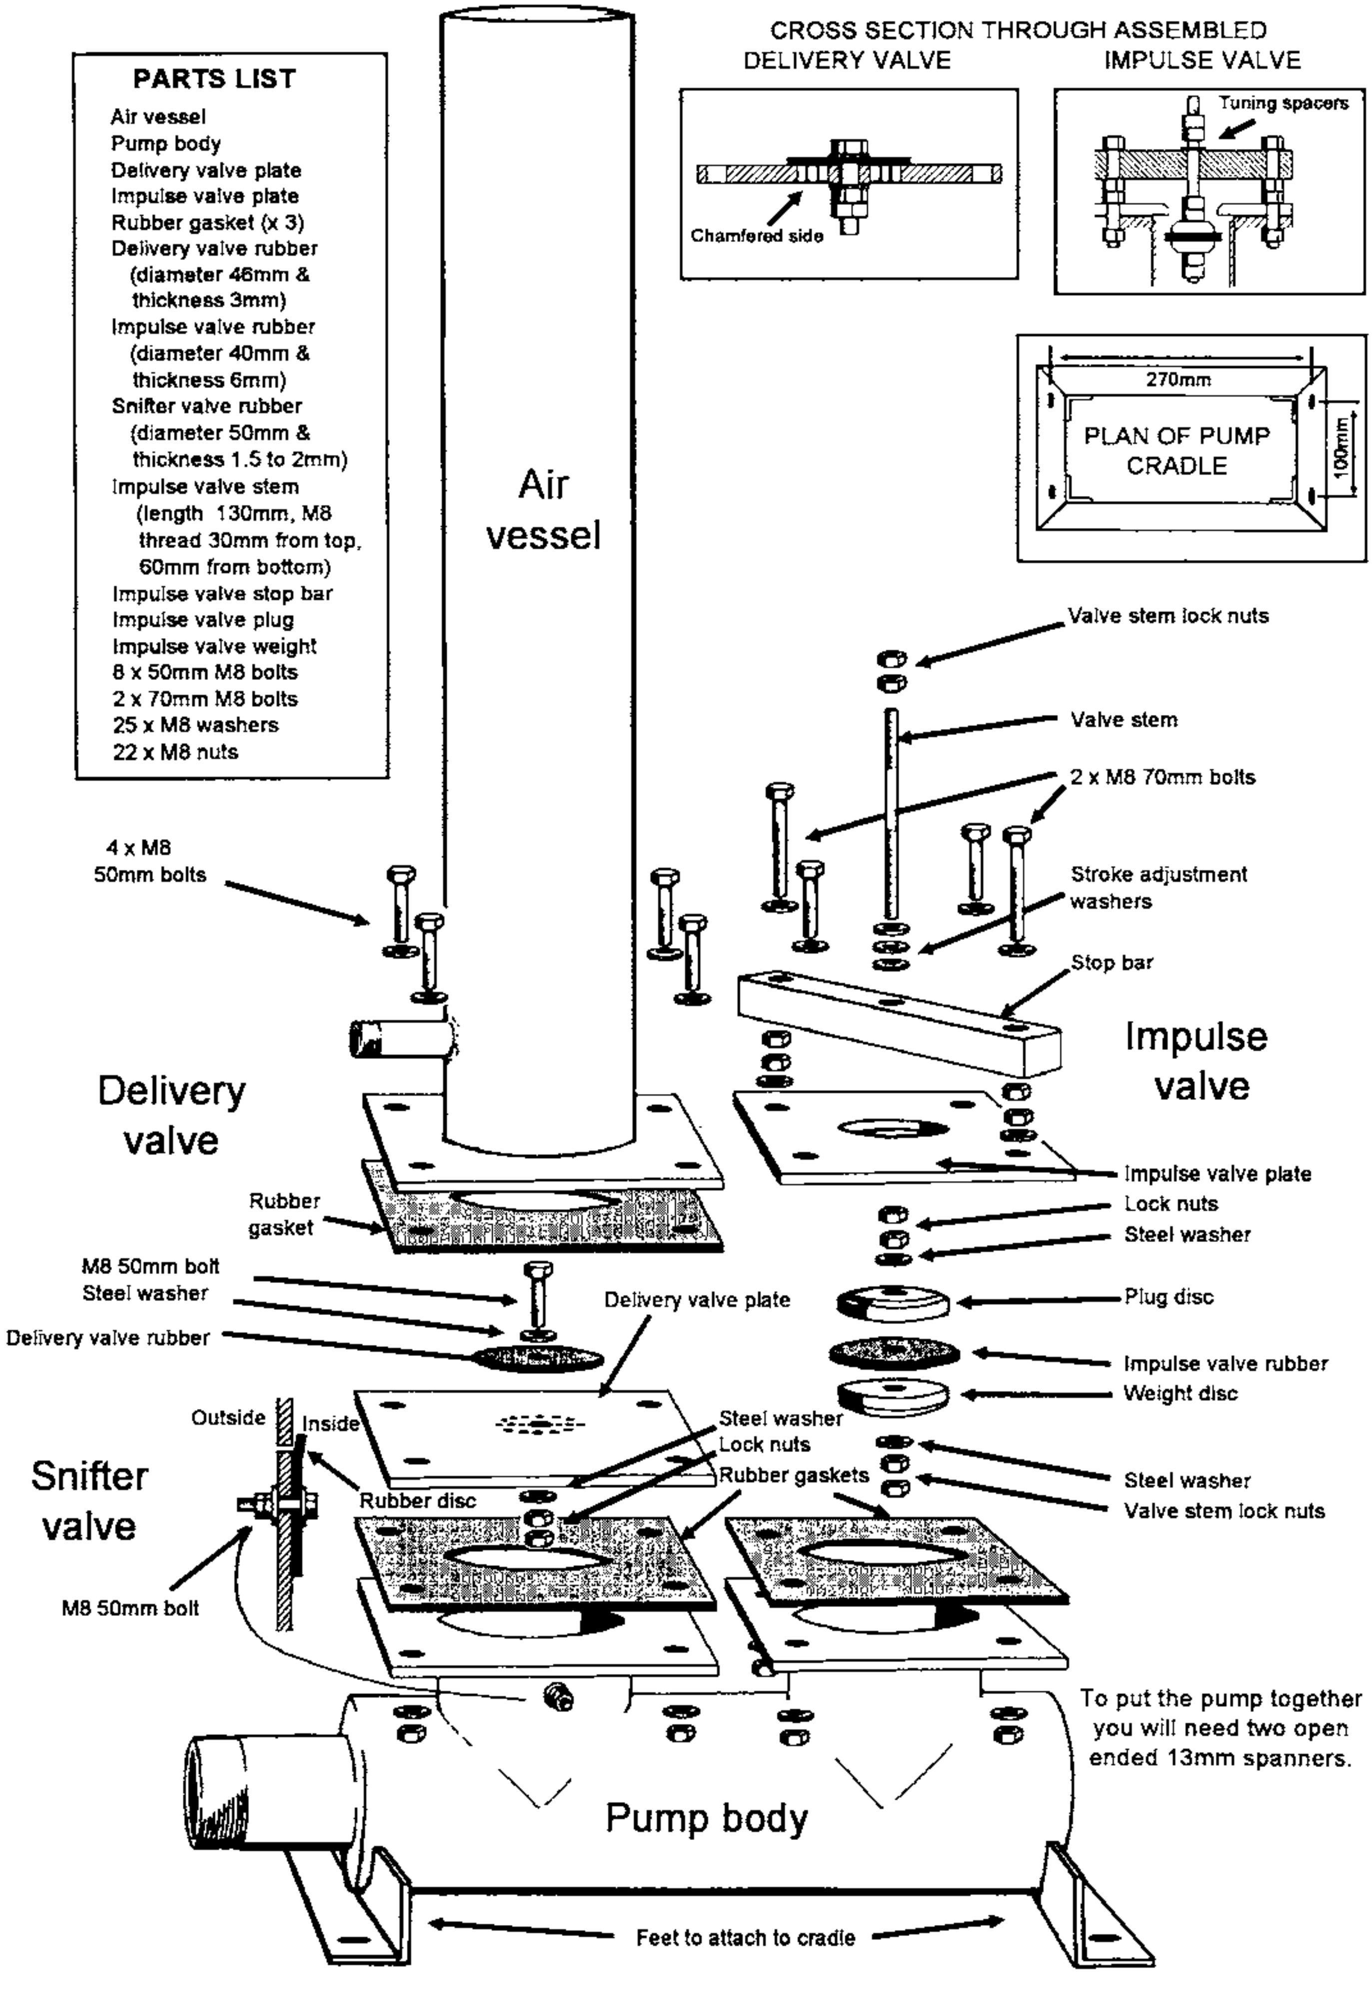
RELEASE

DTU S1 PUMP: USER INSTRUCTIONS

AN EXPLODED VIEW OF THE DTU S1 PUMP

PARTS LIST

- Air vessel
- Pump body
- Delivery valve plate
- Impulse valve plate
- Rubber gasket (x 3)
- Delivery valve rubber (diameter 46mm & thickness 3mm)
- Impulse valve rubber (diameter 40mm & thickness 6mm)
- Snifter valve rubber (diameter 50mm & thickness 1.5 to 2mm)
- Impulse valve stem (length 130mm, M8 thread 30mm from top, 60mm from bottom)
- Impulse valve stop bar
- Impulse valve plug
- Impulse valve weight
- 8 x 50mm M8 bolts
- 2 x 70mm M8 bolts
- 25 x M8 washers
- 22 x M8 nuts



To put the pump together you will need two open ended 13mm spanners.

Pump repair

If the pump stops or starts delivering less water than usual, it may require adjustment or repair.

Look at the pump and if there is no obvious fault start it again if you can. Watch the pump and listen for irregular pumping or unusual noises. A worn impulse valve, for example, is usually obvious because water squirts through when the valve is closed. Some parts of your ram pump may need occasional replacement. the frequency of this will depend on how hard the pump is working and on the cleanliness of the drive water.

Tools you will need:

2 x 13mm ring/open end spanners to disassemble and assemble the pump
2 x Adjustable wrenches - to loosen a union joint on the delivery pipe (if fitted)

Taking the pump apart

Depending on the fault it may be necessary to disassemble the impulse valve and/or the air vessel. Before attempting to take apart the pump:

1. Make sure that the drive pipe valve is closed and the impulse valve is open. This will allow you to work on the impulse valve ONLY.
2. Depressurise the air vessel.

WARNING - Before attempting to remove the air vessel, always release the pressure in it slowly. An ideal system will have a gate valve or one-way valve and a union fitted between the air vessel and the bottom of the delivery pipe and the optional bleed screw fitted to the air vessel. With the pump stopped, close the gate valve in the delivery pipe to stop it draining back. If a one-way valve is fitted it will close automatically. Then loosen the bleed screw to release the pressure in the air vessel. If none of the above are fitted, the only other way to release the pressure in the air vessel is to loosen each of the air vessel flange bolts one turn at a time until the water and air escapes through the join at the flange. You will certainly get wet this way.

Checks

1. Check the delivery valve rubber for wear and blockage of the valve holes.
2. Check that the snifter valve is in good condition.
3. Remove the impulse valve and check the impulse valve rubber. Check the nuts on the valve stem and check for excessive wear of the stem. Replace things if necessary.
4. Check the pump body is firmly bolted down, then reassemble the pump, ensuring that all bolts are greased.

Putting the pump back together

Assembly of the pump is shown in the exploded view drawing, but the following important points need to be kept in mind:

1. Assembling the delivery valve
   Put together the delivery valve plate, the rubber and the bolt. Make sure the side of the plate with the chamfered holes is on the opposite side to the rubber, and that the rubber is on top.
   Screw on the first nut until it is finger tight and then undo it by one turn. Care must be taken not to overtighten the bolt and nuts as this will affect the performance of the valve. Next, screw on the other nut and tighten it up against the first. Use the spanners to tighten them firmly together. This will lock them together, and also allow a small up-and-down movement of the bolt and rubber.
2. Assembling the snifter valve
   Put the 'shaped' bolt and washer together, feed the bolt through the valve rubber, then push this through the pump body. Make sure that the shaped curve of the bolt head and washer align with the curvature of the body.
   Screw on the first nut until it is only finger tight. If the nut is on too tight the rubber will curl away from the pump body and will need to be slackened off slightly. Then screw on the second nut and tighten the two nuts firmly together using the spanners. Then check that the rubber has not distorted. If it has, slacken the nuts half a turn and tighten the outer one again.
3. Assembling the air vessel and delivery valve
   Align the delivery valve, air vessel, pump body and rubber gasket mounting holes and feed through the bolts. Make sure the delivery valve is the correct way up (the valve rubber facing upwards) and then tighten the nuts by hand. Use the spanners to tighten each nut and bolt a little at a time, working around the flange. This will draw the assembly together evenly.
4. Assembling the impulse valve
   The first parts to assemble are the valve stem, discs and rubber. Screw two nuts onto the longer threaded end of the stem up to the end of the thread. Push a steel washer on up to the nuts. Follow this with the valve plug disc, with the chamfered side towards the nut. Slide the valve rubber up against this, then the weight disk with the chamfered side facing away from the rubber. Follow this with another steel washer. Screw a nut up to them until it is finger tight. Thread on another nut and use the spanners to tighten the nuts together. This part of the assembly is sometimes known as the valve plug.
   Hold the impulse valve plate and the valve plug together, with the chamfered side of the plate opposite to the side against which the valve rubber presses. Slide the stop bar onto the top of the stem and thread a nut loosely on the stem.
   Push the two longer bolts through the ends of the stop bar and thread two nuts onto each. Use spanners to lock the nuts tightly. Align the valve assembly, pump body and rubber gasket and feed through the flange bolts.
   Thread on the four washers and nuts by hand, then use the spanners to tighten the two shorter bolts that hold down the valve plate. Again care must be taken to ensure that these nuts are tightened evenly. The next step is to make sure the closed valve plug is centred in the valve plate hole before tightening down the two remaining nuts that secure the stop bar. To check the alignment, open and close the valve manually turning the valve plug to make sure it does not catch on the hole in the valve plate.

Now you only need to set the stroke length of the valve for the pump to be ready for use.

Spare parts to keep on the site

- impulse, delivery and snifter valve rubbers
- an impulse valve stem
- a few spare M8 nuts, bolts and washers

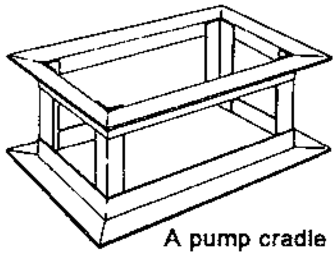
Installation notes

The DTU S1 pump should be installed in a properly designed system. To prevent vibration causing breakages, it should be firmly bolted to a steel frame (called a pump cradle) that is half buried in a concrete base. The cradle is usually made from 40 x 40mm angle iron and will vary in size depending on the number of pumps installed. Hole locations for just one pump are shown on the previous page.
All pipes in the system should be supported firmly, and buried where possible. The drive and delivery tanks should be constructed on good foundations by experienced tradesmen. Pipe joints to the drive tank should allow the pipes to move slightly without damaging the tank walls or leaking badly.



A pump cradle

Starting and stopping the ram pump

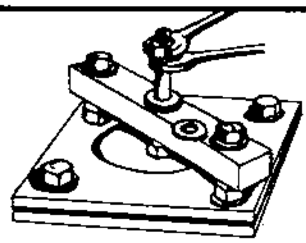
Although ram pumps often start very easily, they can be awkward the first time they are run.
To start the pump:

1. Make sure that any valve fitted on the delivery pipe is open and then open the drive pipe valve. Water will flow out of the open impulse valve until it suddenly shuts. If it reopens automatically, the pump should continue to run on its own. If it does not, you must prime the delivery system as described in Step 2 alongside.
2. Push down on the top of the impulse valve stem with your foot to reopen it (wear strong boots). Again, water will flow out of the open impulse valve until it suddenly shuts, then push down immediately to re-open the valve. Keep helping the valve to re-open until it will do so by itself.

To stop the pump, hold the impulse valve stem up to close it or shut the valve at the bottom of the drive pipe.

Tuning for best performance

The DTU S1 can be tuned to adjust performance. This is done by changing the up and down movement of the impulse valve, which is normally set to about 12mm. Tuning is usually done to achieve either the maximum delivery flow or the most efficient use of the drive water available.



Maximum delivery

When there is plenty of drive water available, the pump can be tuned to deliver as much water as possible. To do this, remove all washers from the impulse valve stem so that the valve has as much up and down movement as possible.

WARNING: - this also puts the pump parts under greater stress and makes them wear more quickly.

Low drive flow

If the pump uses more drive flow than is available it will soon stop. If this happens it must be tuned to use less. The impulse valve should be tuned down to use 90-95% of the water available from the source. To tune the pump down, add washers onto the impulse valve stem so that the valve has less up and down movement. The shorter the stroke, the smaller the amount of drive flow needed, and the less water is delivered. The minimum stroke length is about 7mm.

Routine maintenance

While the pump is running normally, a visit should be made once a week to check that bolts are tight and that there are no leaks. Once a month an inspection of the whole system should be carried out. It is also recommended that a log book is kept to record the checks and repairs that have been made.

Monthly maintenance check list (without stopping the pump):

1. Inspect all the joints to check for leaks.
2. Check if there is sufficient air in the air vessel. This can be done by listening carefully to the pump. If there is insufficient air in the air vessel, the pump will be much louder than usual. This means that the snifter valve is probably blocked and will need to be cleared.
3. Clean any filters installed in the system.
4. Remove excess silt or debree from tanks or from behind the intake dam or weir if necessary.
5. Walk along all pipes looking for damage. Also, inspect the tanks for leaks, particularly at pipe joints.

RELEASE

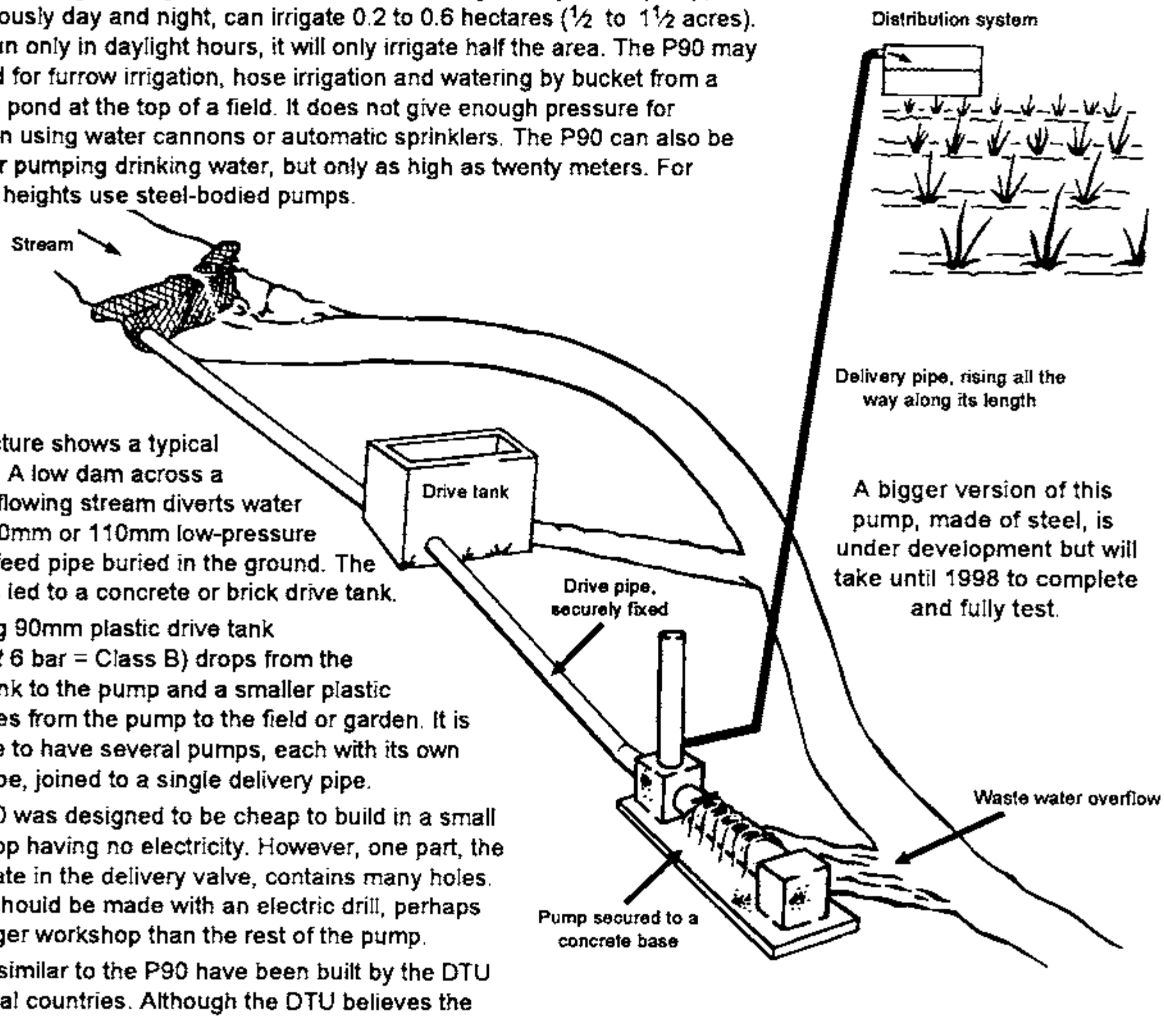
DTU P90 PUMP

DTU P90

The name "P90" stands for a Plastic pump with a drive pipe of 90mm in diameter.

hydraulic ram pump

The P90 is a plastic-bodied hydraulic ram pump designed mainly for the irrigation of vegetable gardens from streams running nearby. Each pump, used continuously day and night, can irrigate 0.2 to 0.6 hectares (½ to 1½ acres). If it is run only in daylight hours, it will only irrigate half the area. The P90 may be used for furrow irrigation, hose irrigation and watering by bucket from a storage pond at the top of a field. It does not give enough pressure for irrigation using water cannons or automatic sprinklers. The P90 can also be used for pumping drinking water, but only as high as twenty meters. For greater heights use steel-bodied pumps.



This picture shows a typical system. A low dam across a rapidly flowing stream diverts water into a 90mm or 110mm low-pressure plastic feed pipe buried in the ground. The water is led to a concrete or brick drive tank.

A strong 90mm plastic drive tank (*at least* 6 bar = Class B) drops from the drive tank to the pump and a smaller plastic pipe rises from the pump to the field or garden. It is possible to have several pumps, each with its own drive pipe, joined to a single delivery pipe.

The P90 was designed to be cheap to build in a small workshop having no electricity. However, one part, the steel plate in the delivery valve, contains many holes. These should be made with an electric drill, perhaps in a bigger workshop than the rest of the pump.

Pumps similar to the P90 have been built by the DTU in several countries. Although the DTU believes the P90 will operate for two years, only one pump trial (in Zimbabwe) has been run for that long.

A bigger version of this pump, made of steel, is under development but will take until 1998 to complete and fully test.

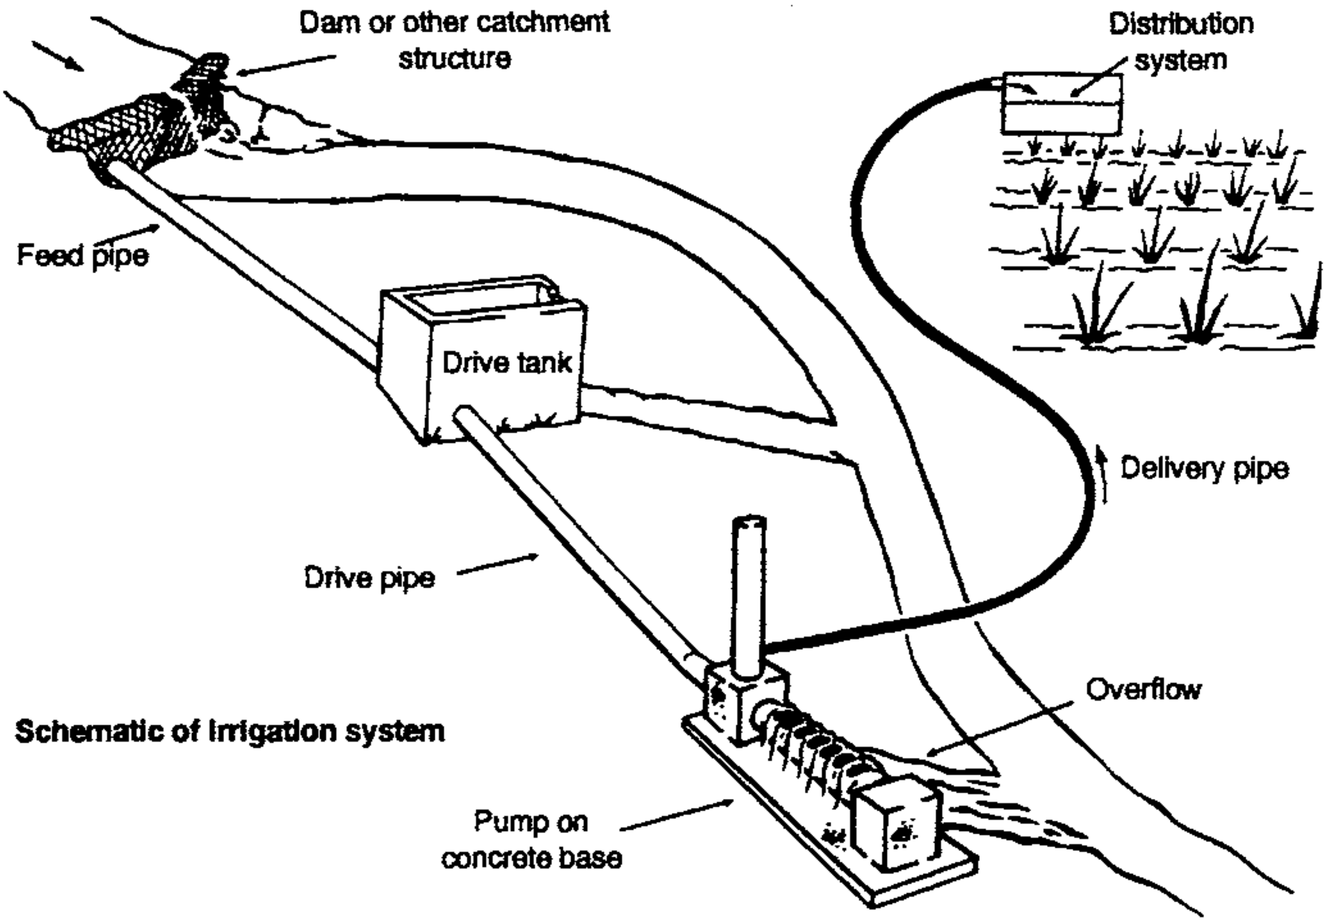
DTU P90 ram pump specifications

The normal specifications of the DTU P90 ram pump are given here. Sometimes you can operate pumps outside these limits, but they may not work well.

drive head range	—	up to 3 meters
drive flow range	—	100 to 360 liters a minute
drive pipe material	—	PVC or ABS (*at least* 6 bar or Class B)
drive pipe diameter	—	90mm
delivery head range	—	up to 20 meters
typical delivery range	—	3 to 40 liters a minute
delivery pipe diameter	—	25mm

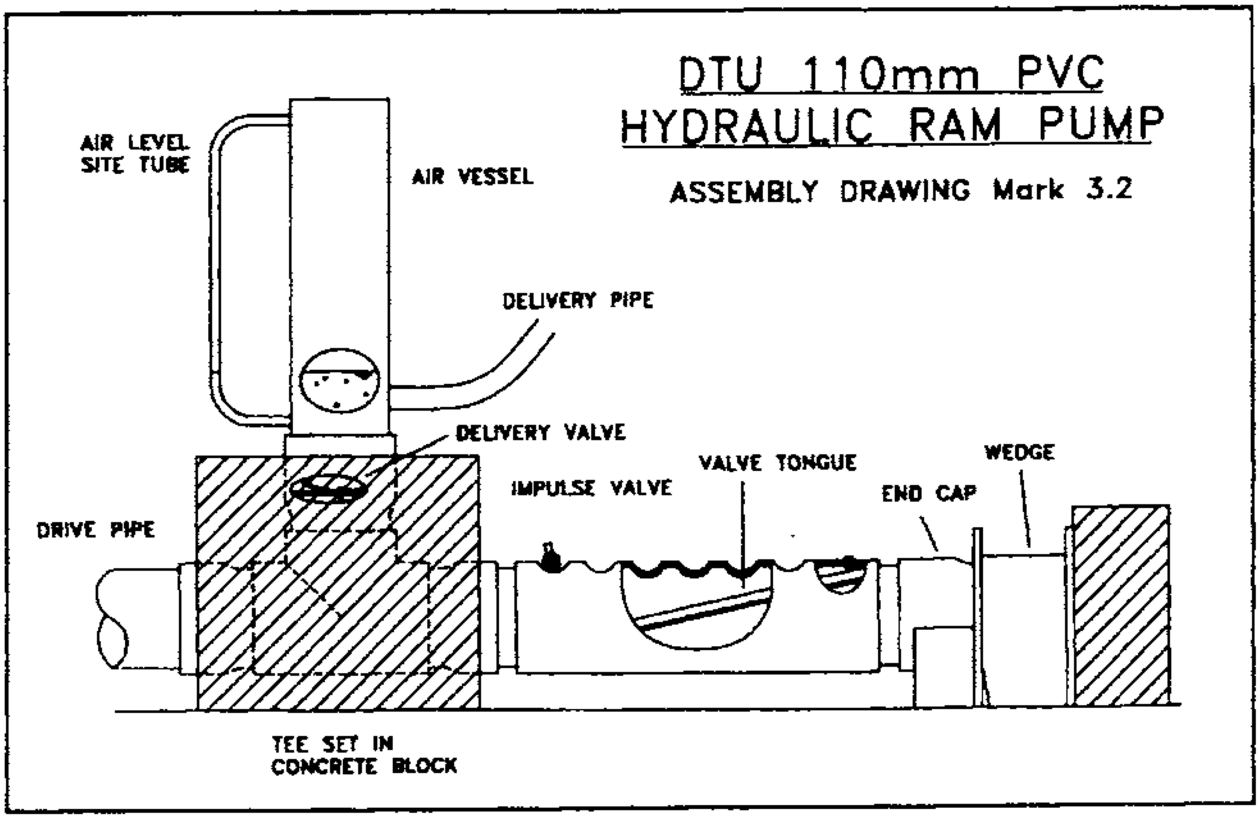
The DTU plastic irrigation pump

Most ram pumps being manufactured are designed to supply water for domestic use because the low flows produced and the costs generally make ram pump systems unsuitable for small-scale crop irrigation. Sufficient water for 1000-1500 people, for example, would only irrigate a plot of around 1 hectare! Some very large bore (12") ram pumps have been built to supply water for irrigation but the capital costs of such schemes restricts their application. In many parts of the world there is a large potential for low-lift, low-cost irrigation of small garden plots to improve yields, allow alternative crops to be grown and increase crop security in unpredictable weather conditions.



Schematic of irrigation system

The material the DTU selected as the only viable alternative to steel is plastic pipe. PVC 110mm (4") diameter pipe is now widely available in many developing countries and provides the scale of flow necessary for small-scale irrigation.



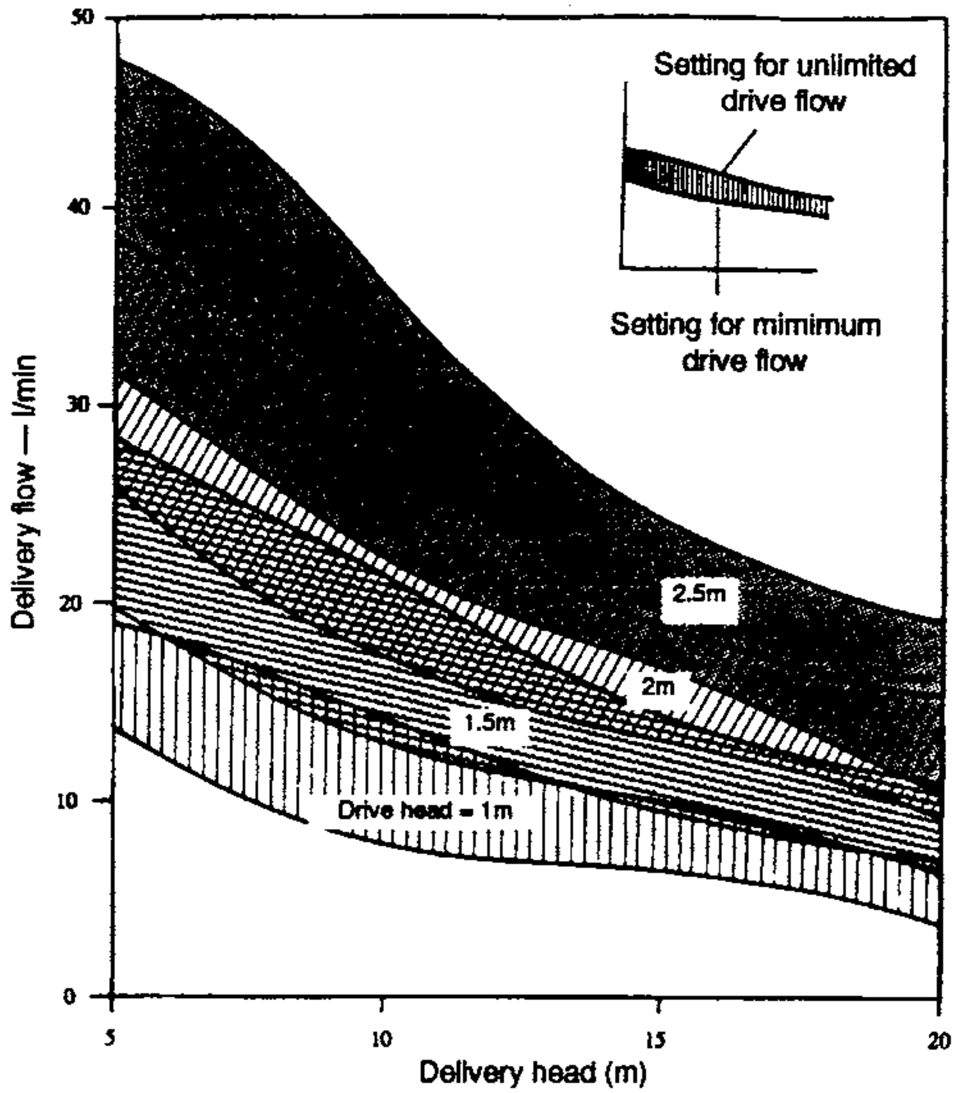
The DTU pump has the following specification:

- all major parts can be manufactured from 110mm pipe (with a minimum of other materials such as bolts, rubber, etc.);
- all parts can be manufactured using hand tools in small rural workshops;
- the system can be maintained by the user and all parts are capable of simple replacement in case of wear, damage or theft;
- designs have been extensively tested for performance and endurance (including extensive field tests);
- pumps should be easy to tune to suit a broad range of site conditions.

It meets the following performance specifications:

1. The drive head (fall of water) can be between 1 and 3 metres.
2. The drive flow available can be between 3 and 7 litres/second.
3. The maximum delivery head is 12m.
4. The energy efficiency exceeds 50%.

At 2 metres drive head, maximum delivery to 15 metres is 35,000 litres per day, adequate to irrigate ⅔ of a hectare.



DTU PVC ram pump — Typical performance data

The shaded areas on the performance data chart above indicate the normal operating range for different values of drive head.

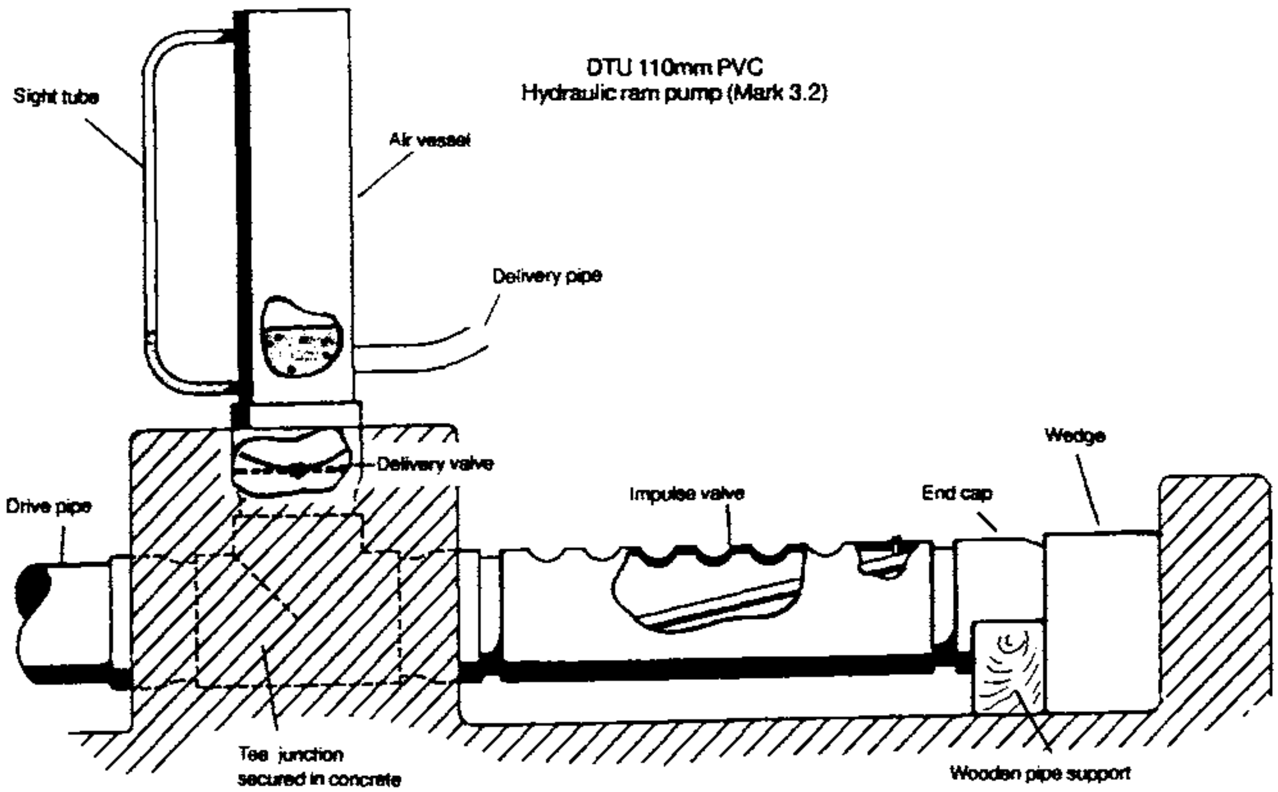
Pump designs have been developed over a number of years with increasing performance and component life. Plastic pipe is more prone to fatigue failure than steel, reducing the life of some components to two years. The current design has been extensively tested in Zimbabwe but is still (1993) at the proving stage of development.

Manufacturing notes

The first DTU ram pump to be built using plastic materials was tested in 1986 as part of an undergraduate project. It was constructed largely from standard PVC drain pipe fittings with a wooden impulse valve. The major interest in the use of plastic for ram pumps stemmed from the low cost of materials and the ease of manufacture using plastic components. There was some question initially whether the thin PVC material would withstand the continual fatigue loading and simply break under the first cycles. With the success of this first design, research was continued on its development and the horizontal axis impulse valve was introduced. Since then laboratory tests and field trials have significantly refined the design of the pump and produced data concerning its durability and pumping limitations.

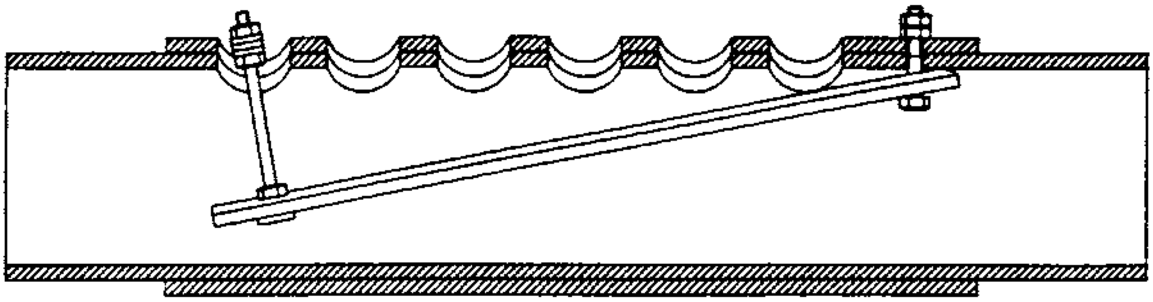
Plastic ram pumps can provide a cheap and simple means of supplying water to elevations of less than 15m. The scale of flow produced and the limitations on their pumping head make them ideal for local manufacture and use for small scale irrigation in developing countries.

This Working Paper details the design of the M3.2 pump. It lists each component and describes any significant features and considerations. Drawings of all the components are also included along with some graphs showing the typical performance of the pump.



Impulse Valve

The design of impulse valve on the DTU M3.2 is unique amongst current ram pump designs. It aims to achieve a flow area through the valve equal to, or greater than, the area of the drive pipe whilst using the drive pipe material for its construction. This greatly simplifies the materials required for pump construction and reduces the need for steel components.



The M3.2 impulse valve

The valve operates under conditions similar to those that cause the aerodynamic lift of an aircraft wing. The velocity of the water flowing over the top of the tongue and out to waste, creates a slightly lower pressure on the top side than that underneath it. As the water accelerates, this pressure differential across the tongue increases until it is sufficient to begin to close the valve. As the tongue rises the velocity over it is increased, which in turn increases the pressure differential, causing the valve to close faster and further increasing the velocity. In this way the tongue accelerates and closes very rapidly producing the sudden deceleration of the water necessary to raise the pressure in the pump body to the delivery pressure.

The valve design works well using PVC materials due to its slight flexibility. When the valve closes the subsequent pressure rise actually flexes the tongue ensuring a good seal even though the tongue may not fit perfectly to the valve body. The same valve design has been tried using steel pipe material but was found not to work well as the tongue could not easily be contoured to the exact shape of the inside of the valve body and didn't have sufficient flexibility to deform under the normal working pressure. Provided that the tongue of a PVC pump fits sufficiently well to just operate it will deform over a number of days of operation until it seals properly.

The development of the this design from the basic concept has taken some time in using different configurations; hole sizes, spacing, valve length and in finding a design with sufficient strength to withstand the continual loading. PVC is not a material recommended for use in situations where a high fatigue loading is likely. Its use would therefore not normally be advisable in ram pumps where there is a highly fluctuating load from the pressure transients in the pump and drive pipe. Research has shown that provided the delivery pressure is kept within recommended limits, the pump and pipe material are sufficiently thick, and the pump well manufactured with no potential stress concentrators, that the normal fatigue loading experienced is well within the tolerance of the material. A Working Paper is available from the DTU detailing the research and findings of work undertaken on fatigue in PVC.

Impulse Valve Design and Manufacture Notes

1) Great care is needed in the manufacture of the holes in the valve body to ensure that there are no small cuts, indentations or cracks from the initial shaping of the holes. Once the holes have been roughly shaped they should be carefully filed until they are completely smooth to the touch and show no visual defects. This will help prevent the formation and propagation of cracks.

2) The tongue hinge is a potential source of rapid wear of the PVC material used both for the tongue and the valve body. The hinge is simply a bolt about which the tongue has some freedom to move. To prevent wear of the tongue, the hole that goes through it is lined with a piece of metal, either a small section of pipe with the correct I/D or a specially fabricated liner made from sheet steel.

3) On two occasions impulse valve cracks were found running down the valve parallel to the pipe axis at the upstream end that was pushed into the tee piece. These cracks were caused by the valve being wedged too hard into the tee piece socket. This created a significant additional hoop stress at that end of the valve and led to a crack propagating from some small imperfection in the first valve hole back to the end of the pipe. The main cause of this problem was the method of wedging the impulse valve into the tee piece against the concrete end block. It is possible to prevent this type of cracking by wedging the impulse valve more carefully. However this does not provide a fool proof solution and still allows the possibility of valve failure. The simplest method of preventing this problem is to shorten the length of the pipe that can fit into the tee socket so that the double skin of the impulse valve butts up against the tee before the valve is pushed in too tight.

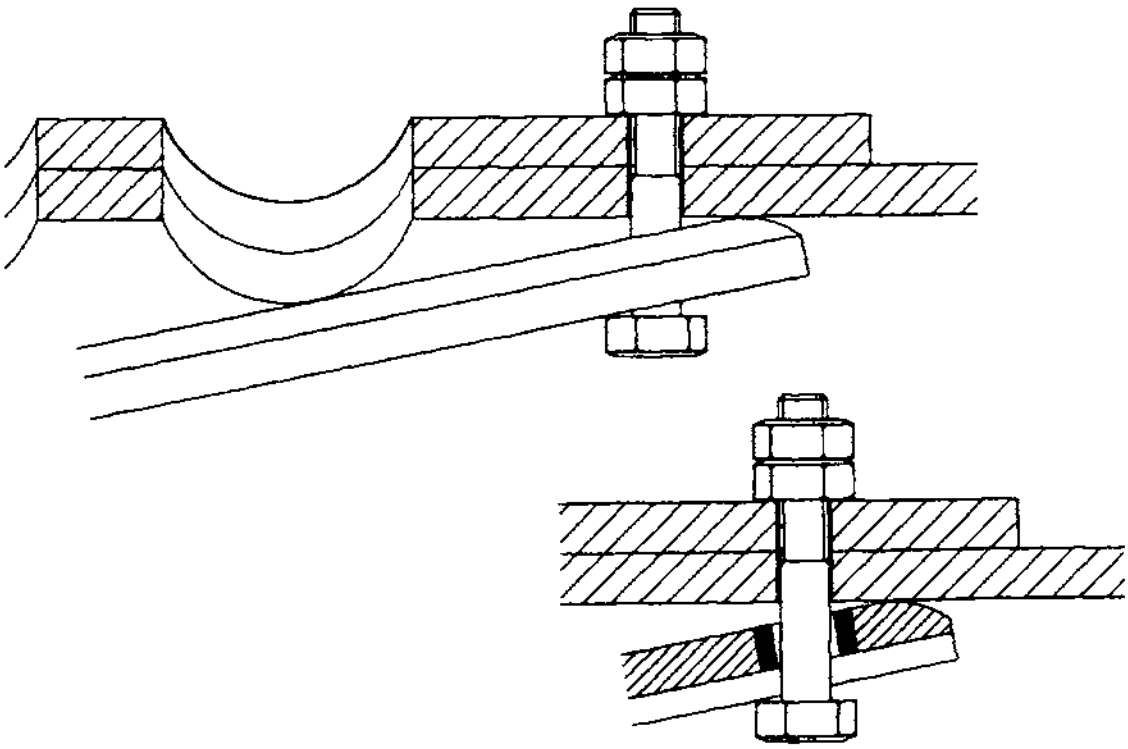


Diagram showing hinge arrangement of impulse valve tongue

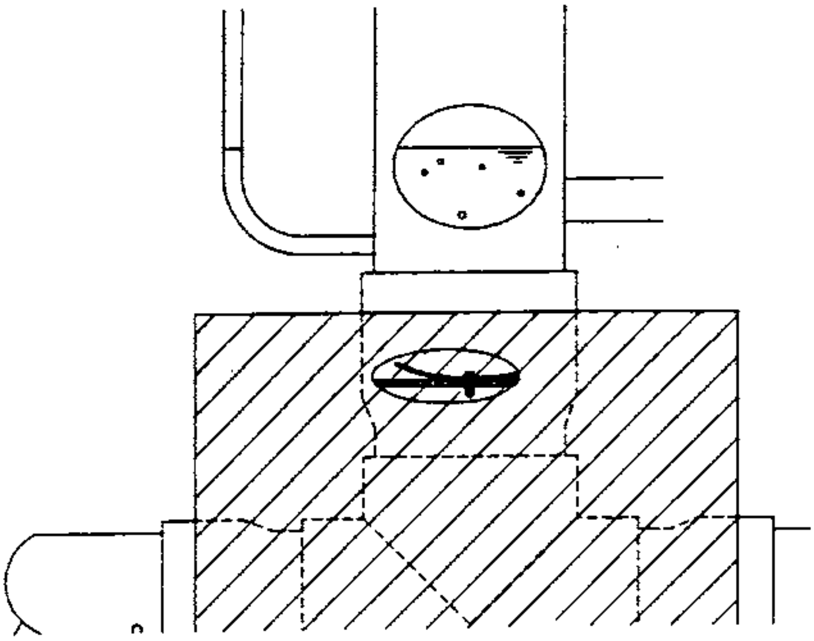
Delivery Valve Design

The delivery valve for a low cost ram pump must satisfy all of the following requirements;

1) produce good performance by; opening quickly with a low pressure differential across it; have a low resistance to flow through it; allow little backflow by closing quickly with a small pressure differential.

2) have an acceptable working life with any disposable rubber parts lasting a minimum of 6 months.

3) be cheap and simple to manufacture.



Position of the Delivery Valve

Laboratory tests have been carried out on a number of different types of delivery valve to assess their performance. These were simply designed to compare the throughput of the valve under a controlled set of conditions. Backflow of water through the valve from the air vessel during the period of recoil had been found to be significant on tests of steel ram pumps, reducing the delivery flow by up to 40% in the worst cases. With identical impulse valve settings, the delivery head and flows were measured for 5 different delivery valves. The results of the tests are shown in the following graphs.

The original flap type delivery valve proved to give the best performance over a wide range of conditions with two thicknesses of rubber to increase the rigidity of the valve. The rubber used in the tests was 3mm thick commercial sheet. One thickness of rubber gives lower performance due to its lower response to closure allowing more backflow to occur. Increasing the number of rubbers above 2 also reduces the delivery flow as the resistance of the valve to opening increases and the friction through the valve during delivery reduces the flow. Unfortuneately the quality and availability of rubber sheet varies enormously around the world and it is important to be able to make use of locally available materials to guarantee access to spare parts. Good quality inner tube from truck wheels is often the most available and reliable source of rubber. It is recommended that a number of thicknesses be used to make the total thickness of rubber between 4 and 6mm. Some experimentation with the materials available is advised. measuring performance with varying amounts of rubber to find an optimum and assess the rubbers' vulnerability to tearing and stretching.

One problem experienced with the standard flap type valve, that has been extensively used, is splitting of the rubber at the point where it is clamped. The continual movement of the valve has often been found to lead to a stress related failure at the point about which the rubber trys to hinge. This occurs most frequently when the retaining bolt holding the valve rubber is over tightened, compressing the rubber. Using a curved washer reduces the problem by not having a sharp edge about which the rubber bends and eventually is cut. The rubber instead follows a more gentle curve along its length reducing the likelihood of stress concentration and splitting of the rubber.

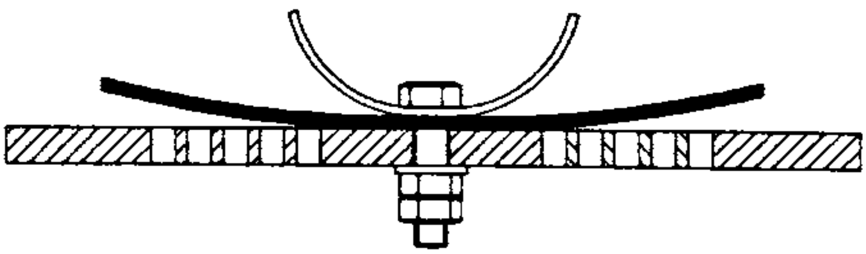

Diagram showing curved washer used in delivery valve.

Another important factor in manufacturing the rubber discs is the cutting of the central hole. This must be done cleanly with no ragged edges or flaws where cracks could start and then spread with the continual movement and stretching of the rubber. To do this it is recommended that a hole punch be bought or manufactured ensuring holes with clean edges can be accurately and repeatably made.

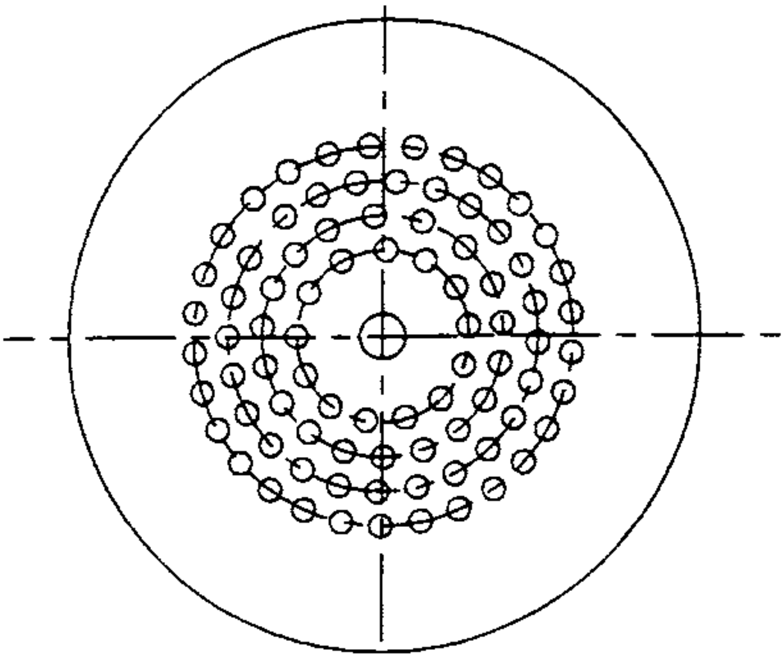

Diagram showing arrangement of delivery valve holes

The valve disc itself should be manufactured from steel plate with a minimum thickness of 3mm (10 swg) and preferably be up to 6mm. The arrangement and size of the holes in the plate is important for a number of reasons;

1) The hole size must be large enough to allow high flows with little resistance.

2) The hole size must be small enough to prevent the pressure of water in the air vessel from pushing the rubber into the holes thus deforming it and causing potential cracks.

3) The radius from the center in which the holes are confined needs to be as large as possible to maximise throughput but limited to allow sealing of the rubber around the outside of the valve plate.

4) The holes should not be too close together to prevent cracking of the valve disc between holes due to the continuous fatigue loading.

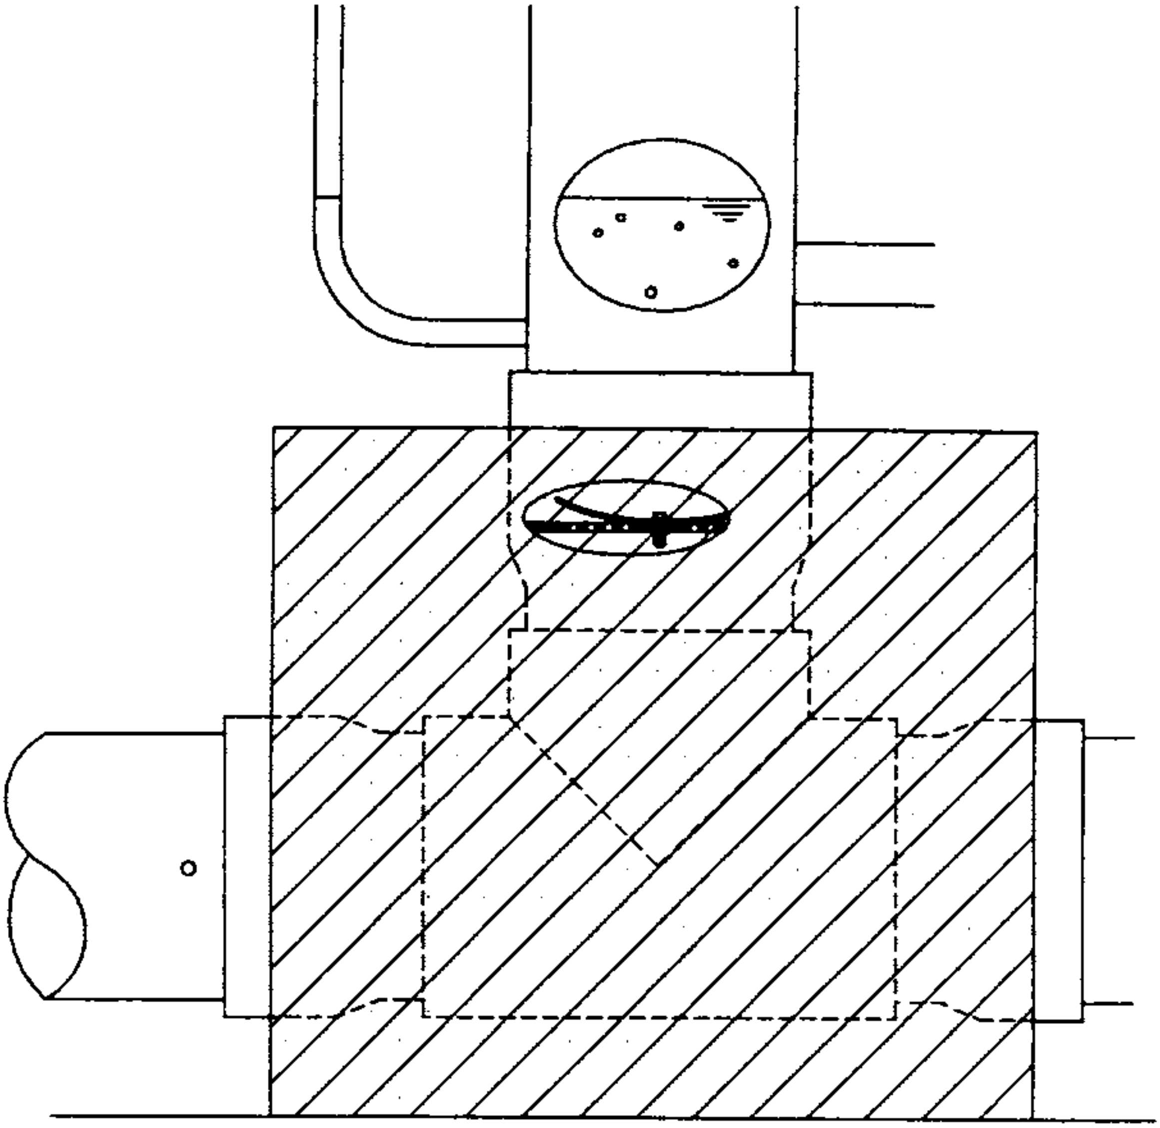
Valve plates using thick plastic material have been tested in an attempt to do without the need for a metal component. The life of such discs however was found to be too short under the loading experienced.

Marking out and accurately drilling the arrangement of the large number of holes required in the valve plate can be an arduous and time consuming process. If a number of pumps are to be made it is well worth making a jig, both to cut down on the time taken and to ensure accuracy. Under the manufacturing aids section there is a drawing of one design of a valve plate jig. It ensures both the accuracy of the circumference of the plate and the accuracy of the spacing and number of holes.

Snifter Valve

During operation of the pump, air will be constantly taken into solution at the air/water interface in the air vessel. This slowly reduces the amount of air in the air vessel leading to inefficient operation and pressure spikes significantly higher than the static delivery head. Air therefore has to be constantly and reliably introduced into the air vessel to replenish that being lost in order to keep the air vessel full and the pump working at peak efficiency. This is done by the snifter valve allowing air to enter into the body of the pump each time the pressure recoil opens the impulse valve. The slight negative pressure during the recoil phase of the cycle draws air in through the snifter valve. It is placed to enable the air to travel to the under side of the delivery valve waiting to enter the air vessel at the next delivery cycle.

There are a number of types of snifter valve that have been used on ram pumps over the years. The main design considerations are that the valve is reliable and lets in the correct amount of air each cycle. On initial start-up of the pump the volume of air in the air vessel (at atmospheric pressure) is compressed as the delivery pressure builds up. The flow of air into the air vessel from the snifter valve needs to be sufficient to re-fill the air vessel over a period of time. If too much air is entering through the snifter, the air vessel will fill up quickly and then the excess air will simply be taken up the delivery pipe where it may create problems of air locks. The snifter therefore needs to be large enough to allow sufficient air to ensure replenishment of the air vessel but not so large that the delivery pipe has a large amount of air travelling in it.



The simplest type of snifter is a hole drilled in the pump body close to the underside of the delivery valve. In the DTU M3.2 the best place for this is just upstream of the tee piece that connects the drive pipe to the pump. A small jet of water will squirt through the hole with the pressure inside the pipe until the recoil cycle occurs when air will be sucked through the hole into the pipe. As the water accelerates beginning the next cycle, some of the air rises up and sits under the delivery valve. This snifter hole should be drilled in the side of the pipe after the pump has been started for the first time.

Use the following procedure;

1) On initial start-up of the pump allow it to settle and stabalise at the system delivery pressure.

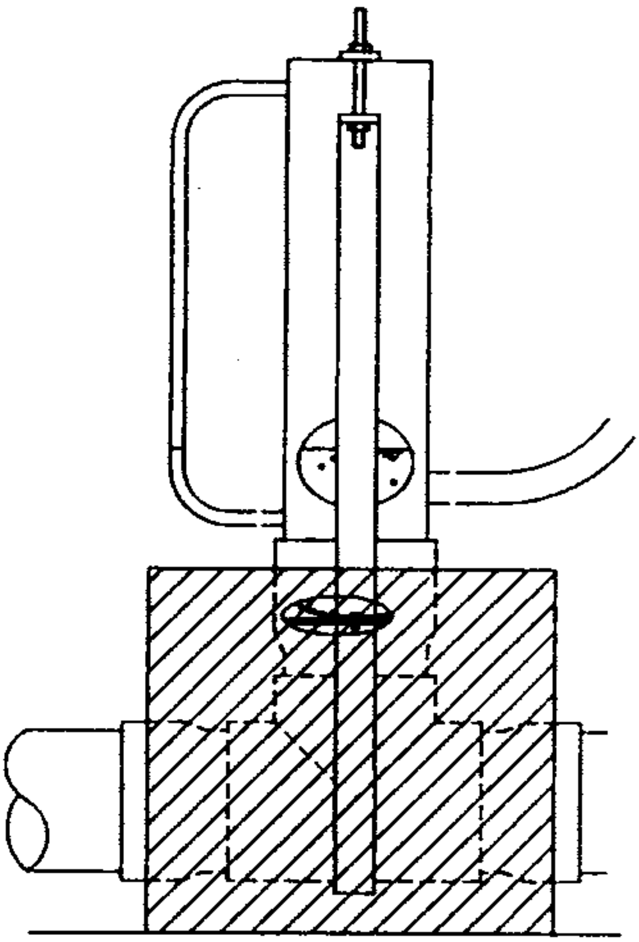
2) Make a note of the level of the air in the air vessel using the air sight tube.

3) Drill a 1.5mm dia hole in the tee/pipe as specified above.

4) Wait for 30 mins to 1 hour to see if the amount of air changes. If the air level continues to increase until it reaches the top of the delivery pipe connection, then the snifter valve is probably about the right size. If the amount of air remains constant or reduces then increase the hole diameter to 2mm. Repeat this process until the hole is big enough to allow the air level to drop down to the delivery pipe connection.

Air Vessel Size.

Over the years that ram pumps have been used there have been a number of different theories proposed and used to design air vessels. One purpose of the air vessel is to turn the intermittent flow through the delivery valve into a steady, continous flow up the delivery pipe. The air vessel provides the pump with a constant head to pump against, limits the size of the damaging pressure spikes, and removes the inefficiencies associated with intermittent flow in the delivery pipe. The size of the air vessel therefore should ensure that conditions (ie pressure) in the air vessel are little affected by the sudden inflow of water each cycle coming through the delivery valve. The volume of air in the air vessel therefore should be at least 20 and preferably nearer 50 times the expected delivery flow per cycle. An air vessel with a volume many times that of the water entering per cycle will experience little change in conditions at each delivery. Pumps running to low heads with large delivery flows therefore actually require air vessels larger than ones pumping smaller flows to high delivery heads.



For example; A pump delivering 30 l/min and operating at 60 cycles per minute has a flow per cycle of 0.5 litres. The minmum air vessel volume for this case should be 20 x 0.5 = 10 litres.

The design of the DTU M3.2 110mm PVC pump is attempting to use the fewest number of components possible. The air vessel has therefore been restricted to the same 110mm pipe used in the rest of the pump. This pipe typically has an internal cross sectional area of around 7500mm^2 and therefore a 130mm length of pipe is required per litre volume of air vessel. The maximum expected delivery flow under normal conditions is 0.5 litres per cycle requiring a 10 litre air vessel that is 1300mm long.

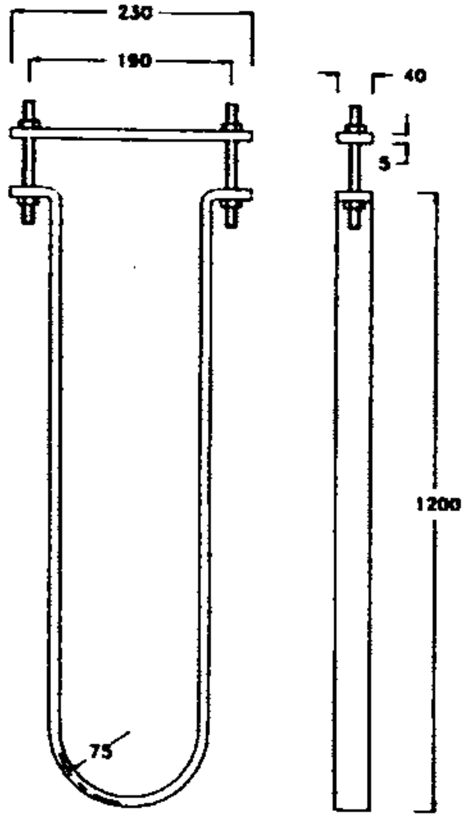
Sight tubes on an air vessel provide a very simple way of checking the level of air and therefore the effectiveness of the snifter valve. A number of problems have been encountered with the manufacture and use of air vessels that are worth mentioning:

1) Small bore, 'see-through' plastic tubing is not always easy to find.

2) Most tubing that is available deteriorates over a few months, becoming cloudy so that it is very difficult to distinguish the water level inside. Fitting a sight tube is still worthwhile under these circumstances as it is during commissioning of the pump and sizing the snifter valve that the sight tube is most useful.

3) Making connections onto the air vessel can be quite difficult. Reinforcing strips of pipe can be used over areas where the connections are to be made to increase the wall thickness of the pipe for glueing or threading.

Air Vessel Strap

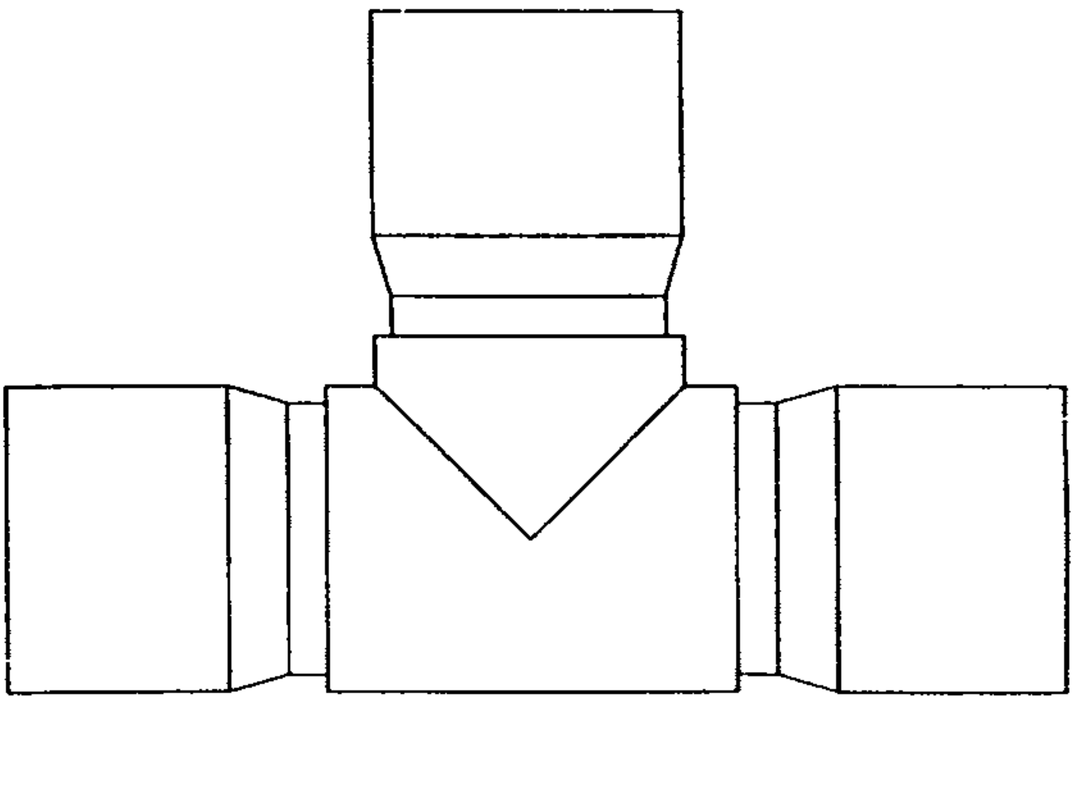


The air vessel has to be held down to prevent the pressure inside it blowing out from the tee piece. The concrete block holding the tee piece makes a good solid anchor for this strap and allows the air vessel to be securely clamped. A variety of types of clamp have been used and the one shown in the drawings section of this paper is probably the simplest.

Pipe Fittings

Tee Piece

The original design of the DTU PVC ram pump had the drive pipe connected directly with the impulse valve. The impulse valve then pushed into an elbow that was incased in concrete and fixed to the concrete pump base. The delivery valve sat in the top of the elbow and the air vessel was pushed down on top of it. With an increased understanding of pump operation and after some laboratory testing it was decided to place the delivery valve and air vessel upstream of the impulse valve. On the DTU steel pumps this had given a number of operational advantages, particularly in reducing peak pressures and so it was also applied to the plastic pumps. This altered configuration overcame some installation problems but created others.



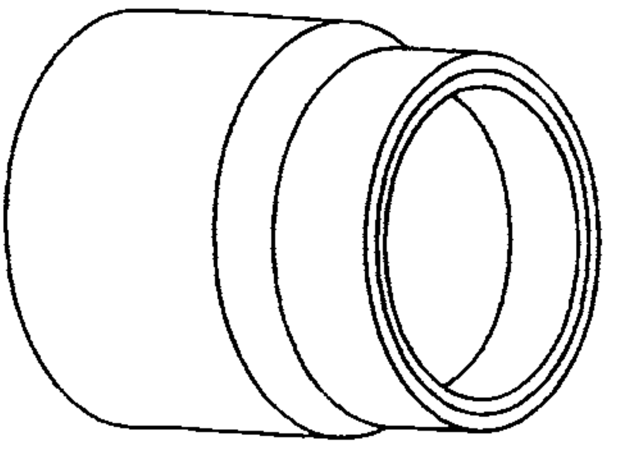
With the elbow solidly fixed downstream of the impulse valve the shocks during each pump cycle were transfered through the elbow into the concrete block. This provided good anchoring for the pump but led in some instances to cracking of the elbow. As the end of the drive pipe entering the drive tank is also fixed (and the pipe often buried) a removable section of pipe was required to allow fitting and removal of the impulse valve. This often proved to be a weak point as a good seal had to be made once the impulse valve was installed. With the revised arrangement the impulse valve is downstream of the concrete block and so provides no anchorage to prevent movement of the valve. So a further anchoring block has to be installed at the end of the impulse valve leaving enough room to allow the valve to be slid in and out of the tee piece. The gap between this second anchoring block and the valve is filled using a wedge once the valve is in place. The end of the valve also required an end cap for sealing (see below) which had to be capable of withstanding the constant shock loading. The elbow that previously experienced a substantial shock loading from the movement of the impulse valve was replaced by a tee piece that was free of this fatigue problem.

Tee fittings are commonly used in plastic pipework installations and are normally made by injection moulding. These fittings are often available in developing countries but in many cases, even where plastic pipe is manufactured, they have to be imported. They tend to be extremely expensive and are often of low quality. Experience of installations in Zimbabwe showed that the cost of a suitable tee piece was the equivalent to 3-4 meters of drive pipe - a significant cost. Such fittings were not only expensive but also in very short supply. In line with the goal of manufacturing pumps from standard pipe material a method for tee manufacture using small sections of pipe was developed. Sockets for the connection of pipes are formed by heating the ends of the pipe in an oven or oil bath and forcing them over a specially made, tapered former. Diagonal cuts are then made at 90 degress and the two sections glued together. (see drawing section). Fittings made in this way are much cheaper than those available commercially and overcome the problems of availability.

End Cap

The new pump configuration required that the end of the impulse valve be sealed with a cap. Commercially manufactured end caps are generally available and provide a good seal. However the constant movement of the impulse valve at each pump cycle crushes the end cap between the valve body and the solid end block.

It is not possible to significantly prevent this movement as the plastic material has a high degree of flexibility and so joints tend to move under the pulsing pressure experienced in the pump. Thin walled, injection moulded end caps were found to last a very short time before cracking due to the high fatigue loading experienced. On the first site installed in Zimbabwe with this configuration a number of end caps of increasing strength were fabricated. The final solution was to make a thick walled socket using the socket former, reinforced at the end with a number of extra rings of pipe. A 5mm metal disc was then shaped to fit into the end of the socket and sealed firmly in place using plumbers putty.

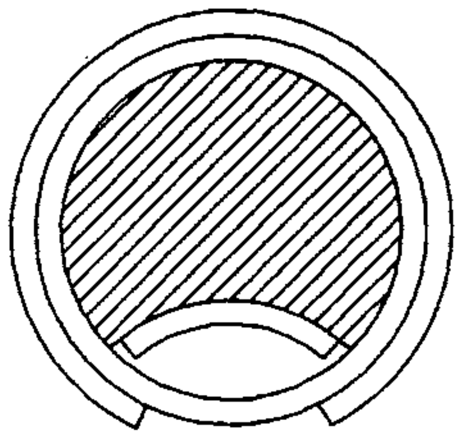


Drive Pipe

Drive Pipe Diameter

Throughout the DTU research into PVC ram pumps, the diameter of drive pipes used has been standard 4" 110mm O/D. Pumps have been designed specifically for this common size of pipe that has been found to be widely available in developing countries. The pump components themselves are now made almost entirely from this basic pipe material in order to reduce cost and simplify the raw material requirement.

The body of most ram pumps, and particularly the section housing the impulse valve, tend to be of a larger cross-sectional area than the recommended drive pipe. In the DTU steel designs for instance a 4" diameter body is used to match a 2" drive pipe diameter. This ensures that the frictional loss of water flowing through the impulse valve is low enough to allow sufficient flow in the drive pipe thus matching pump to drive pipe. A general rule that simplifies the initial sizing and design of an impulse valve is to ensure that, at all points through the pump body and impulse valve the area available for water flow is equal to, or greater than the area of the drive pipe. The design of the DTU PVC rams however is restricted to using the same 110mm pipe for the body of the impulse valve as is used for the drive pipe. The flow area through the holes of the valve is greater than the area of the drive pipe but at the leading edge of the tongue even at maximum stroke the flow area is reduced by around 20%. This is illustrated in the diagram below.



Cross-section of Impulse Valve showing restriction to flow.

Whilst it is possible to achieve drive flows in excess of 350 l/min with this arangement it became clear that particularly at low strokes the size and design of the impulse valve was not allowing full use of the diameter of the drive pipe. This situation is greatly exaggerated at lower strokes when the pump is tuned down in order to use less drive water. In effect the velocity of water in the drive pipe when the valve begins to shut is considerably lower than the maximum capacity of the pipe. As the kinetic energy available for pumping is proportional to the mass of the water and to its velocity squared, it makes sense to keep velocities high and lose a little mass by reducing pipe diameter.

Laboratory tests have been carried out in order to compare the 110mm drive pipe with the next common size down: 90mm. The results of these tests are summarised in Graph Nos X,X and show quite clearly that under most conditions both the efficiency and power output of the pump are improved by using the smaller drive pipe size.

Whilst the pump will work perfectly well with a 110mm drive pipe over the complete range of operating conditions it is now recommended that a 90mm pipe be used if available. This may also give a small saving in system cost and gives a greater potential range of pipe that can be used if one size is not available. In situations of particularly low drive flow the pump may not actually be able to operate with the larger sizes of drive pipe. The maximum head to which a pump can deliver is dependant upon the velocity of the water in the drive pipe. To reach a given delivery head there has to be a corresponding drop in velocity turning kinetic energy to potential energy. If the velocity drop required to reach a given pressure is larger than the maximum velocity of the water in the drive pipe then the pump will never reach the required delivery head although it can appear to be operating. Smaller diameter drive pipes will have a higher water velocity for a given flow and therefore will permit operation in situations where larger diameter pipes would not work. The graph below shows the typical lower boundary of the commonest pipes used for DTU M3.2 PVC pumps

Drive Pipe Length

One critical factor with PVC ram pumps for small irrigation schemes is cost. The pump and system constraints have been designed to give good performance, reliability, local manufacture, availability of spare parts, all for the smallest possible cost. One of the major cost components of any ram pump system is the drive pipe which can often equal or even exceed the cost of the pump unit itself! As drive heads are comparatively small for PVC pumps, the physical layout of the site can often allow drive pipe lengths to be very short. Systems have been installed and successfully run with drive pipe lengths of only 6m. Plastic pumps generally can utilise shorter drive pipes than their steel equivalents due to the much lower wave speeds of the transients moving in them. Longer drive pipes can increase the pumping energy available by increasing the mass of water moving in the drive pipe and increasing the length of the delivery cycle during operation. Longer drive pipes introduce greater friction into the system so that less of the drive head is available to the pump. This consideration of pipe friction imposes an upper limit on the length of drive pipe that can be used for a given drive head.

Bearing the all important cost factor in mind it is recommended that drive pipe length normally be kept in the range 6 to 30m with 12m being a rough guide to the optimum when balancing cost and performance. If a combination of a necessarily long drive pipe (greater than 20m), high drive flow (greater than 300l/min), and low delivery head (less than 8m) occurs it is recommended that a 110mm rather than the standard 90mm drive pipe be used as the friction in a 90mm pipe would be more significant in such a situation.

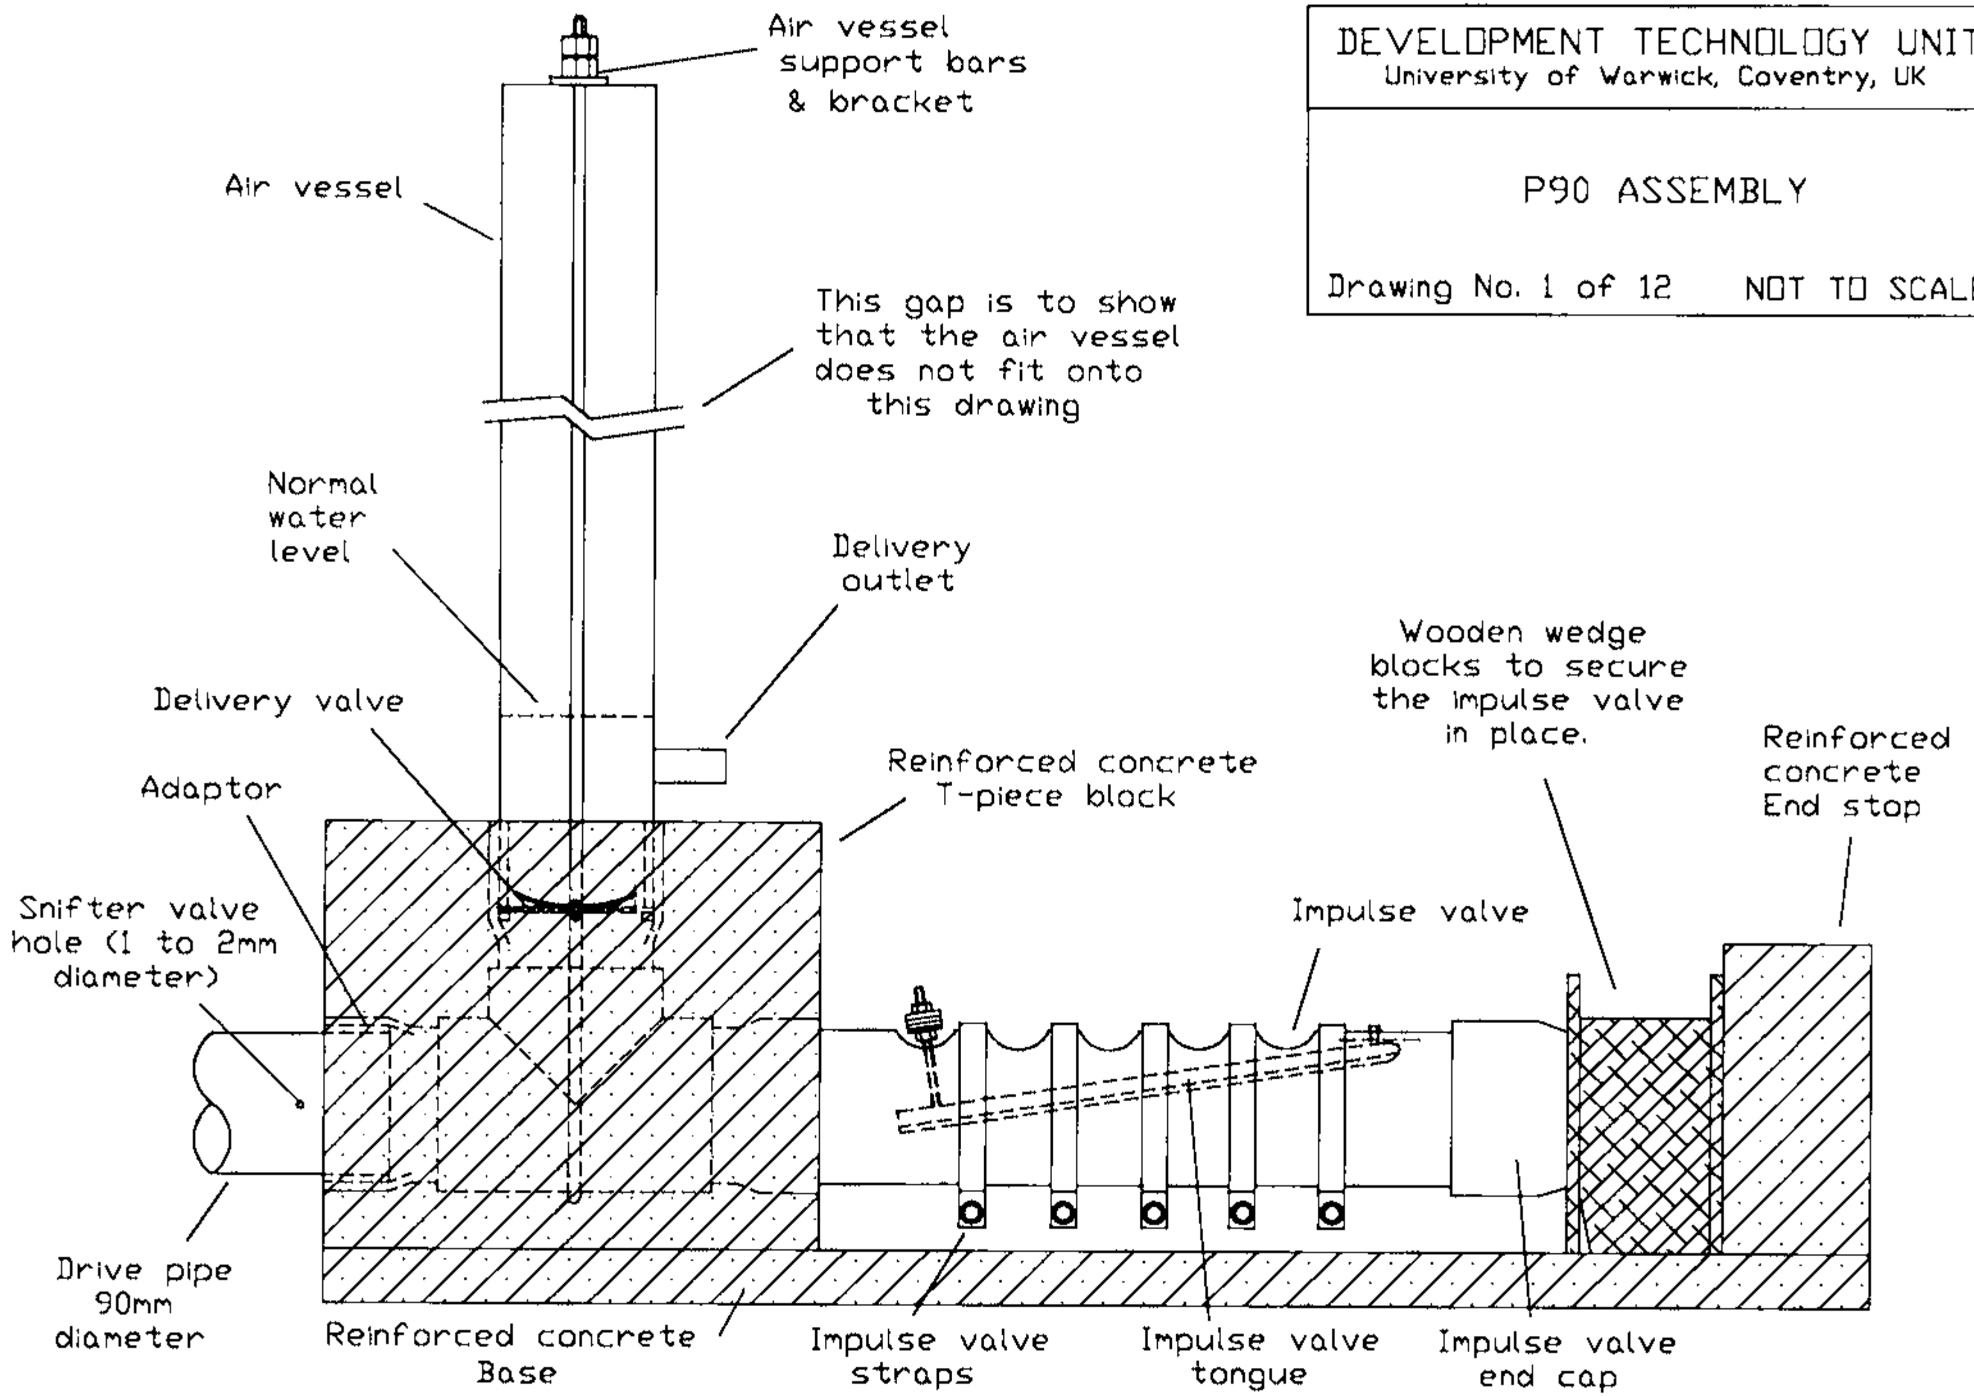
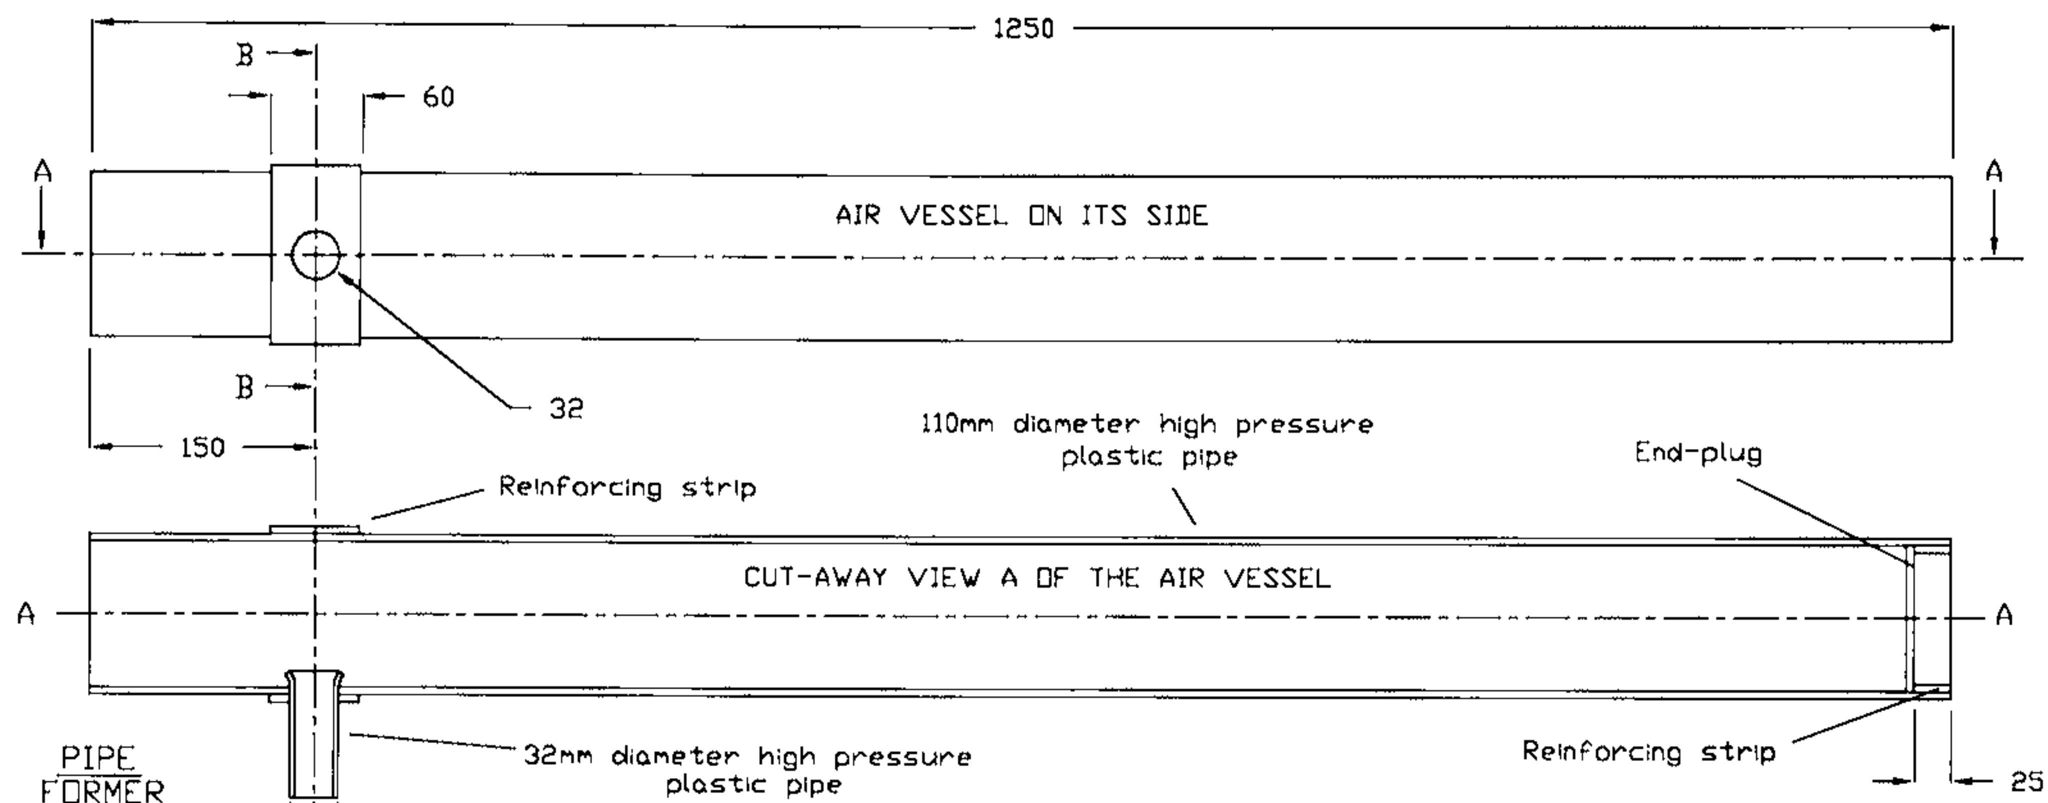
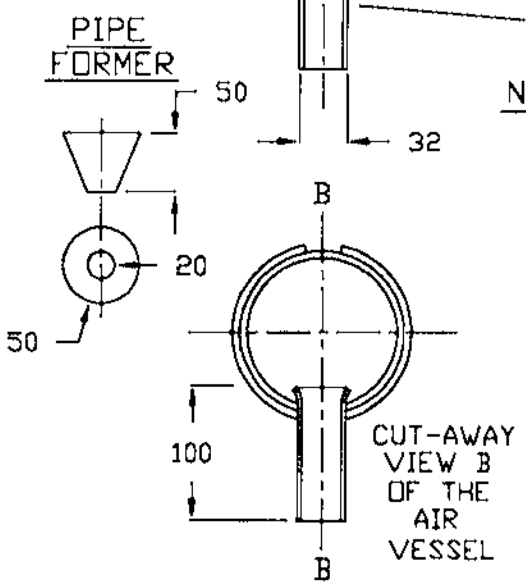
P90 ASSEMBLY

Drawing No. 1 of 12 NOT TO SCALE







ALL DIMENSIONS IN mm

NOTES:

1 - The air vessel is made using 110mm diameter high pressure plastic pipe and 32mm diameter plastic pipe for the delivery pipe outlet.

2 - The reinforcing strip is also 110mm diameter high pressure plastic pipe. It is cut and glued into place using a good plastic adhesive

3 - To make the end-plug, a section of pipe is cut along its length, heated and flattened. Once cooled, a disc is cut out of this to form the correct shape.

4 - To secure the delivery outlet pipe to the air vessel, firstly, heat the end of the pipe until it starts to soften. Push the pipe through the hole in the air vessel and widen the pipe end. using a tapered wooden or steel former. (as shown).

5 - Use a good plastic adhesive to bond all the sections together.

ALL DIMENSIONS IN mm

NOTES:

1 - The material used to make the strap is 25 x 3mm mild steel.

2 - 5 straps are needed for the impulse valve.

3 - Mark the measured fold lines on the cut lengths of steel. After folding the straps wrap them around the impulse valve and check that there is a minimum gap of about 10mm between the folded up-rights.

4 - When the straps are assembled, paint them before adding them to the impulse valve.

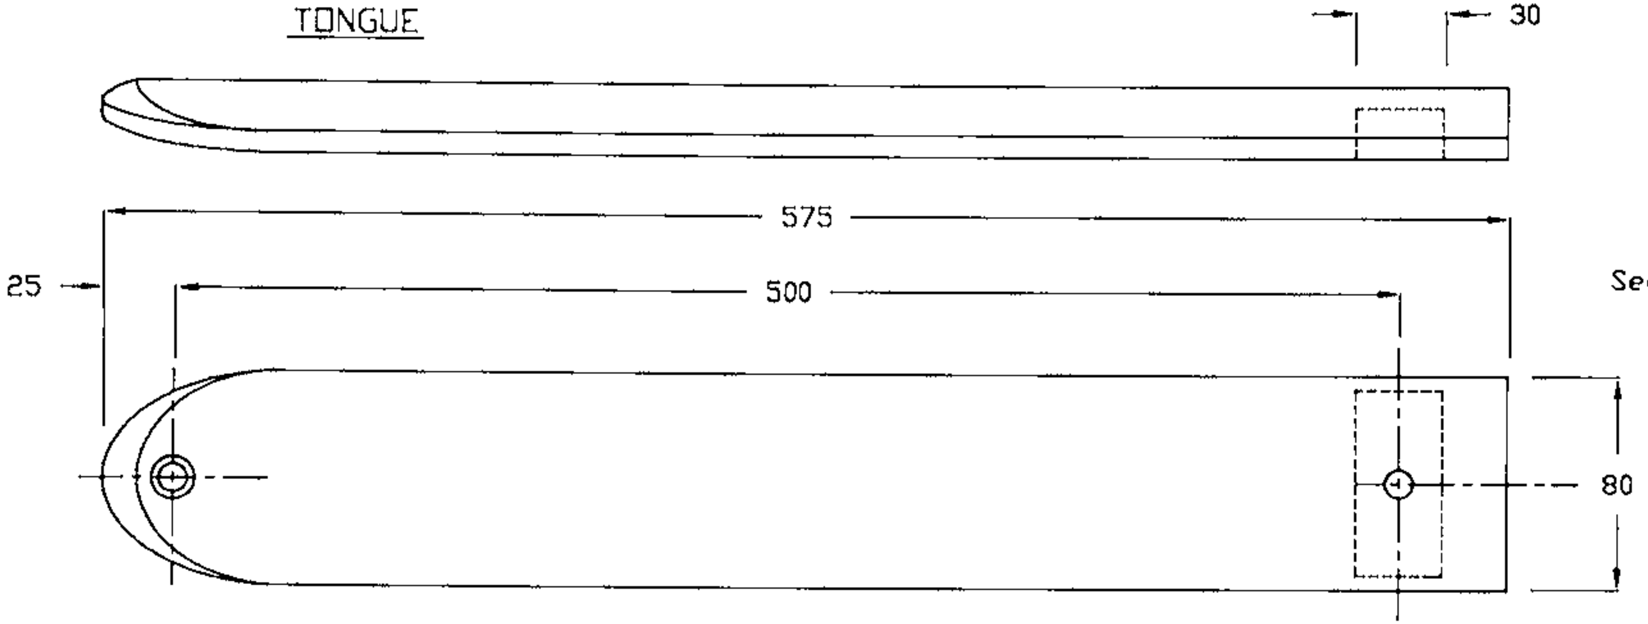
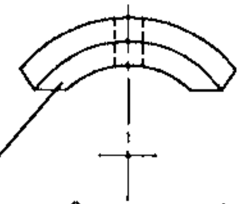
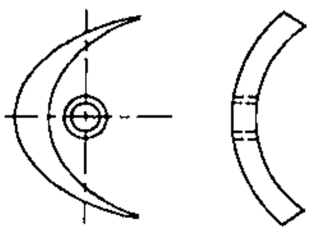
TONGUE

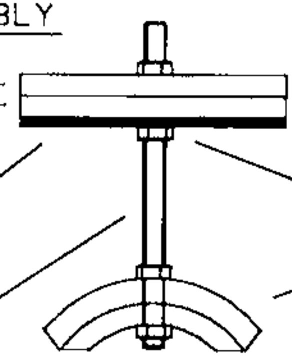




TONGUE MOUNTING



TONGUE STEM ASSEMBLY



A steel ring with an internal diameter of approx. 10mm (3/8' pipe) is pushed into a hole in the tongue using an interference fit. Use a 50mm M8 bolt, 2 nuts and washers to fit the tongue to the impulse valve.

FITTING THE TONGUE

Hold the tongue in place inside the impulse valve. Feed the bolt through a washer and through the impulse valve and tongue mounting holes. Hold the tongue in the 'full-open' position, add another washer onto the bolt and screw on a nut until it just touches the tongue. Add a second nut and tighten the two nuts securely together.

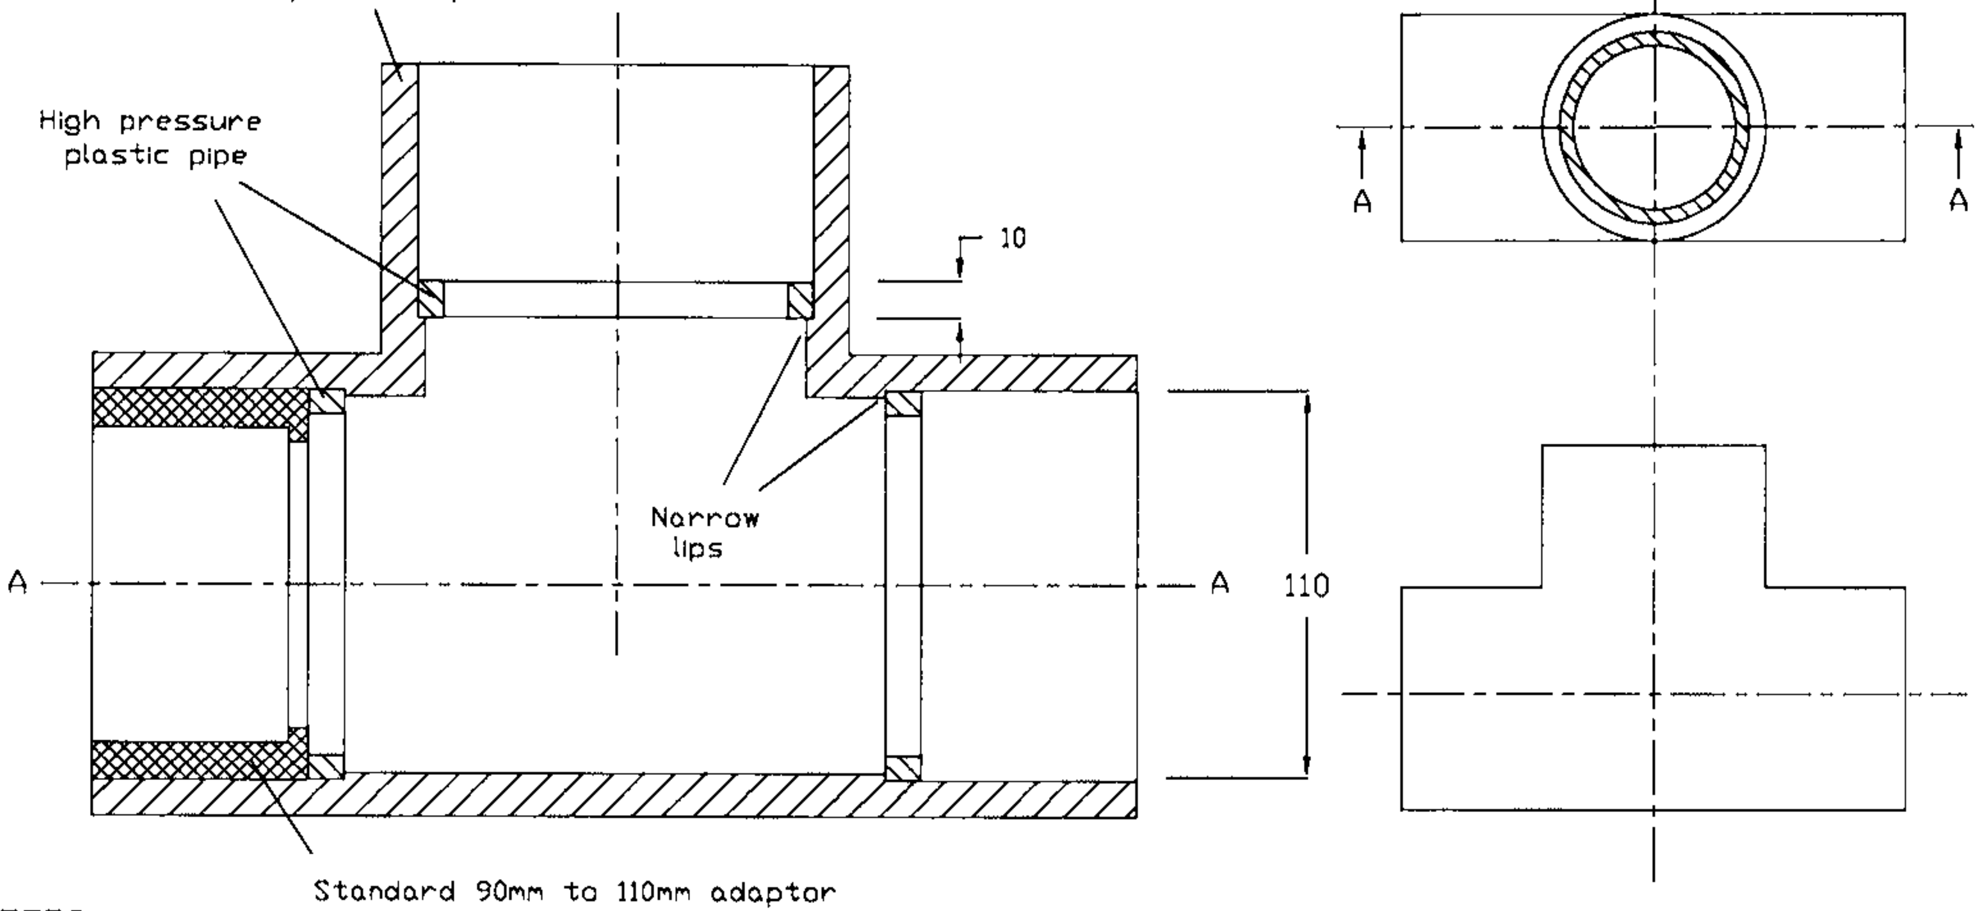
STANDARD T-PIECE



NOTES:

1 - The T-piece for the P90 may be bought commercially or made by hand. The drawing above shows an example of a commercial T-piece (high pressure plastic) that is suitable for 110mm diameter pipe.

2 - T-pieces available on the market tend to have narrow support lips as shown above. These need to be reinforced and this is done by gluing into place a 10mm length of high pressure plastic pipe as shown.

3 - When purchasing a 110mm high pressure plastic T-piece, also buy a 90mm to 110mm adaptor. This is because the drive pipe for the pump has a 90mm diameter and will have to be adapted to fit the T-piece.

ALL DIMENSIONS IN mm

DEVELOPMENT TECHNOLOGY UNIT University of Warwick, Coventry, UK
P90 - USING A STANDARD T-PIECE & ADAPTOR
Drawing No. 8 of 12 NOT TO SCALE

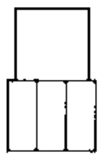
MAKING A T-PIECE

PART A

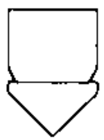
Cut 150 & 400mm lengths of pipe. Cut the shorter pipe down its length and heat it until workable. Open the heated shorter pipe and fit it over the center of the longer section using glue and clamp it in place.

Using the T-piece former, form sockets at each end of PART A. Next, cut out a 90 degree 'V-Notch as shown. Make sure the gap on the shorter outter pipe is opposite the @V-Notch'.

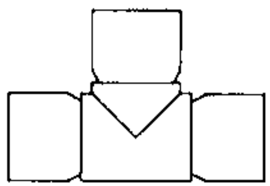
PART B



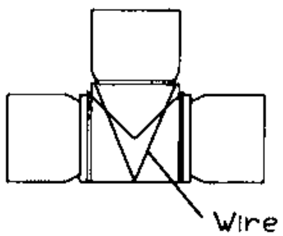
Cut 75 & 200mm lengths of pipe. Cut, heat & glue the shorter pipe flush with one end of the longer. Cut a piece of pipe to fit the gap left on the outer pipe. Heat & glue this into place.



Form the socket on the end of PART B and cut the other end to fit the 'V-Notch' on PART A.



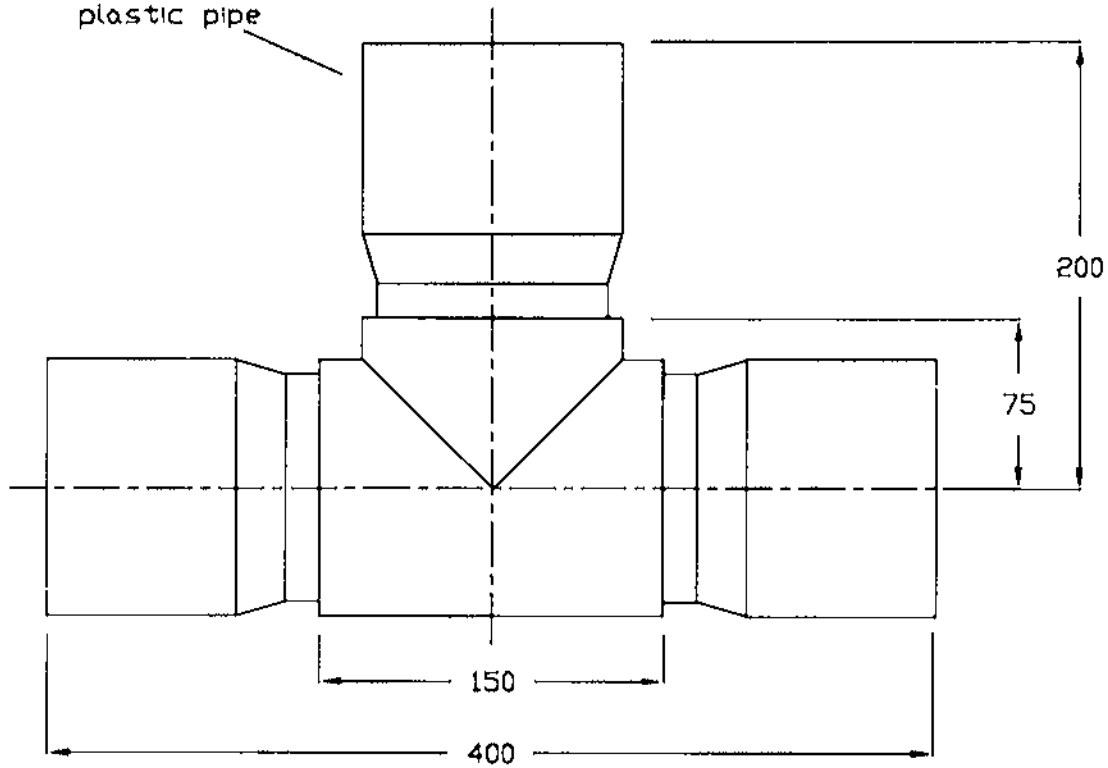
File both PARTS A & B until a reasonable fit is obtained. Glue together both parts using a mixture of PVC glue and pipe shavings to fill the gaps.



Wire may be wrapped around the glued parts to hold them more securely together. The T-piece is now ready to be set into a concrete base.

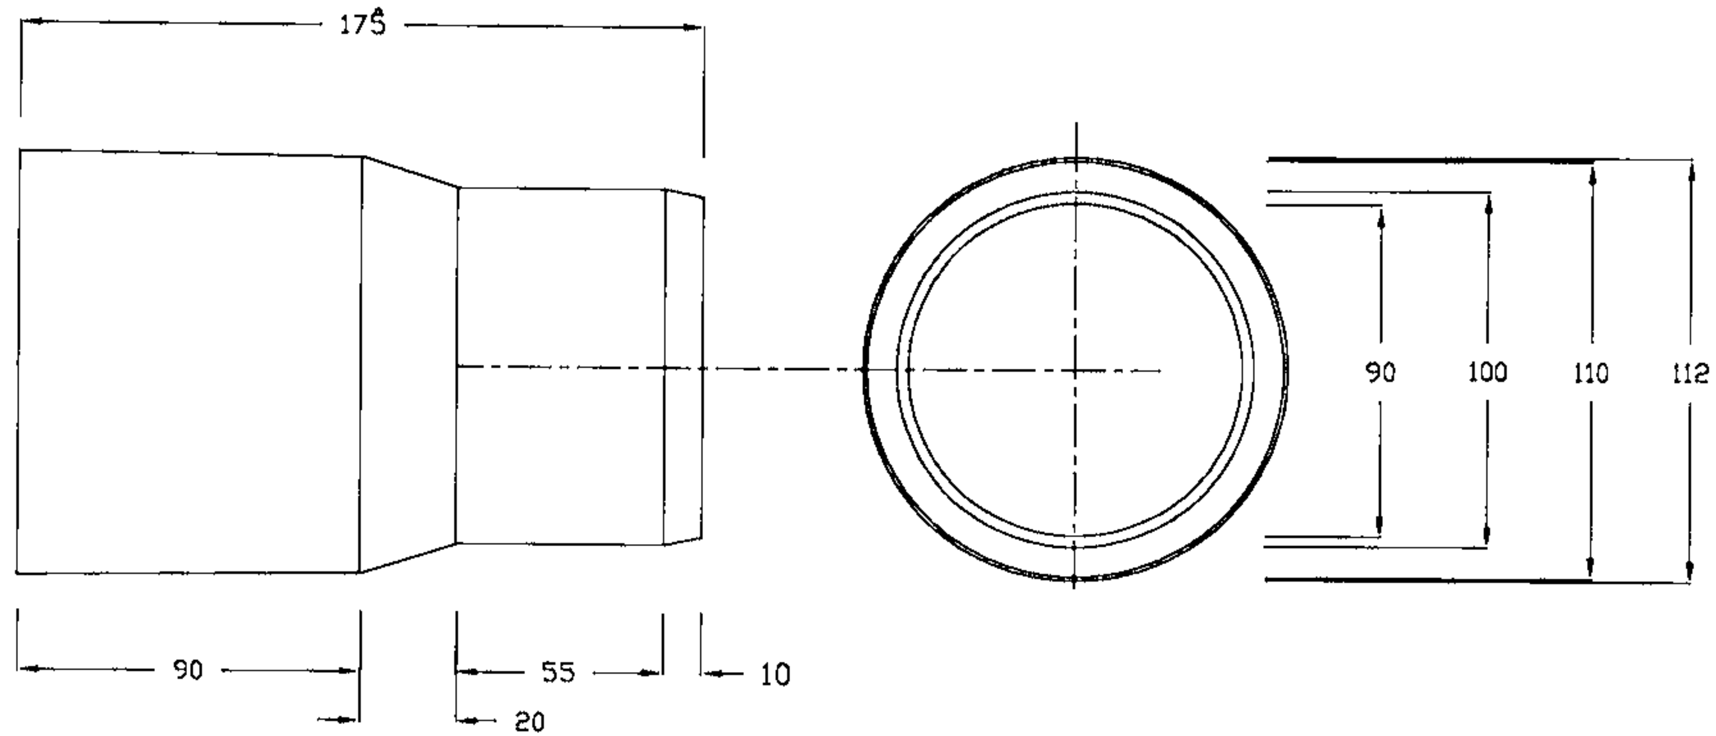
ALL DIMENSIONS IN mm

COMPLETED T-PIECE



NOTE: The drive pipe for the P90 has a diameter of 90mm. Therefore, to fit the drive pipe into this T-piece, a 100mm to 90mm adaptor should be purchased or made up using available pipe.

DEVELOPMENT TECHNOLOGY UNIT University of Warwick, Coventry, UK
P90 T-PIECE MANUFACTURE
Drawing No. 9 of 12 NOT TO SCALE



NOTES:

1 - This socket former is designed to be used with 110mm outside diameter plastic pipe.
2 - This former may be made from steel, aluminium or wood.
3 - The former is used to to make both the pump T-piece and End cap.

INSTRUCTIONS FOR USE

1 - The first step is to heat up the plastic pipe to make it soft and workable. This may be done by immersing the pipe in hot oil at about 130 C or by rotating the pipe slowly over a heat source.
2 - When the pipe is soft enough push it quickly and firmly over the former.
3 - Let the pipe cool and harden before removing it from the former.

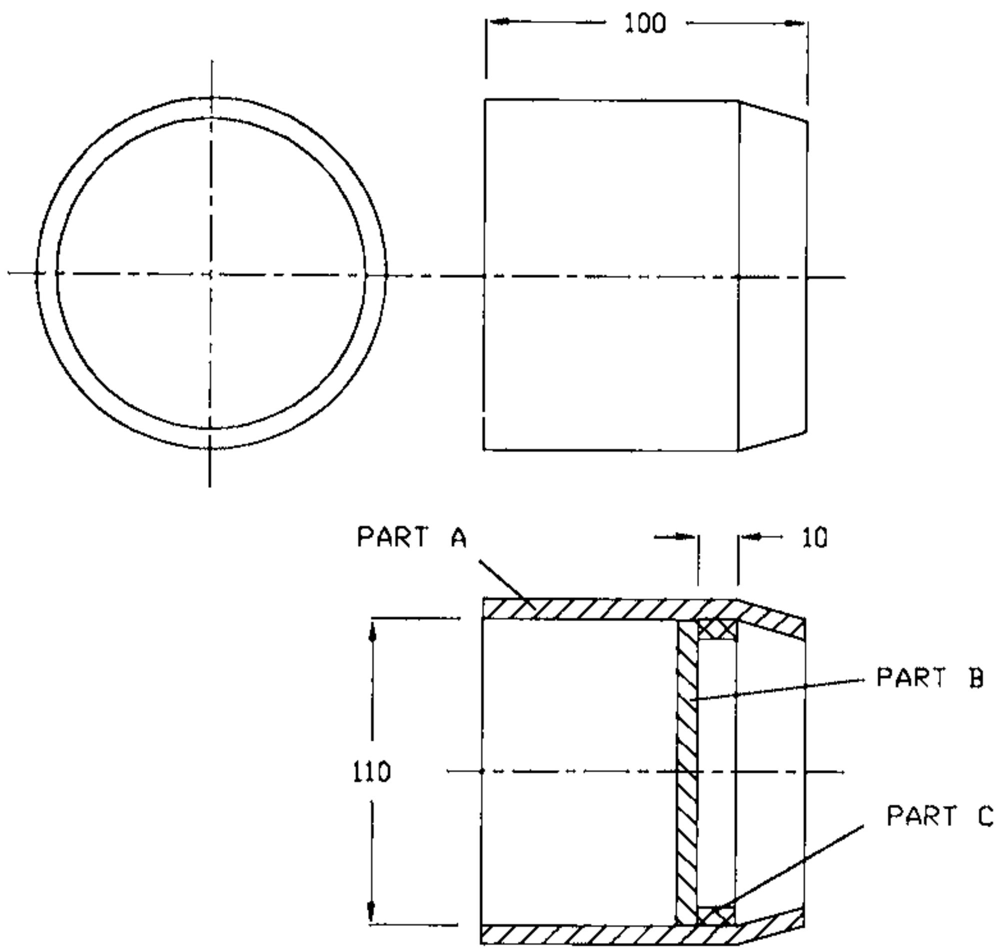
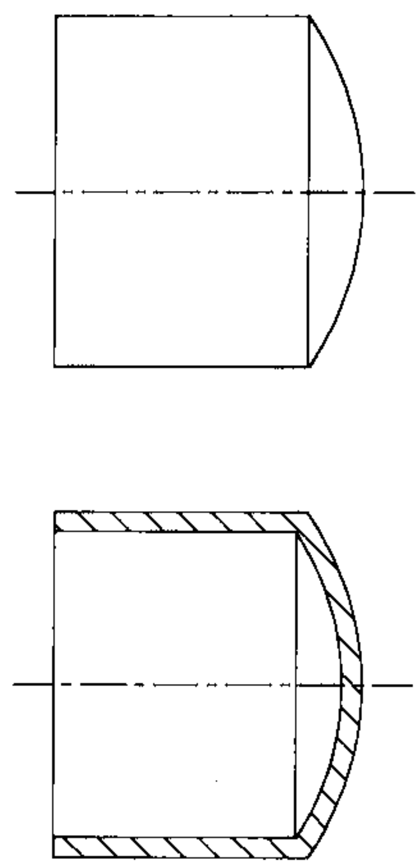
P90 SOCKET FORMER Drawing No. 10 of 12 NOT TO SCALE

MAKING AN END CAP



STANDARD END CAP



NOTE: The End cap may be purchased commercially or made as shown.

MANUFACTURE INSTRUCTIONS

1 - Cut a 100mm length of high pressure plastic pipe and heat it as per the socket former instructions.
2 - Push the softened pipe quickly and firmly over the socket former to shape PART A.
3 - PART B, the end cap plug, and PART C, the reinforcing strip are made by the same methods used to make the Air vessel.
4 - When PART A has cooled, use a good plastic adhesive to glue in the reinforcing strip followed by the end cap disc. When dry the end is ready for use.

ALL DIMENSIONS IN mm

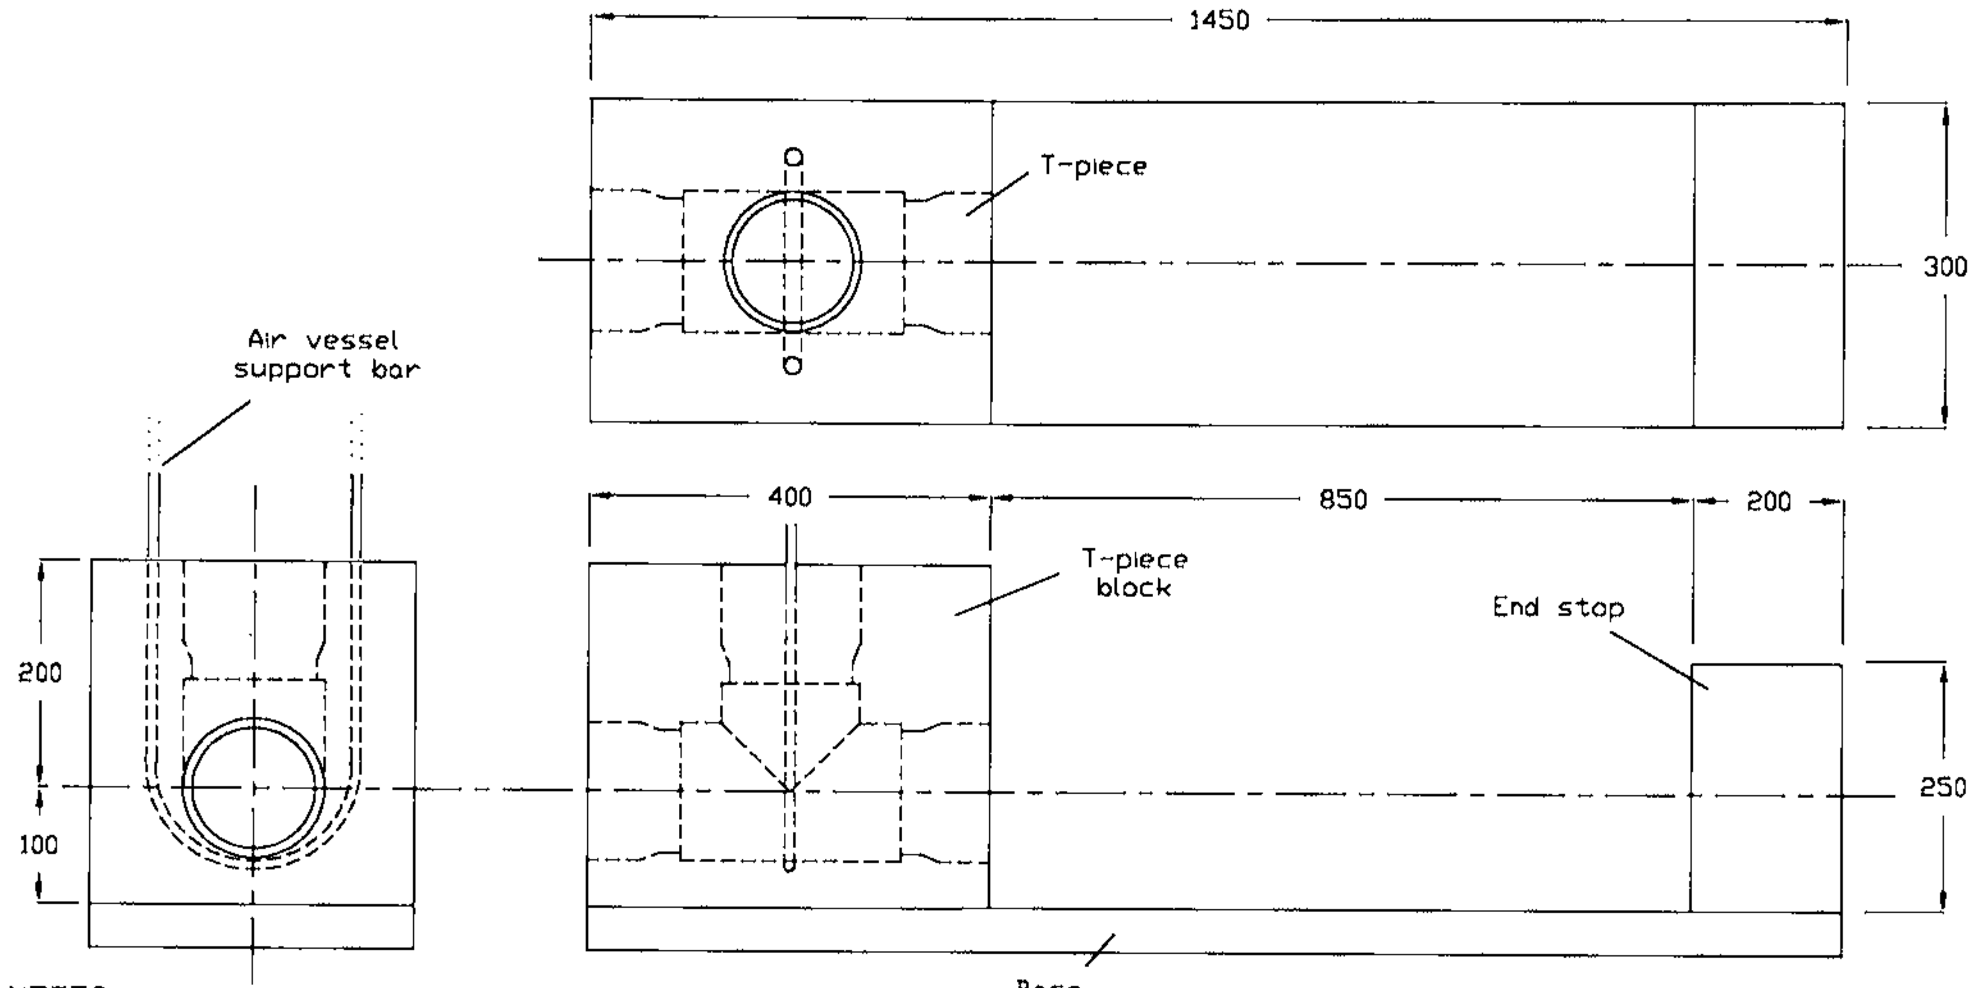
P90 IMPULSE VALVE END CAP
Drawing No. 11 of 12 NOT TO SCALE



NOTES:

1 - The height and length of the T-piece block will be shorter when a standard T-piece is used. If a standard T-piece is used make sure the bottom of the T-piece is about 50mm above the top of the base.

2 - The depth of the base should be at least 75mm. The depth may be greater if a more solid foundation is needed.

3 - Use steel reinforcing in the base, T-piece block and end stop to join the three sections together and to reinforce each section. A local builder will know how to do this.

Hydraulic Ram Pump
Research Programme

NEW DEVELOPMENTS IN HYDRAULIC RAM PUMPING

Technical Release 13

1996

Development Technology Unit
School of Engineering, University of Warwick

This technical release has been written more for ram pump enthusiasts, researchers and manufacturers than for installers and users. It describes the main current trends in system and pump design.

1 GENERAL TRENDS

The ram pump is a 'mature' technology. Over the last two centuries pump designs have stabilised and many variations to the basic configuration (of drive pipe, pump, pump house and delivery pipe) have been tried. One might think that no further significant change was likely in the ram pump itself or in the system in which it is used. However there are changes occurring in both pumping needs and in materials.

Before the invention of petrol engines or the arrival of electricity on farms, the ram pump was in many locations the only feasible way of lifting water from streams or springs to neighbouring hillsides. In consequence a high cost was tolerated; strong but expensive pumps made from cast steel, gunmetal and brass were used. Today there are more alternatives, so that ram pumping can only hold its 'market share' in water supply for humans and for cattle by becoming cheaper and simpler.

All over the world water is getting scarcer and dirtier. In consequence ideal sites for rarn pumping - where a large flow of clean water drops steeply - are becoming fewer. Quite often the water requires cleaning if it is to be used for domestic purposes. There are various possible responses to this problem of polluted drive flow. One is to filter the delivery flow. A second is to use an indirect ram pump that permits falling dirty water to power the raising of clean water from a nearby source. A third is to concentrate on applications like cattle watering and irrigation where water quality is less important.

Filtering and disinfection are well understood, and the technical options for applying them are increasing in number. The availability of only one or two watts of electricity, say from a small photo-voltaic panel, now enables chemical or ultra-violet sterilisation to be performed at a household or village scale. Adding such processes to a ram pumping system may require other design adjustments, for example those to permit delivery flow only in day light hours.

Indirect pumping is a technique known for a hundred years or more. Indirect pumps are still manufactured but they are complex and hence costly. They have more wearing parts than normal ram pumps and they require a source of clean water close to the dirtier flow that drives them. One might argue that to require such elaboration in system installation and maintenance is to head in the wrong direction. Field experience suggests that the use of ram pump technology is already severely limited by people thinking it is 'too complicated'.

It is the authors' experience, mostly in an African context, that even after a 3 weeks' training course many water technicians do not have the confidence to survey, design and install a ram pump system. The design rules seem complex and they fear making any mistake that might cause a system to fail. Yet systems do occasionally fail - through wear and corrosion, insufficient drive flow or flood damage, siltation or blockage, theft or malicious damage. It is not possible to build a perfect system.

With petrol-engine pumping at its simplest, the user carries the pump to site, drops a suction hose into the water source, rolls out the delivery hose and starts the pump. With electric powered pumping using mains, photo-voltaics or transported batteries, the procedure is a little more complex. Ram pumping is more complex again. There has therefore been a growing interest in simplifying the technology, especially in order to serve irrigation operated by peasant farmers.

2 SIMPLER PUMPS

A pump normally comprises an adjustable impulse valve, a (non-return) delivery valve, a pressure vessel to smooth out the pulsating delivery flow and an anchorage or cradle. Where 'free' air is the buffering medium in the pressure vessel (which must be vertical to work properly), a third ('snifter') valve is needed to replenish this air.

Simplifications can take a number of forms, but the main ones of current interest are

- removing the mechanism to adjust the drive flow,
- replacing 'free' air by 'contained' air,
- simplifying the anchorage of the pump and its attachment to drive pipe and delivery.

Removing the tuning mechanism of course removes all the benefits of tuning, namely the ability to adjust the pump to match the drive flow locally available. Under some circumstances, especially when only a small fraction of stream flow is needed, there is no great merit in being able to tune. Where a manufacturer produces a range of pumps it is normal for each step up in size to correspond to a two or three fold increase in maximum drive flow. An untuned pump is effectively permanently set to its maximum (or 'rated') drive flow. Thus using such pumps singly will restrict the drive flow, and hence delivery, to one of a few widely spaced values. If however several (say three) identical pumps, or two pumps of different size, are used in parallel, it is usually possible to get within 25% of any ideal drive flow. In fact there are four distinct alternatives to on-site tuning for matching pumps to available flow, two of them applicable when the system is installed and two when it is in use.

During *installation* the drive flow capacity of a system can be roughly selected by choosing the right number and size of pumps to be run in parallel. Alternatively pump(s) can be used that are 'preset' to a particular drive flow. This lower level of adjustability not only simplifies pump design (e.g. it can be provided by having two or three different weights of impulse valve), but removes the possibility that the user completely mistunes his pump. Such mistuning through operator ignorance is quite common in high technology systems as well as in the simple ram pump ones we are discussing here.

During *operation*, there may be a need to respond to a fall in available stream flow. If pumps are not tunable this can only be done by reducing the number of pumps in operation or by running them all intermittently. Using the 'three same size pumps' or 'two different size pumps' arrangement recommended above, it is possible to follow any changes in stream flow by changing the number of pumps in use. Intermittent operation by contrast can be used with only a single pump but requires much more operator activity and also a reservoir capable of storing at least 2 hours drive flow. In practice intermittent operation, where the user turns on the pump when the reservoir is full and off when it is empty, is very rare. It could become more common where small-farm irrigation is the pumping application. Technically it should also be possible to use a self-priming siphon to achieve intermittent operation without human intervention: the authors know of no example of this being done.

Given the desirability of having more than one pump running in parallel for reliability reasons, the relative rarity of requiring very close matching of system drive flow to stream flow (often extremely variable) and the likelihood of mistuning by inexperienced operators - we may expect to see more simple pumps that are untunable or are tuned ('preset') only during manufacture.

Using "contained " air to buffer the pulsations in delivery flow has real advantages over using a conventional air vessel. By "contained" air or "air packet" we mean air in a bladder or closed-cell foam. Normal commercial pressure-surge limiters in water pipelines use diaphragms to separate the air from the water, however such diaphragms are difficult to make and to seal and are therefore expensive. By contrast closed-cell foam such as bubble-wrap has already been used in a number of small ram pumps. The advantages of substituting air packets for the free air of a conventional pressure vessel are several. The containing chamber need no longer be vertical, air cannot be lost through tiny holes in welds or fittings, the snifter valve is no longer necessary, the pump can be operated under water. Disadvantages are the possible fatigue failure of the air-containment materials, slow loss of air through the walls of bladders or foam and the significant reduction in air volume at start up.

Consider a conventional air vessel of volume 10 litres in a pump delivering to 90 meters. Initially, before start-up, the air is at atmospheric pressure (1 bar). At start-up the absolute pressure rises rapidly to 10 bar (9 bar 'gauge') as the air is warmed and compressed. It then cools until its volume is about 1 1itre, namely one tenth of its initial value: the air vessel is now nearly full of water. Over a period of hours however the air is replenished via the snifter valve to its original volume of 10 litres. The pump may run rather noisily until this has taken place.

If however a closed air packet replaces the conventional free air, there is no replenishment mechanism, so throughout the run time it remains at 1 litre. It therefore is necessary to provide an air packet whose initial volume is equal to:

V_{init} = air volume required in operation (V_{op}) $\times$ delivery pressure in bars absolute.

(Note that 10 meters delivery head corresponds to 2 bars absolute, 20 meters to 3 bars etc.)

Recent research and experimentation suggest that the air volume in operation (V_{op}) can safely be as little as twice the volume of water delivered per cycle. [The pump efficiency does not fall significantly compared with when V_{op} is large, and the overpressure of about 30% is usually also tolerable from a fatigue point of view.] An irrigation pump may only lift to 20 meters, so initial air volume V_{init}, is only 3 times V_{op}, whereas a domestic supply pump may lift to 80 meters (V_{init} = 9 times V_{op}) or higher. We would therefore expect this air compression problem to be more severe with high-lift pumps. However as the delivery head is increased (while the drive head and drive flow are kept constant) the volume delivered per cycle goes down. The combination of these effects means that for a given size of pump, the appropriate initial air packet size does not vary much with delivery head. In practical terms, the minimum initial packet size relates to pump size roughly as shown in Table 1:

This table indicates an initial air packet volume, and therefore vessel size, equivalent to 1 m of drive pipe (or less length of a larger diameter) should be sufficient: this is a tolerable size.

With an air packet, pump design can be simplified to essentially an impulse valve followed by a packet-enclosing horizontal tube entered via the non-return delivery valve. This results in a fairly compact design of pump that can be placed under water to maximise drive head and to reduce noise. Although there are some particular problems that can arise when operating under water – for example sucking debris in through the impulse valve, increased vulnerability of flood damages and difficulty of access for tuning – in many situations the advantages outweigh the disadvantages.

As materials further improve we may expect more ram pumps to incorporate air packets or even a diaphragm instead of traditional air vessels.

Simplifying the pump attachment is a particular requirement for irrigation use where ram pumps and even drive pipes may be removed at night and will certainly need to be removed at the end of the dry season. The shock forces on pumps when they are in use are large, so any anchorage has to be sturdy. Already it is usual to bolt pumps onto a permanent (i.e. concreted-in) cradle. There is now interest in providing clip-on arrangements both between pump and cradle and between pump and drive pipe, rather than using nuts, bolts or wedges.

3 NEW MATERIALS, LOWER COSTS AND HIGHER PERFORMANCE

Materials For long-life pumps, traditional construction materials are largely suitable. By contrast, new materials have particularly found their place in cheap ram pumps of modest but adequate performance. During the last twenty years metal piping has largely been superseded by plastic, especially PVC, ABS and HDPE. It is therefore

Table 1

Drive pipe size (ID)	mm	25	50	75	100
Assumed driveflow	litres/min	25	100	250	500
Packet size (for *drive* head of 2 meters)	litres	0.15	0.60	1.50	3
of 6 meters)	litres	0.45	1.80	4.50	9
Volume of I meter of drive pipe for comparison	*litres*	*0.5*	*2.0*	*4.4*	*8*

tempting to use these rust-proof and easily worked materials for constructing ram pump bodies. Unfortunately the poor stiffness, fatigue strength and sunlight resistance of plastics poses problems.

The water-hammer effect that underlies ram pump operation is dissipated in very elastic, or worse energy absorbing, materials. For this reason we try to avoid accumulation of air in drive pipes and we look for a high level of wall stiffness in them. The maximum height a ram pump can deliver to is approximately $h_{max}=\nu\ C_{dp}/g$. Where ν is the maximum water velocity in the drive pipe and C_{dp} is the velocity of sound in that water. It can be shown that for an infinitely stiff pipe, C_{dp}/g is about 140 meters height per meter/second, in a steel pipe it is typically 120 but in a plastic pipe it is only about 30.

[The formula normally used is:

$$C_{dp} = C\sqrt{\frac{1}{1+\frac{DG}{tE}}}$$

Where C is the velocity of sound in water, D and t the diameter and thickness of the plastic pipe, G the stiffness of water and E the stiffness of the plastic.]

This effect shows itself in a plastic system being only able to deliver to about 30% the height of an all-steel system. For really high head deliveries steel drive pipe is essential. For delivery height under 50 meters, plastic drive pipe is adequate

All materials show 'fatigue' in that a loading that they can tolerate easily if it is applied only a few times may cause failure if applied millions of times. In a ram pumping system, the pump and drive pipe experience between 15 million and 100 million pressure pulses per year, so fatigue failure is a real danger. For plastic drive pipes it is usually sufficient to select a pipe pressure rating of 3 times the delivery pressure. For plastic pumps, fatigue failure is so likely that either they are metal reinforced or they are restricted to use with very low delivery heads. Apparently no one is making pumps out of glass reinforced plastics (GRP) despite this material having suitable stiffness and fatigue performance.

Injection moulded plastics are used in centrifugal pumps and hand pumps. They could be used for ram pumps too, but the small production runs do not at present justify the high tooling costs. A few experimental pump bodies have even been made of concrete whose inertia may act as a substitute for strength in the face of sudden forces. The material is cheap, though heavy, but the problems of getting really high densities and of sealing the joints between concrete sections have apparently defeated concrete pump designers.

Certainly the use of simple plastics in small or low-lift ram pumps is now well established alongside that of metals for higher lifts. It seems unlikely that more complex materials or processes will be soon employed to make these devices.

Lower costs come from use of fewer, cheaper or 'easier' materials, from mass production and from design simplifications. Understanding of ram pumps is better than in the past and this had led to a few design changes leading to lower costs.

Mass production of complete pumps is constrained by small markets, while attempts to assemble the pumps from mass-produced fittings have not generally led to either high performance or to much lower costs. Fittings are not cheap if used in any number: pumps made from them are generally clumsy and have too many parts.

For fabricated steel pumps the now ready availability of square section tubing offers simplification of design and assembly compared with traditional round tubing. Square tubing is not efficient at containing high pressures but this is not normally a problem at all but the highest delivery heads. Fabrication is better suited to some pump-using countries than employing iron casting, machining, forging or threaded connectors. Welded joints can be opened again if necessary by cutting them out with an angle grinder

Probably the greatest need for cost cutting is in irrigation applications. If a siphon drive pipe could be developed (requiring the pump to be submerged), the installation costs of irrigation pumps could be reduced substantially. Some effort is being applied to designing essentially portable systems for use with dams as low as 500 millimeters, where the pump and its drive pipe can be quickly disconnected from anchorage and dam respectively.

High performance takes various forms, such as higher efficiency, higher delivery head, quieter operation and greater durability. It seems that little theory was used in the past when designing either pumps, or complete systems. Today ram pumps have something of a fascination for analysts so that there are several publications that aid high-performance design. For example the main sources of inefficiency are well documented and it is not hard to devise an economical system with an overall efficiency as high as 70%.

In Nepal, the Andes, Rwanda and elsewhere there is some need for pumps that lift as high as 200 meters, well beyond the limit of normal machines. The procedures and materials for achieving very high heads are known, but so far the market for such pumps has been too small to cover the costs of fully developing them. DCS, Butwal in the Himalayas have reached 180 meters lift with some reliability.

Quiet operation has been traditionally achieved by placing pumps and drive pipes underground. For years some pumps (for example the Blake's machines) have used rubber impulse valves in otherwise metal systems to reduce noise. The move towards plastic drive pipes may lower efficiency a little, but it beneficially converts high-frequency 'clanging' into less intrusive low-frequency 'thumping'.

Only in the area of durability can one find no significant improvement. Perhaps the lifespan of cheap pumps has increased a little from its former low level, but it is still far below that achievable with traditional 'over-designed' machines.

DTU

Ram Pump Programme

DTU S2 PUMP

TECHNICAL
14
RELEASE

DTU TECHNICAL RELEASE NO.14 : THE DTU S2 PUMP

INTRODUCTION

This Technical Note is in four parts.

The first part (1 page) is a 'Stop Press' UPDATE containing amendments (dated November 1998) to the original which was written in 1995.

The second part (4 pages) is a summary of the pump's design and performance, suitable for copying, laminating and posting in the pump house.

The third part (20 pages numbered 1-20) is a detailed description of how to use the drawings to make an S2 pump. It should be read in conjunction with the amendments mentioned above.

The fourth part is a set of 16 drawings, of which Nos. 11a, 13, 14 and 14a have been added as amendments and offer alternatives to earlier drawings.

The 'Status' of this pump is that several dozen have been made, mostly in Africa, but that none has been run continuously for years on end. The pump is not a 'very-long-life' design although, in normal applications and incorporating the amendments in the UPDATE, continuous use should require only occasional replacement of worn parts. The Drawings deliberately do not precisely define the materials to be used, because the design is supposed to be somewhat adaptable to what is available. If all the metal parts are of mild steel, corrosion will cause some problems - especially affecting nuts and bolts and the impulse valve stem. If possible these parts should be made of stainless steel.

It is not the intention of the Development Technology Unit to undertake further development of this pump. However the Unit's Director would be happy to receive any comments from the field about its performance or any suggestions for further 'UPDATES'.

TR14 UPDATE - November 1998

Since this Technical Release was written in 1995, based mainly on field experience in Zimbabwe and Zaire, the DTU has obtained further experience with this S2 model of ram pump. The following modifications derive in particular from observations during extended testing in Staffordshire, England during Summer 1998. The modifications are expressed as variants on the production procedure of the (original) pages that follow. Extra drawings have been added (Dwgs. 11A, 13, 14 and 14A).

1) [*Problem of steel washer cutting into delivery valve rubber disc*]
   Refer to page 14 - Making the S2 pump delivery valve.

Fit a rubber washer, made from the same material as the valve disc and of the same diameter as the steel washer, between the steel washer and delivery valve disc.

2) [*Wear and tilting wobble of impulse valve stem*]

Refer to page 12 - Making the S2 pump impulse valve - and to old Drgs Nos.9, 11a & 12 and new Drawing No.11a.

Fit a second (upper) stage to the impulse valve guide. This requires that a longer valve stem and longer guide bolts are made/used than those shown in drawing number 12. The plain section of the valve stem is 50 mm longer (i.e. 100 mm overall length), the bolt shank is 50 mm longer (i.e. 130 mm long).

If a *new* two stage guide is to be used then the assembly should be welded together *before* the holes are drilled. However if the second stage of the guide is fitted *as an addition to/modification of* an existing impulse valve, then (to ensure correct location and operation of the valve itself) any welding should only be undertaken *after* the impulse valve is fully assembled and bolted to the pump body, as detailed on pages 17 to 18.

3) [*Problem of delivery valve gasket blowing out midway between the clamping bolts*]

Refer to old Drawing No.3 & new Drawing No.13

New gasket size, internal diameter = 95 mm, outside diameter = 165 mm. Using the internal diameter of the gasket shown in Dwg.13, which is a little smaller than that of the flange in Drg. 3, ensures that it protrudes slightly inside the flange. This wider gasket is primarily required between the air vessel and delivery valve plate, but can also be used between delivery plate and pump body and in the impulse valve.

4) [*Problem of rusting bolts*]

Thoroughly grease all bolts prior to assembly and use nuts or washer/nut combinations that extend to the end of the bolt threads, leaving almost no thread exposed. Of course if stainless steel bolts and nuts are available and affordable, they should be used in preference to plain steel.

5) [*Problems in aligning pump with drive pipe*]

If possible, the drive pipe, pump and cradle should be assembled in situ within the shuttering for the concrete base *prior* to any concrete being poured

6) [*Problems with marking out delivery valve plate for drilling*]

Refer to old Dwg. Nos. 5, 6 & 7 and new Drgs. Nos. 14 & 14a.

An alternative layout of holes in the delivery valve plate is to have them in parallel staggered rows as shown in Drawing number 14. The delivery valve rubber disc now flexes as a butterfly's wings and has to be retained by a bar or rod held in position by two bolts (rather than the original single central bolt) - see Drawing 14A. Slightly inferior pump output may be experienced (due to more back-leakage before the delivery valve recloses) but this layout is easier to mark out and make, so there is less chance of having too thin a wall between adjacent holes. As before, care should be taken to not so tighten the bar-retaining bolts that the valve rubber disc no longer lies flat on the valve plate. The nuts on these bolts should if possible be self-locking or held on with a locking compound such as 'Locktight'. The alternative of using a second locknut on each bolt is not so good.

7) [*Problems with silting up of intake pool*]

Ram pumps driven by water drawn from immediately below springs, or from large reservoirs, have little problem with silting. Pumps drawing water from behind small dams (e.g. 400mm high) on streams may experience major silt problems, with the 'pool' silting up by as much as 300mm after a single storm. Drawing all drive water through silt will almost certainly overload the silt-settling capacity of the drive tank. There is no easy way of automatically keeping such a pool silt-free and such locations are therefore not suitable for ram pumps unless someone is on site to apply frequent manual desilting procedures to both pool and drive tank.

DTU S2

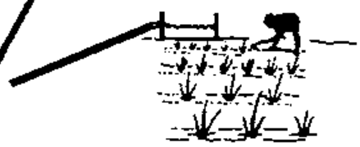
hydraulic ram pump

The name "S2" stands for a Steel pump with a drive pipe up to 2" in diameter.
The S2 replaces the DTU M8 pump

The DTU S2 hydraulic ram pump is a steel machine, using a 1.5" or 2" diameter galvanised drive pipe, that can lift water up to a height of 100 meters. It was designed for village water supply but may also be used for irrigation, and is being used successfully in many African countries. The pump has been designed to be made in small workshops with welding equipment and a pillar drill. A lathe can be useful but is not essential.

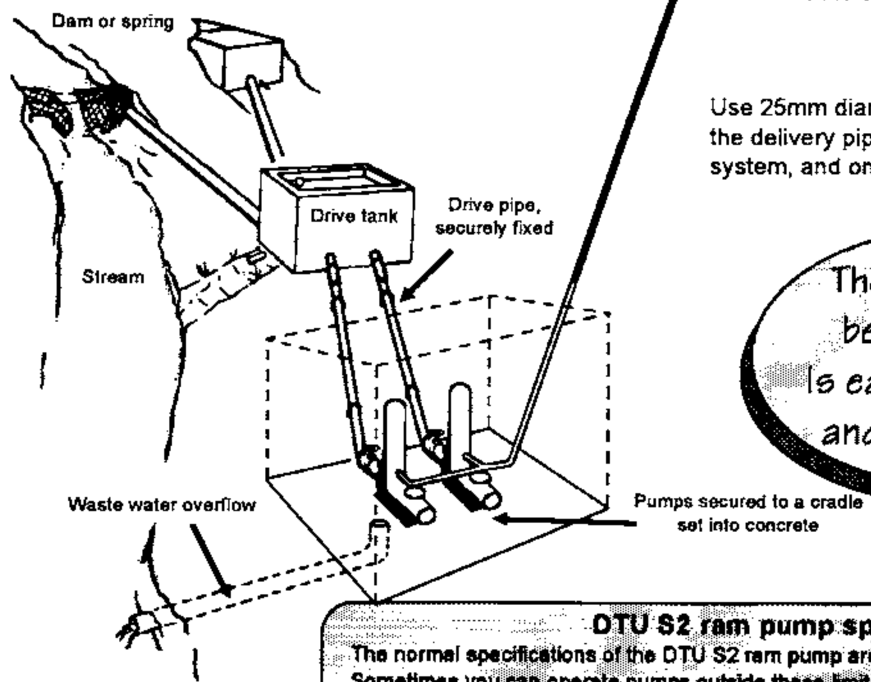
A ram pump is powered by falling water. Water from a stream or spring is diverted and dropped through a drive pipe into the pump. The power of the falling water is used to pump some of the water where it is wanted. The amount of power in the falling water limits how high you can pump, and how much water you can pump. Generally, the more water you drop and the further you let it fall, the more power there will be.

In areas where the water source flow varies greatly during the year, more than one pump can be installed, all sharing the same delivery pipe as shown in the drawing below.



Distribution system, for domestic or irrigation use. A tank is always recommended.

Delivery pipe, rising all the way along its length (no ups and downs). The pipe should be buried where possible and protected if it has to be above ground.



Use 25mm diameter plastic pressure pipe for the delivery pipe if there is one pump in the system, and one size larger if there are two.

The DTU S2 can be locally made
Is easy to maintain
and cheap to run!

DTU S2 ram pump specifications

The normal specifications of the DTU S2 ram pump are given here.
Sometimes you can operate pumps outside these limits, but they may not work well.

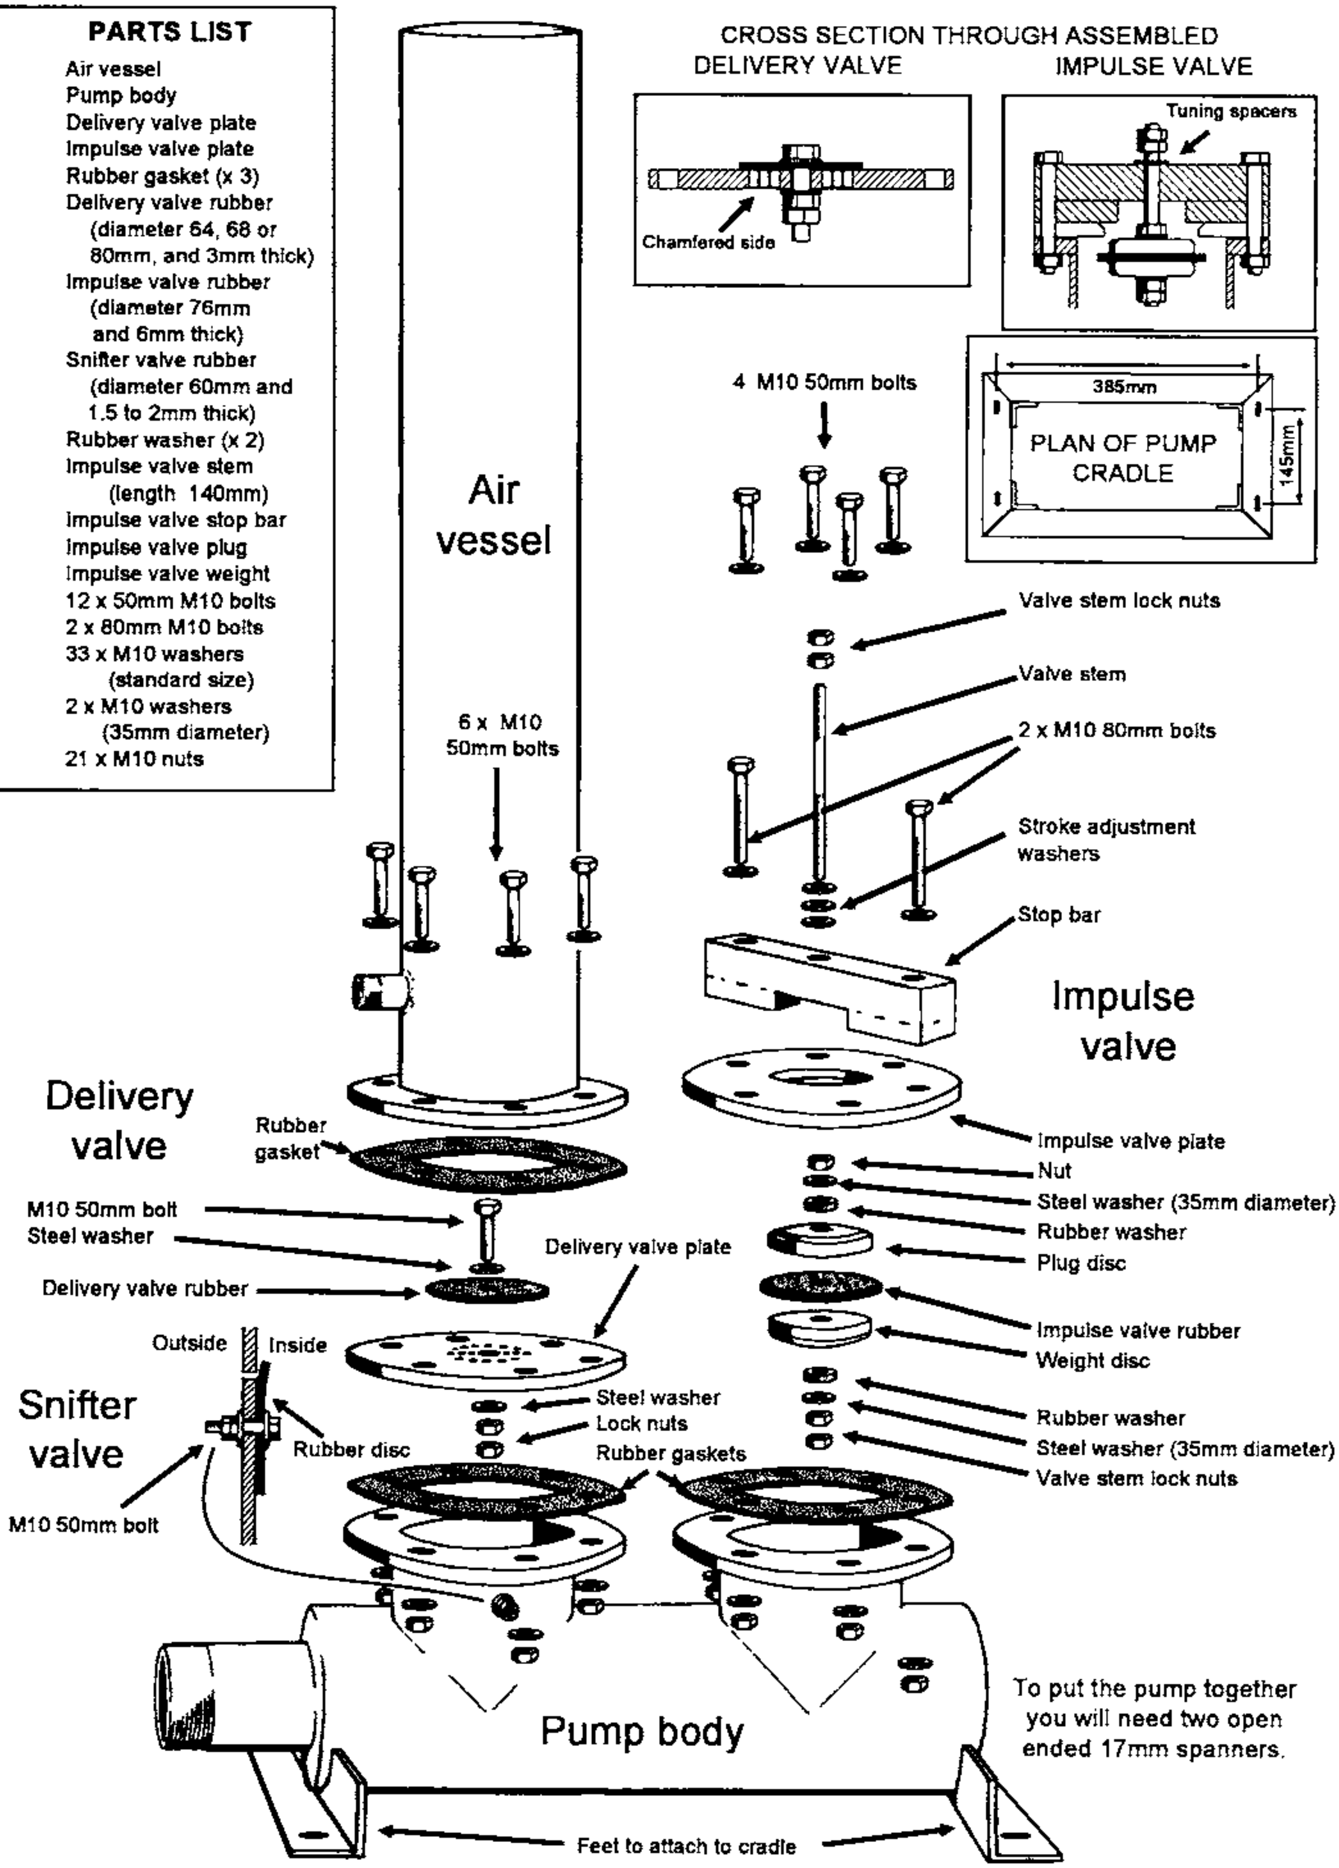
drive head range	—	2 to 15 meters
drive flow range	—	40 to 120 liters a minute
drive pipe material	—	Galvanised iron
drive pipe diameter	—	1.5" for flows from 40 to 60 liters a minute
drive pipe diameter	—	2" for flows from 60 to 120 liters a minue
delivery head range	—	up to 100 meters
typical delivery range	—	1 to 25 liters a minute
delivery pipe diameter	—	25mm

DTU S2 PUMP: USER INSTRUCTIONS

AN EXPLODED VIEW OF THE DTU S2 PUMP

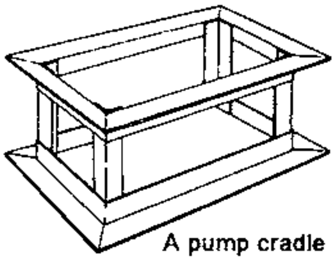
PARTS LIST

- Air vessel
- Pump body
- Delivery valve plate
- Impulse valve plate
- Rubber gasket (x 3)
- Delivery valve rubber (diameter 64, 68 or 80mm, and 3mm thick)
- Impulse valve rubber (diameter 76mm and 6mm thick)
- Snifter valve rubber (diameter 60mm and 1.5 to 2mm thick)
- Rubber washer (x 2)
- Impulse valve stem (length 140mm)
- Impulse valve stop bar
- Impulse valve plug
- Impulse valve weight
- 12 x 50mm M10 bolts
- 2 x 80mm M10 bolts
- 33 x M10 washers (standard size)
- 2 x M10 washers (35mm diameter)
- 21 x M10 nuts



To put the pump together you will need two open ended 17mm spanners.

Installation notes



A pump cradle

The DTU S2 pump should be installed in a properly designed system. To prevent vibration causing breakages, it should be firmly bolted to a steel frame (called a pump cradle) that is half buried in a concrete base. The cradle is usually made from 40 x 40mm angle iron and will vary in size depending on the number of pumps installed. Hole locations for just one pump are shown on the previous page.

All pipes in the system should be supported firmly, and buried where possible. The drive and delivery tanks should be constructed on good foundations by experienced tradesmen. Pipe joints to the drive tank should allow the pipes to move slightly without damaging the tank walls or leaking badly.

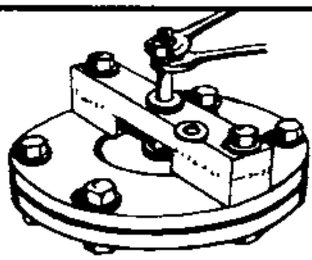
Starting and stopping the ram pump

Although ram pumps often start very easily, they can be awkward the first time they are run.
To start the pump:

1. Make sure that any valve fitted on the delivery pipe is open and then open the drive pipe valve. Water will flow out of the open impulse valve until it suddenly shuts. If it reopens automatically, the pump should continue to run on its own. If it does not, you must prime the delivery system as described in Step 2 alongside.
2. Push down on the top of the impulse valve stem with your foot to reopen it (wear strong boots). Again, water will flow out of the open impulse valve until it suddenly shuts, then push down immediately to re-open the valve. Keep helping the valve to re- open until it will do so by itself.

To stop the pump, hold the impulse valve stem up to close it or shut the valve at the bottom of the drive pipe.

Tuning for best performance



The DTU S2 can be tuned to adjust performance. This is done by changing the up and down movement of the impulse valve, which is usually set to around 15mm. Tuning is usually done to achieve either the maximum delivery flow or the most efficient use of the drive water available.

Maximum delivery

When there is plenty of drive water available, the pump can be tuned to deliver as much water as possible. To do this, remove all washers from the impulse valve stem so that the valve has as much up and down movement as possible (about 20mm).

WARNING: - this also puts the pump parts under greater stress and makes them wear more quickly.

Low drive flow

If the pump uses more water than is available it will soon stop. If this happens it must be tuned to use less. The impulse valve should be tuned down to use 90-95% of the water available from the source. To tune the pump down, add washers onto the impulse valve stem so that the valve has less up and down movement. The shorter the stroke, the smaller the amount of drive flow needed, and the less water is delivered. The minimum stroke length is around 10mm.

Routine maintenance

While the pump is running normally, a visit should be made once a week to check that bolts are tight and that there are no leaks. Once a month an inspection of the whole system should be carried out. It is also recommended that a log book is kept to record the checks and repairs that have been made.

Monthly maintenance check list (without stopping the pump):

1. Inspect all the joints to check for leaks.
2. Check if there is sufficient air in the air vessel. This can be done by listening carefully to the pump. If there is insufficient air in the air vessel, the pump will be much louder than usual. This means that the snifter valve is probably blocked and will need to be cleared. If a bleed screw is fitted, when opening it, air or a small amount of water followed by a rush of air means the air level is OK. If only water emerges, then again the snifter valve will have to be checked for blockage.
3. Clean any filters installed in the system.
4. Remove excess silt or debree from tanks or from behind the intake dam or weir if necessary.
5. Walk along all pipes looking for damage. Also, inspect the tanks for leaks, particularly at pipe joints.

Pump repair

If the pump stops or it delivers less water than usual, it may require adjustment or repair.

Look at the pump and if there is no obvious fault start it again if you can. Watch the pump and listen for irregular pumping or unusual noises. A worn impulse valve, for example, is usually obvious because water squirts through when the valve is closed. Some parts of your ram pump may need occasional replacement. the frequency of this will depend on how hard the pump is working and on the cleanliness of the drive water.

Tools you will need:

2 x 17mm ring/open end spanners to disassemble and assemble the pump

2 x Adjustable wrenches - to loosen a union joint on the delivery pipe (if fitted)

Taking the pump apart

Depending on the fault it may be necessary to disassemble the impulse valve and/or the air vessel. Before attempting to take apart the pump:

1. Make sure that the drive pipe valve is closed and the impulse valve is open. This will allow you to work on the impulse valve ONLY.
2. Depressurise the air vessel.

WARNING - Before attempting to remove the air vessel, always release the pressure in it slowly. An ideal system will have a gate valve or one-way valve and a union fitted between the air vessel and the bottom of the delivery pipe and the optional bleed screw fitted to the air vessel. With the pump stopped, close the gate valve in the delivery pipe to stop it draining back. If a one-way valve is fitted it will close automatically. Then loosen the bleed screw to release the pressure in the air vessel. If none of the above are fitted, the only other way to release the pressure in the air vessel is to loosen each of the air vessel flange bolts one turn at a time until the water and air escapes through the join at the flange. You will certainly get wet this way.

Checks

1. Check the delivery valve rubber for wear and blockage of the valve holes. Check that the lock nuts on the valve bolt are tight.
2. Check that the snifter valve is in good condition.
3. Remove the impulse valve and check the impulse valve rubber and the rubber washers for wear. Check that the nuts on the valve stem are tight and check for excessive wear of the stem. Replace parts if necessary.
4. Check the pump body is firmly bolted down, then reassemble the pump, ensuring that all bolts are greased.

Putting the pump back together

Assembly of the pump is shown in the exploded view drawing, but the following important points need to be kept in mind:

1. Assembling the delivery valve
   Put together the delivery valve plate, the rubber and the bolt. Make sure the side of the plate with the chamfered holes is on the opposite side to the rubber, and that the rubber is on top.
   Screw on the first nut until it is finger tight and then undo it by one turn. Care must be taken not to overtighten the bolt and nuts as this will affect the performance of the valve. Next, screw on the other nut and tighten it up against the first. Use the spanners to tighten them firmly together. This will lock them together, and also allow a small up-and-down movement of the bolt and rubber.
2. Assembling the snifter valve
   Put the 'shaped' bolt and washer together, feed the bolt through the valve rubber, then push this through the pump body. Make sure that the shaped curve of the bolt head and washer align with the curvature of the body.
   Screw on the first nut until it is only finger tight. If the nut is on too tight the rubber will curl away from the pump body and will need to be slackened off slightly. Then screw on the second nut and tighten the two nuts firmly together using the spanners. Then check that the rubber has not distorted. If it has, slacken the nuts half a turn and tighten the outer one again.
3. Assembling the air vessel/delivery valve/rubber gaskets
   Align the delivery valve, air vessel, pump body and rubber gasket mounting holes and feed through the bolts. Make sure the delivery valve is the correct way up (the valve rubber facing upwards) and then tighten the nuts by hand. Use the spanners to tighten each nut and bolt a little at a time, working around the flange. This will draw the assembly together evenly.
4. Assembling the impulse valve
   The first parts to assemble are the valve stem, discs and rubbers. Screw on a nut to the longer threaded end of the stem up to the end of the thread. Push a steel washer on up to the nut, then add a rubber washer. Follow this with the valve plug disc, with the chamfered side towards the nut. Slide the valve rubber up against this, then the weight disk with the chamfered side facing away from the rubber. Follow this with another rubber washer and a steel washer. Screw a nut up them until it is finger tight. Thread on another nut and use the spanners to tighten the nuts together. This part of the assembly is sometimes known as the valve plug.
   Hold the impulse valve plate and the valve plug together, with the chamfered side of the plate opposite to the side against which the valve rubber presses. Slide the stop bar onto the top of the stem and thread a nut loosely on the stem.
   Align the valve assembly, pump body and rubber gasket and feed through the flange bolts. The two longer bolts feed through the cross-bar as well.
   Thread on the six nuts by hand, then use the spanners to tighten the four shorter bolts that hold down the valve plate. Again care must be taken to ensure that these nuts are tightened evenly. The next step is to make sure the closed valve plug is centred in the valve plate hole before tightening down the two remaining nuts that secure the stop bar. To check the alignment, open and close the valve manually turning the valve plug to make sure it does not catch on the hole in the valve plate.

Now you only need to set the stroke length of the valve for the pump to be ready for use.

Spare parts to keep on the site

- impulse, delivery and snifter valve rubbers
- an impulse valve stem
- a few spare M10 nuts, bolts and washers

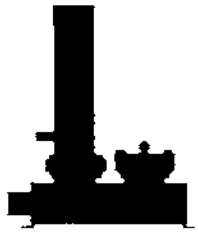
Making a DTU S2 ram pump



When you have decided to make a pump, the first thing you must do is make photocopies of the DTU S2 ram pump design drawings in Technical Release number 14b. The copies can be used in the workshop and it will not matter if they get dirty or are damaged. Some of the drawings can also be used as templates.

It will be useful to have the copies of the design drawings beside you as you work through this Technical Release. The pump's normal operating ranges are on the first drawing.

The manufacture process is presented under the following headings.

- **The parts of the pump**
  This introduces the main parts of the DTU S2 pump.

- **Tools required**
  The DTU S2 pump was designed to be made in small workshops with limited tools. This section describes the tools recommended. We have assumed that you are a workshop technician who already knows how to use the tools.

- **Guides and Templates**
  Simple guides and templates are useful, so we have included descriptions of guides and templates, and suggest ways of making them.

- **Materials needed to make a DTU S2 ram pump**
  A "shopping list" of the materials that you will need is given on page 6. This can be photocopied and taken with you when you buy materials.

- **A step by step guide to manufacture**
  The process of manufacture is described in detail under this heading. It begins with making the pump body and air vessel, and goes on to cover the valves and the pump cradle.

- **Assembly and testing**
  Putting the valves together properly is very important, so the process of assembly is described. The description includes some suggested ways of checking that they work properly.

- **Spare parts**
  This explains which spare parts to supply with a pump. It points out which parts you should expect to wear out or fail.

- **Optional addition**
  The addition of a "bleed" screw in the air vessel can make it easier to find out what is wrong with a pump when it does not perform properly. It can also make the pump easier to maintain. The "bleed" screw is described under this heading.

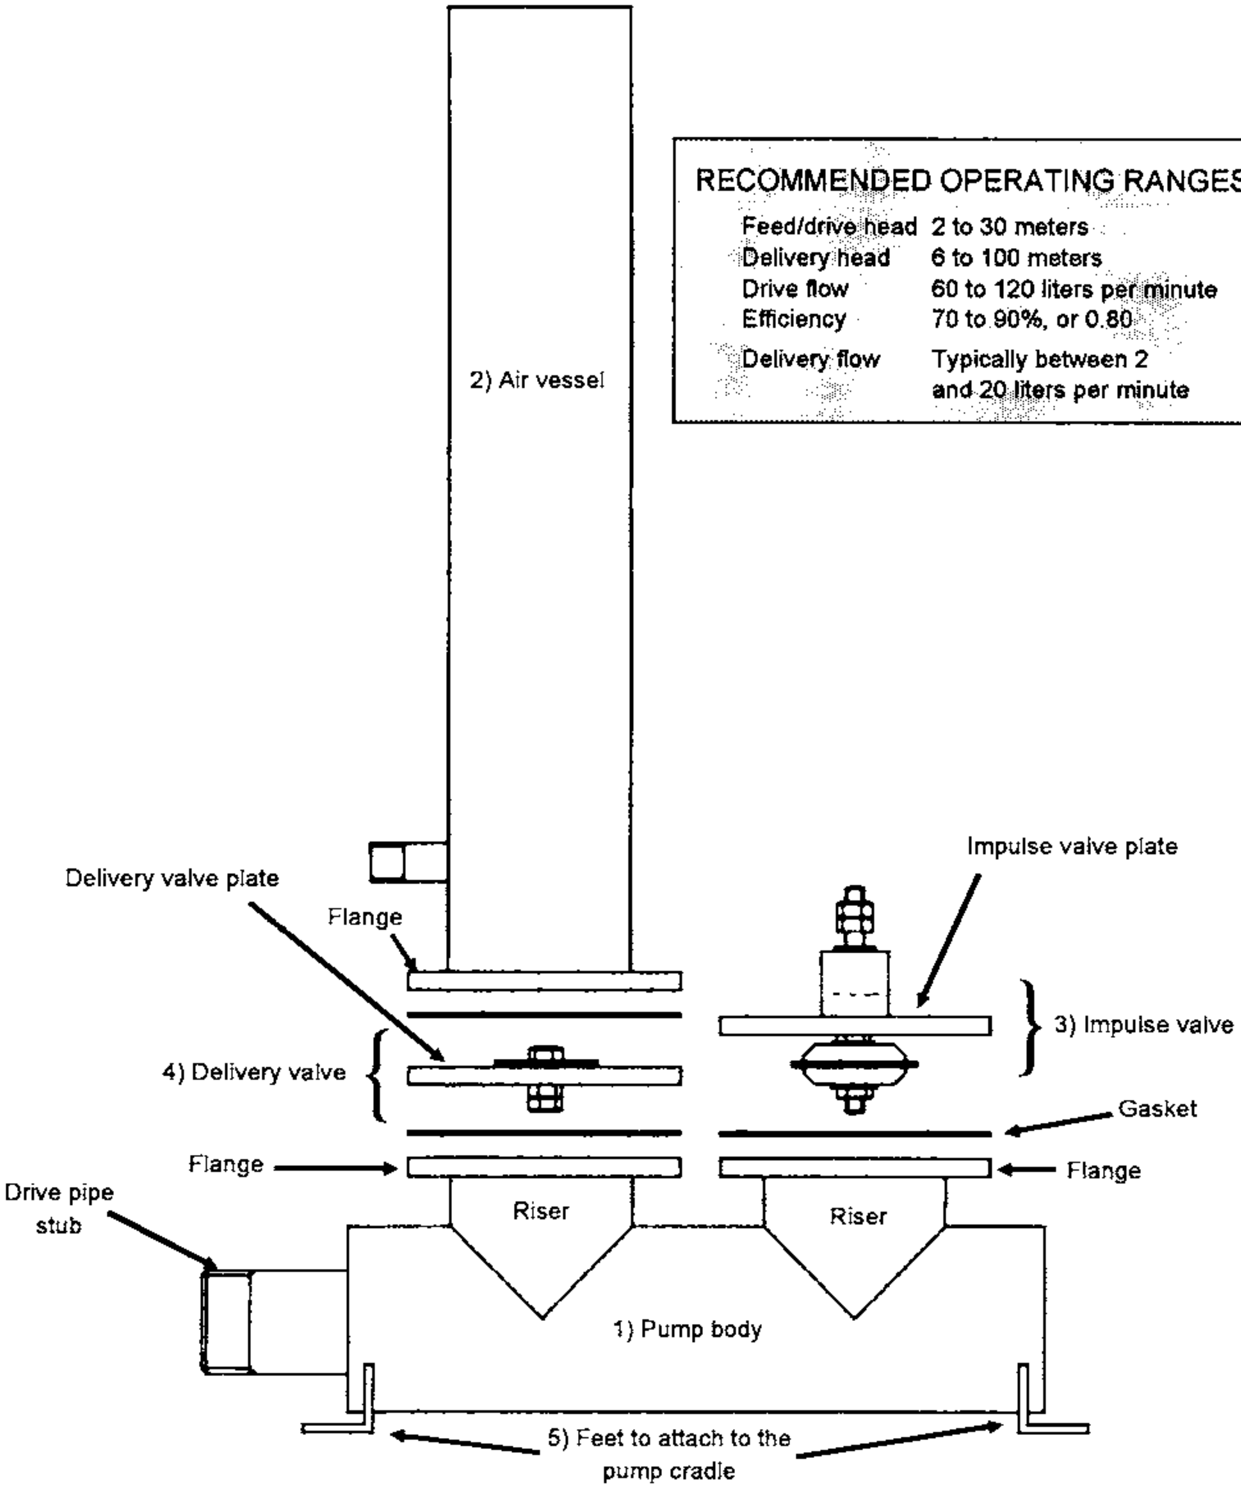
The parts of the pump

The picture here shows the main parts of a DTU S2 ram pump. There are five, apart from the risers and flanges. The pump's recommended operating ranges are given in the box.

1 The pump body
2 The air vessel
3 The impulse valve
4 The delivery valve
5 Feet to attach the pump to the cradle.

RECOMMENDED OPERATING RANGES:

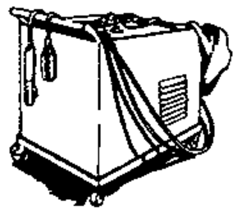
Feed/drive head	2 to 30 meters
Delivery head	6 to 100 meters
Drive flow	60 to 120 liters per minute
Efficiency	70 to 90%, or 0.80
Delivery flow	Typically between 2 and 20 liters per minute



Tools required

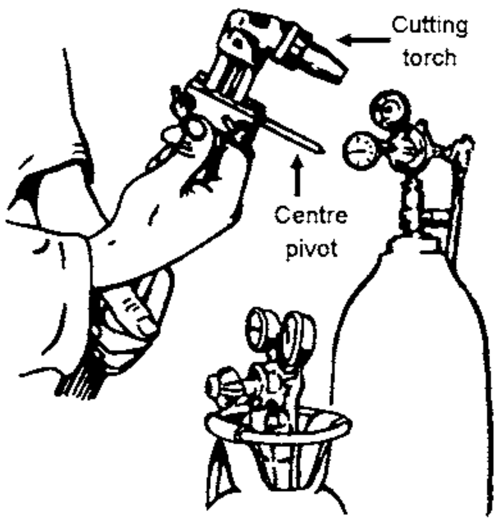
DTU S2 ram pumps can be made in a workshop with welding facilities, a drill, a hacksaw and files. It is hard work making them with as few tools as this. It is also hard to make the pumps to a high enough standard. Cutting and filing the parts by hand will take a very long time and it may not be possible to make the parts accurately. Do not plan to make more than one pump unless you have access to some other power tools.

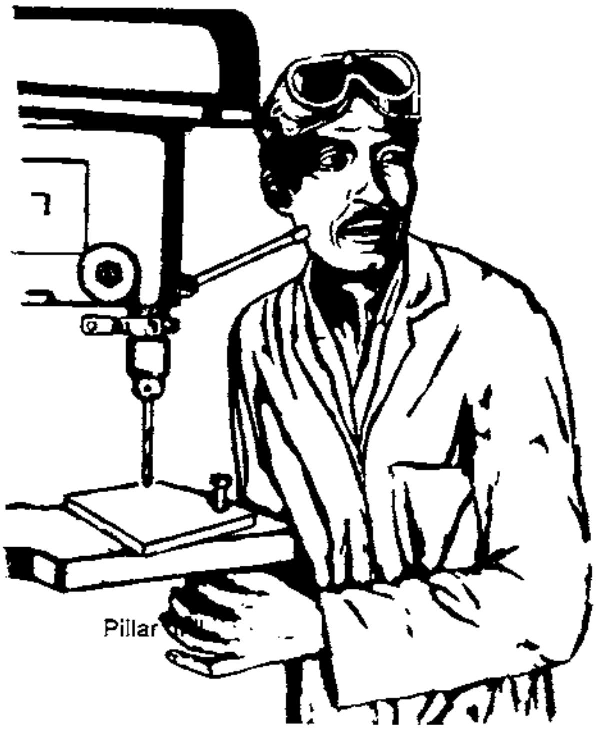
Most small workshops do not have a lathe, but many do have a gas cutting torch. Many also have a bench-grinder and a hand-held angle grinder. The step-by-step manufacturing guide that follows assumes that the pump is being made using a gas cutting torch, an arc-welder, a pillar-drill and grinding machines. Some parts of this guide will be useful to people who are making the pumps using other tools. A lathe can be useful for making parts of the impulse valve when one is available.

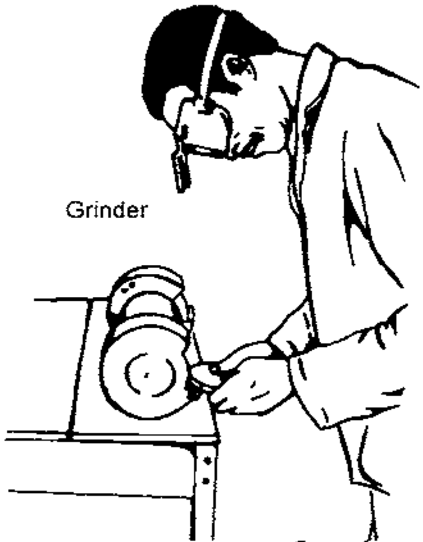


Arc welder

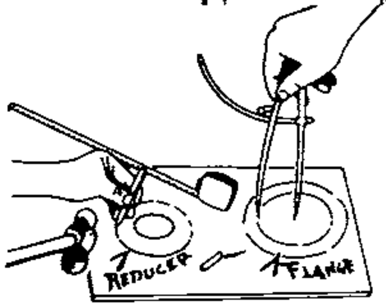
To cut circles accurately with a cutting torch, a centre pivot can be bought or made. The one shown here was made in the workshop where it is used.







You will also need chalk, a scriber, a measuring tape, dividers, a centre punch, files, a 10mm hole punch, an M10 tap and die, drill bits, two 17mm spanners, goggles, gloves, PTFE tape, a setsquare, a feeler-gauge and a hammer.

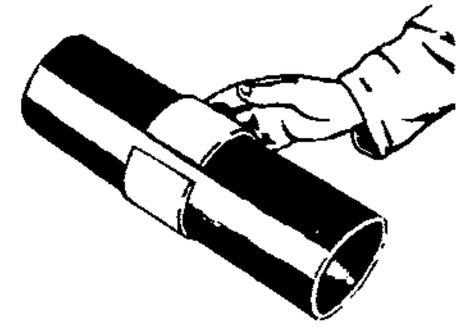


Guides and templates

When you are planning to make a number of pumps, it is worth making a few guides or templates or guides to help when marking up, cutting and drilling.

Guides for marking out the pump body

Use a short piece of PVC pipe of the same size as the pipe to be marked. Cut the PVC pipe along its length and push it over the steel pipe. Hold it in place and use it as a guide to score a line around the pipe.



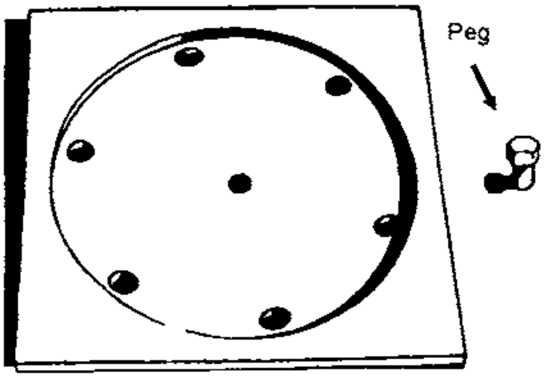
A "V" notch template like the one shown on the left can be made using thin plate (1mm) or PVC pipe. This is a guide for marking up the notches cut into the pump body and for the risers that fit into the notches.

When you have scored the line in the right place you can make it easier to see by rubbing chalk over it. Scored lines can be very hard to see through the protective goggles used when cutting. Use a centre punch to mark dots along the scored line. Use the punch about every 5mm.

It is very important to mark up clearly. If you do not, you may not cut a straight line with the torch and so you may have to start again.

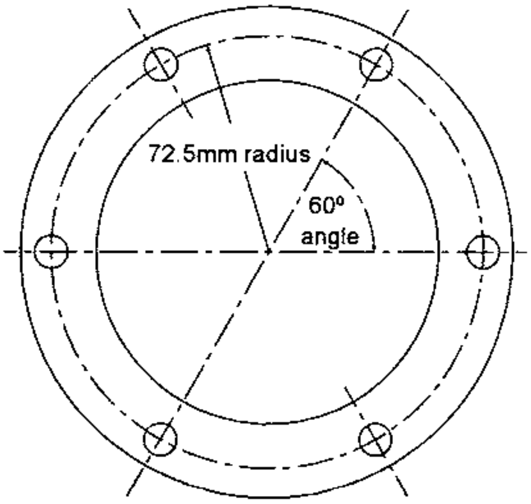
Flange and valve plate template

Design drawings number 3, 5, 6, 7, and 10 can be copied and used as templates. If you want to make a lot of pumps it is probably worth making a a steel template for the flanges. If you do not have access to a lathe, consider having the template made for you in another workshop.

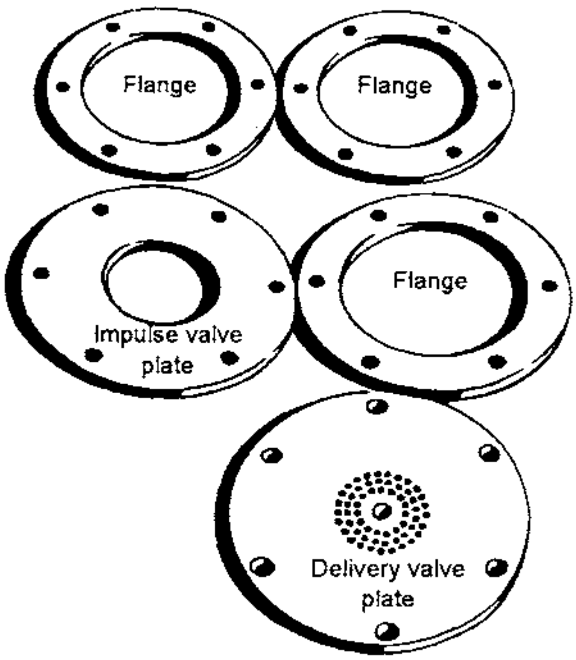


The template can be recessed with a lathe so that the flange drops into it when it is the right size. The example shown is recessed and has a ring of large holes around the outside. The example shown also provides a pattern for the bolt holes on the flanges and both valve plates.

When the first hole in the outer ring has been drilled a "peg" made by cutting a bolt is put into the hole to prevent the disc turning inside the template.



A simple template like this can be made using thin plate



You must drill the flange holes equally spaced and at the correct radius. If you do not, the flanges may not bolt together, or may only bolt together one way around.

Some people simplify the making of flanges by stacking them and drilling them together. Although this will always mean that the holes line up, it can mean that only the holes that were underneath each other when they were drilled line up. When the pump is put together is it important that the holes align whatever way around the parts are turned. Either take great care marking up each flange and be sure that the centre-punch marks are perfectly positioned before drilling, or use a template.

Materials needed to make a DTU S2 ram pump

STEEL	Size	No. of	Length/area	Notes	✔
STEEL PIPE	4" (105mm internal diameter)	1	1350mm	The outside diameter of 4" pipe is 115mm. The wall thickness should be 5mm.	
STEEL PLATE	10 or 12mm	1	330 x 500mm	Do not use plate less than 10mm thick.	
STEEL BAR	25 x 25mm	1	165mm	If this is hard to find, make some by welding together a stack of thinner 25mm wide bars.	
STEEL BAR	25 x 15mm	1	165mm		
STAINLESS OR MILD STEEL ROD	10mm	1	280mm	If this is not available, mild steel reinforcing bar will do. This includes enough to make a spare impulse valve stem to supply with the pump.	
RUBBER	Size	No. of	Area	Notes	
GASKET RUBBER (inner tube)	Car or small truck	1	825 x 170mm	Make sure that it has not perished. This includes enough to make two spare flange gaskets to supply with the pump.	
IMPULSE VALVE RUBBER	6mm	1	152 x76mm	Offcuts of conveyor belt and shoe sole material have been used in the past . This includes enough to supply a spare of each with the pump.	
DELIVERY VALVE RUBBER	3mm	1	160 x 80mm		
NUTS & BOLTS	Size	No. of	Length	Notes	
BOLTS	M10	1	30mm	These must be stainless steel or galvanised. The 4 x 40mm bolts, nuts and washers to hold the pump to the cradle are included. Extra nuts and washers are needed for the valve stem and are included in the totals. The totals also include a few spares that you should supply with the pump.	
BOLTS	M10	10	40mm		
BOLTS	M10	8	50mm		
BOLTS	M10	3	80mm		
NUTS	M10	28			
WASHERS	M10	40			
CONSUMABLES				Notes	
WELDING RODS	The amount you use will vary according to your skills.			Select rods to give good penetration on the 5mm walls of steel pipe and on 10mm steel plate.	
GAS				For the cutting torch.	
PRIMER (PAINT)				Either have the parts of the pump galvanised or paint it. In most cases it is easiest to paint it	
ENAMEL PAINT					
THINNERS					

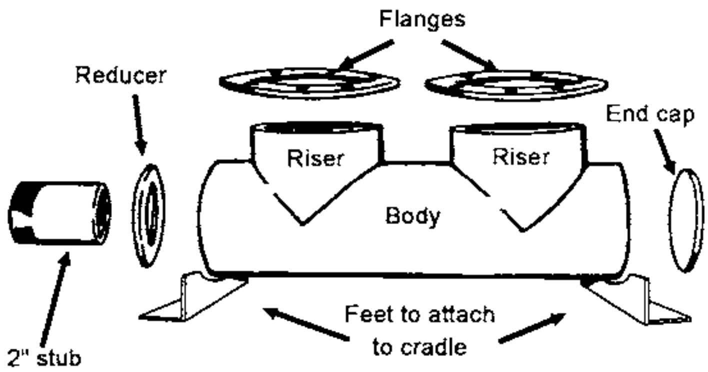
✎ Photocopy this table and tick off the materials as you get them so that you know you have everything you need before you start.

A step by step guide to manufacture

Before starting, decide which delivery valve template you will use. This will depend on the delivery head at the site where the pump is to be installed. If you do not know where the pump will be installed, use drawing number 5, which is the standard design.

Cutting the pump parts

All the cutting for this pump can be done with a cutting torch. To save grinding and to minimise scrap, the metal cut from the centre of the flanges is used as the ends of the pump body. The ends are called the "Reducer" and the "End cap". The pump body is made from steel pipe with an internal diameter of 105mm (4" pipe). The length shown on the S2 design drawings is 365mm.

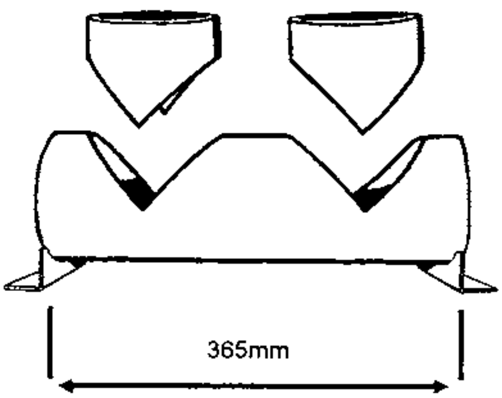


The discs of steel that fall out when the flanges are cut will fit inside the pump body, but are not big enough to cover the ends. So the ends are welded about 5mm inside the body. This should leave enough overlap to weld neatly to.

The feet are cut from 40 x 40mm angle iron. A curve that fits the pump body is cut out of one side of the angle iron.

The body is cut from a length of pipe by using the PVC pattern to score a line around the pipe. Mark it with chalk if it does not show up clearly, then go over the line with a centre punch to make sure it can be seen when cutting.

Skilled use of the cutting torch can result in the cut parts falling apart with clean edges. Even then, they will probably need to be tided up a little with a file or a grindwheel.



It is necessary to have a clean cutting nozzle on the torch, and to set the gas pressures appropriately.

If the pipe being used is galvanised, it can help to grind away the galvanise from the area to be cut. It is not worth using galvanised pipe for the pump body unless it is easy to get because a lot of the galvanised protection burns away by the time the pump is finished.

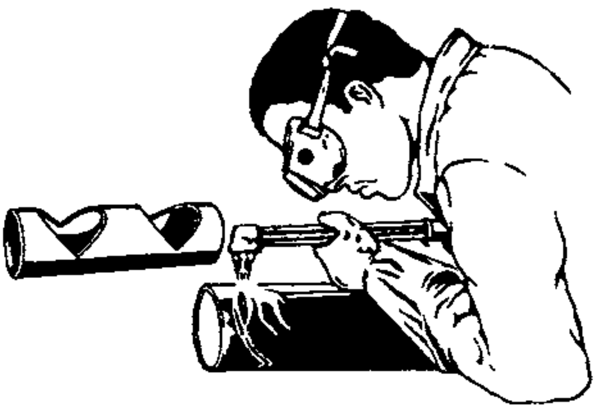
☠ *The fumes given off by burning Zinc galvanising are poisonous and should not be breathed.*

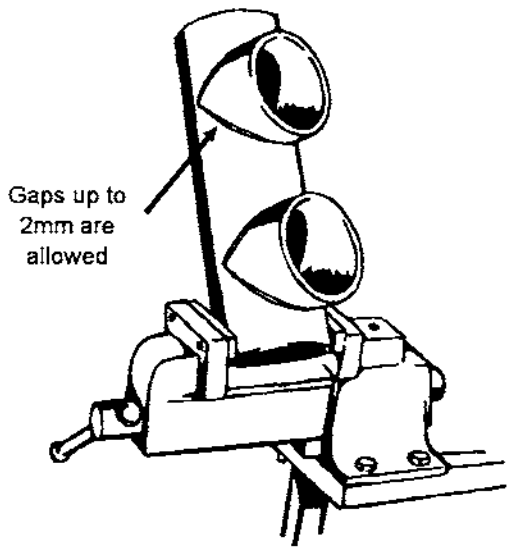
Cutting the S2 pump risers

The risers are made from the same pipe as the pump body. They are welded into "V" notches cut into the pump body. Both the risers and the notches can be marked up using the "V" notch pattern or template. At its shortest point, each riser should be no less than 30mm high. At its longest point it should be 87.5mm high.

Remember to go over the scored lines with a centre punch to make them easier to see.

Use an angle grinder or a bench-grinder to clean up the cuts so that the parts fit together properly. A gap of up to 2mm can be filled with weld.

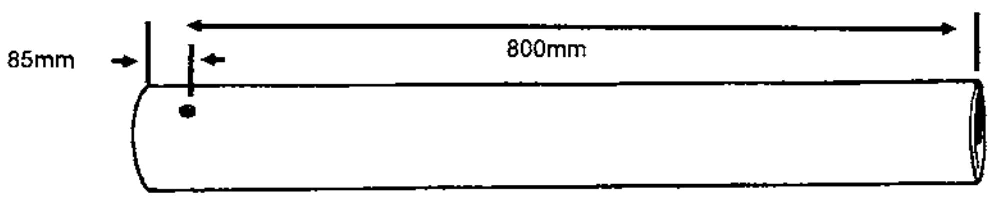




Place the risers in the pump body and grind them to fit. It can be useful to mark the risers and the notches, then grind each riser to fit a particular notch.

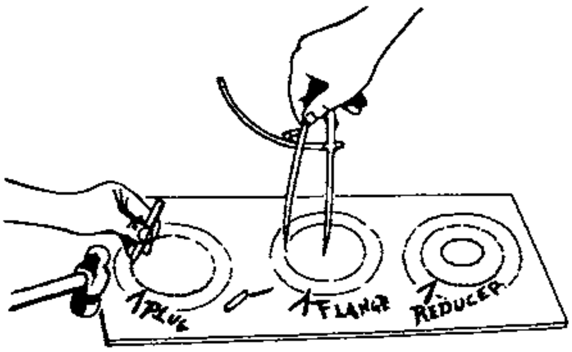
Cutting the S2 air vessel body

The air vessel body is cut from the same 105mm (4") pipe as the pump body. The length should be 800mm. This size will always be big enough, so do not change it. A ¾" hole should be cut (or drilled) with its centre 85mm from one end of the pipe. This is where the delivery pipe stub is attached.

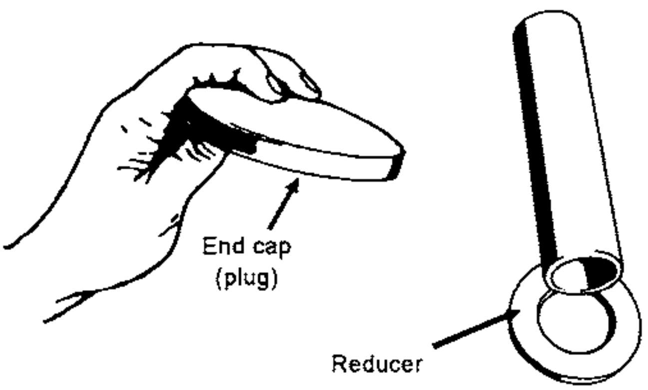


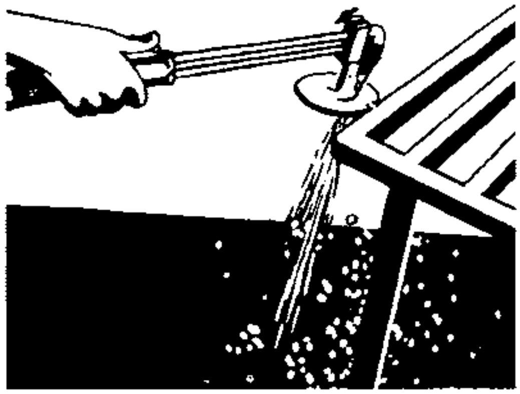
Cutting the S2 pump flanges and plates

The S2 pump body has two flanges and two pump body ends. The ends are called the "End cap" and the "Reducer". The "End cap" is the inner circle cut from a flange. The "Reducer" is the inner circle cut from a flange with another hole cut in the middle of it. The "Reducer" reduces the pipe size from the 4" pump body to the 2" drive pipe, so the inside hole is cut to take a stub of 2" pipe. The S2 air vessel has one flange and one end cap.



Mark up the flanges carefully, and cut the outer circle first. It can be useful to tack-weld the edge of the first circle to the workbench to make it easy to cut the second circle.

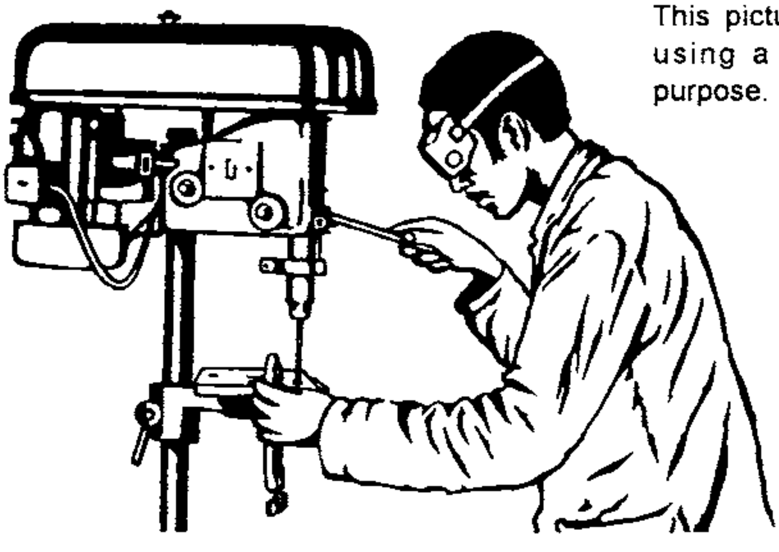




Drilling the flanges and valve plates

It is wise to make a template before drilling the flanges. Use a photocopy of design drawing number 3 as a template. Put it over the disc to be drilled, then use a centre punch to mark the hole centres through the paper template. To make the template last longer, glue it to thin cardboard before you use it.

This picture shows a flange being drilled using a steel template made for the purpose.

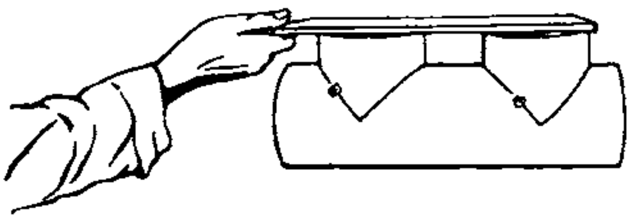


Notice that the holes are drilled before the flanges are welded to the pump body.

Welding the S2 pump body

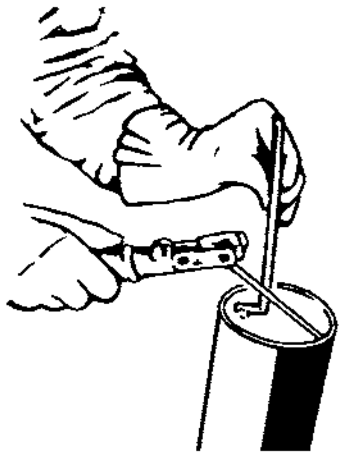
When the parts of the pump body and air vessel have all been cut they must be welded together. The following pictures show a suggested order in which to weld the parts. This order can be changed to suit the person doing the welding. It is important that the welder be skilled because the welds must be strong and not leak under pressure.

[1] Tack-weld the risers onto the body, making sure that their tops are level.

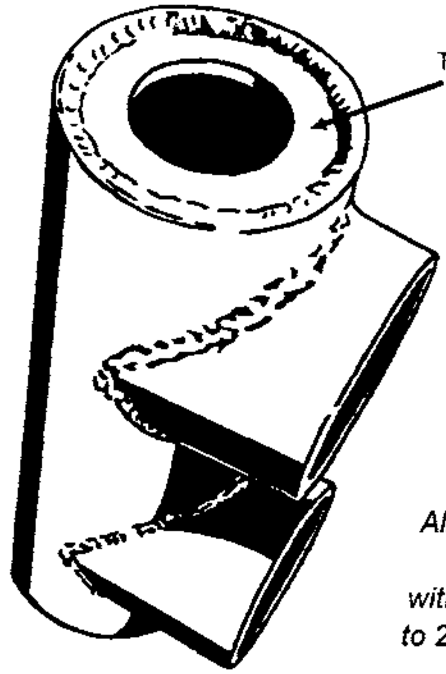


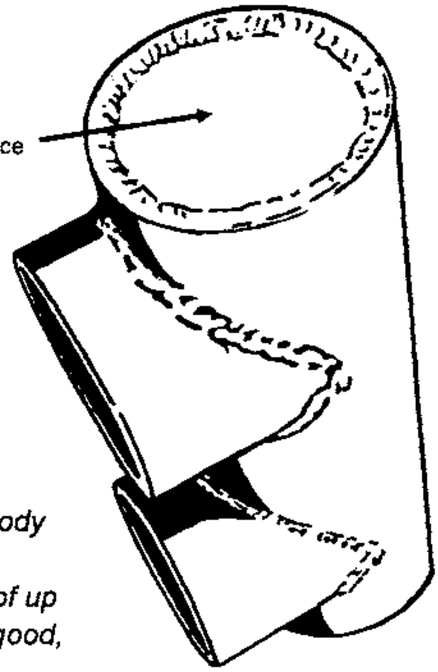
[2] Weld the risers all the way around on the outside of the body.

[3] Weld the end cap and the reducer 5mm inside the ends of the pump body.

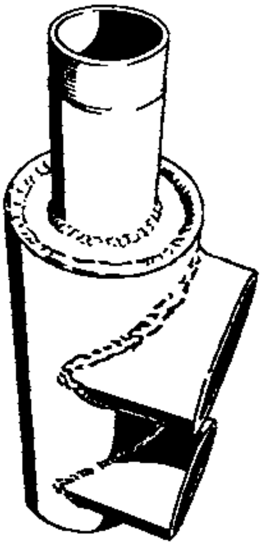


If the ends are a loose fit, tack a rod to them and hold them in place while tack-welding them. Then weld all the way around.



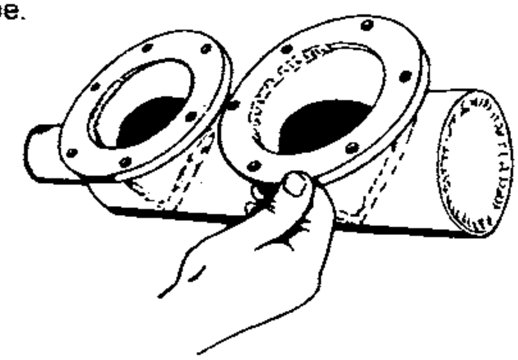


All welds on the pump body must be capable of withstanding a pressure of up to 25 bar. Be sure to get good, even penetration.

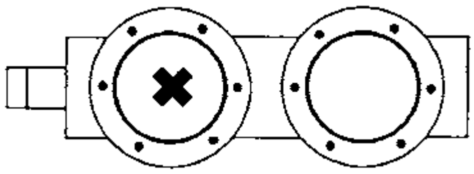


[4] Weld the stub of the 2" drive pipe into the hole in the reducer. Cut a thread on one end of the stub before cutting it from a length of pipe.

[5] Tack-weld the flanges onto the risers and make sure that the flanges are level, then weld all the way around.

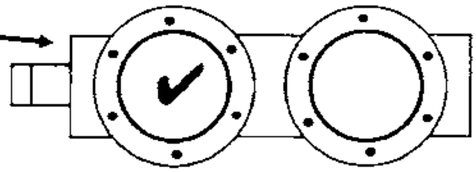


Make sure that the flange holes are not in line with the pump body.

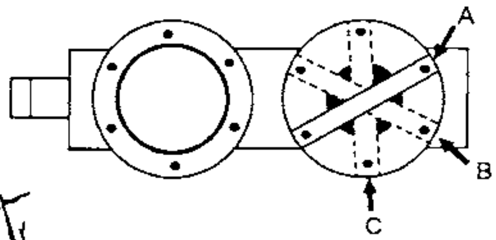


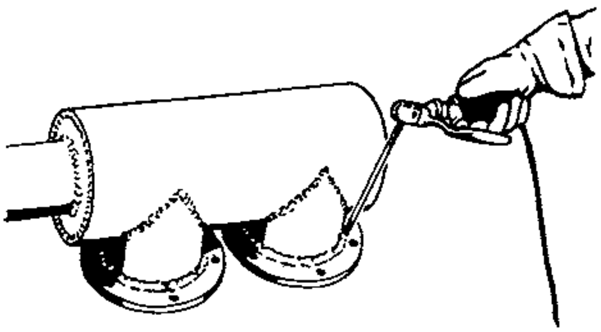
Flange hole alignment

They should be offset like this.

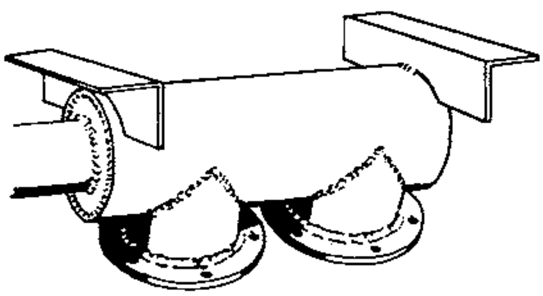


The impulse valve stop bar can later be bolted to the flange in any of the three possible positions, A, B, or C.





[6] Turn the pump body over and weld around the flanges on the other side.



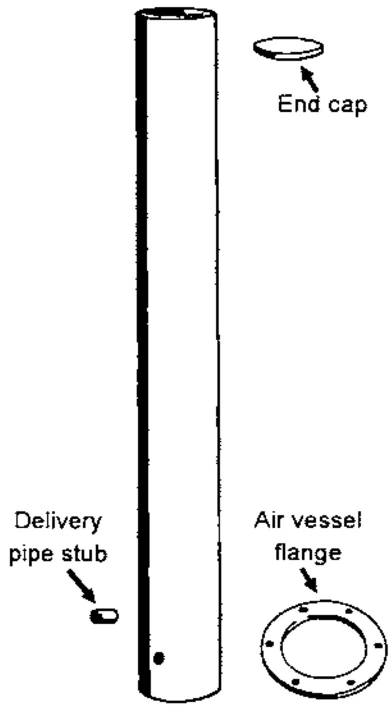
[7] Tack-weld the angle iron feet to the bottom of the pump body, 5mm in from each end. Make sure that they are both level, then weld them on both sides.

Welding the S2 pump air vessel

8 Weld the air vessel End cap in place, 5mm below the top of the air vessel.

9 Weld the air vessel flange in place, being sure to get it level. Weld it inside and outside.

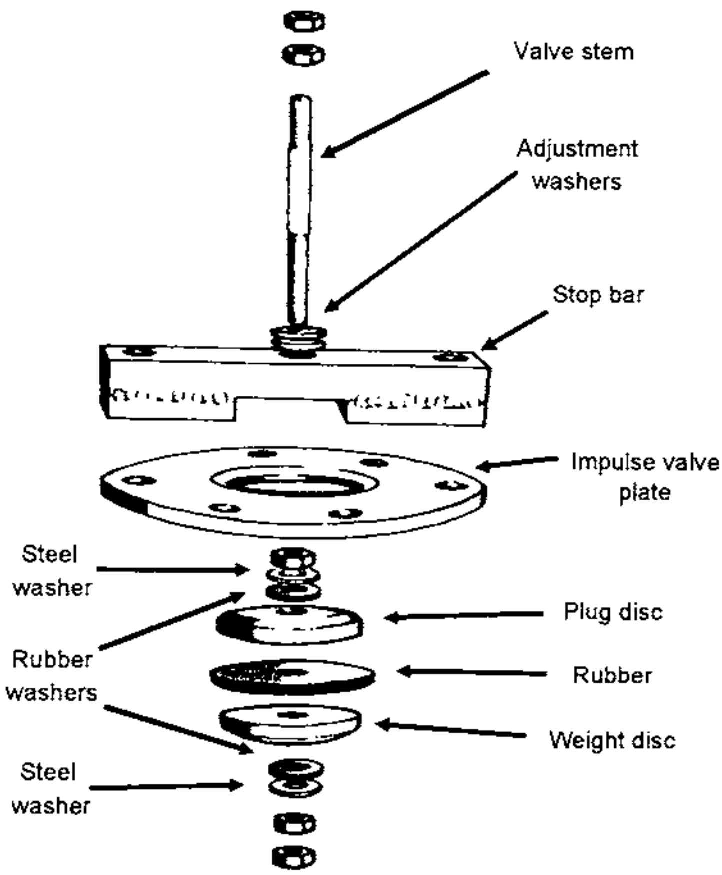
10 Weld the delivery pipe stub into the hole in the air vessel. Cut a thread onto the stub before you cut it from the end of a length of pipe.

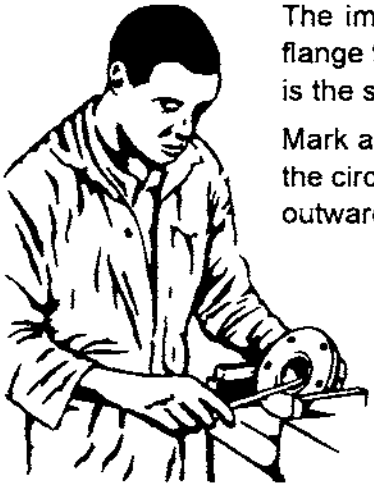


Making the S2 pump impulse valve

The valves are the most important parts of these pumps. They must be made accurately or the pump will not be as efficient as it should be and may be unreliable. If they are made carelessly, the pump may not work at all.

The valve stem rises and falls as the pump works. When it falls it pushes the plug down to allow water to flow through the central hole in the impulse valve plate. When it rises it pulls the plug up to almost block the hole, and the rubber makes a final seal.

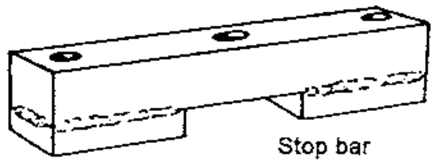




The impulse valve plate is a disc of 10 or 12mm steel plate. Use the flange template to drill holes around the outside. The outside of the disc is the same size as a flange (165mm diameter).

Mark a circle with a radius of 33mm from the centre of the disc and cut the circle out. Use a file to chamfer one side of that hole so that it slopes outward at 45°. The chamfer should be 5mm deep.

The stop bar is a 165mm length of 25mm square steel, with two 58.5mm lengths of 15 x 25mm bar welded to it. The bar is drilled to fit on top of the impulse valve plate.



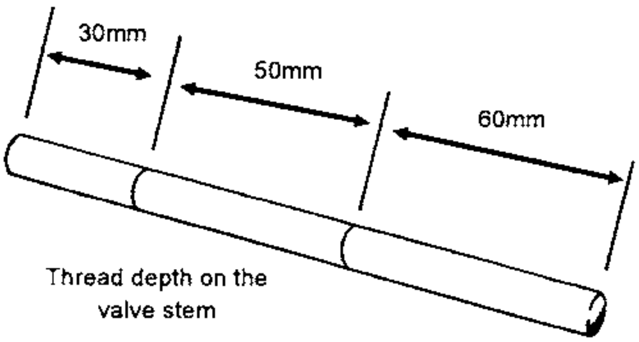
Stop bar

It is important that the holes are drilled upright through the bar, so use a pillar drill when you can.

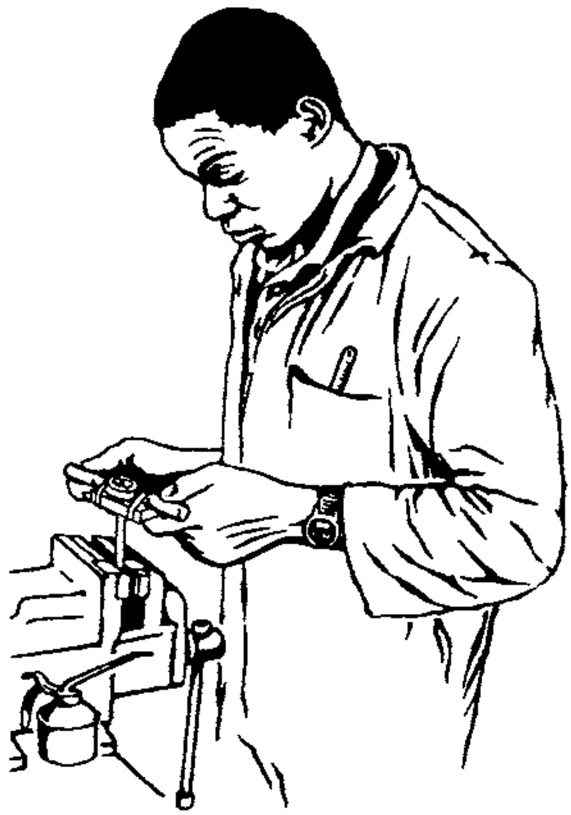
Lathe alternative

Drill the holes in the stop bar and cut the threads on the valve stem with a lathe when you can.

People prefer their pumps to look good, so it is often worth grinding away any excess weld on the stop bar using a grindwheel. In the drawing alongside, a hand-held grinder is held in a vice to make a temporary bench-grinder. If you do this, make sure that the grinder is held firmly.



Thread depth on the valve stem



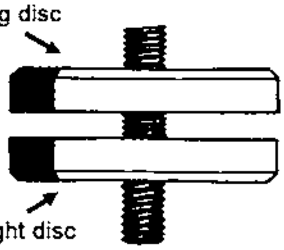
The valve stem is 140mm of 10mm stainless or mild steel bar. If plain bar is not available, reinforcing bar can be used, but it may not last as long. The bar must be straight. A slightly bent bar may break quickly when the pump is being used.

The stem must be threaded at each end. The depth of the thread is greater at the bottom than the top.

The impulse valve plug and weight discs are identical. When they are put onto the valve stem, the second is put on upside down.

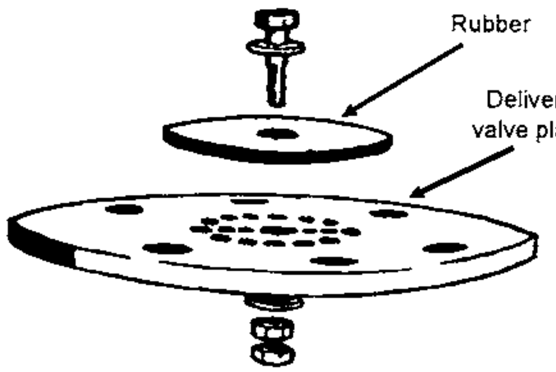
Cut two 60mm disks from the same 10 or 12mm steel plate that you used for the Impulse valve plate, then drill a hole of 11mm diameter in the centre of each. It is important that the holes are straight.

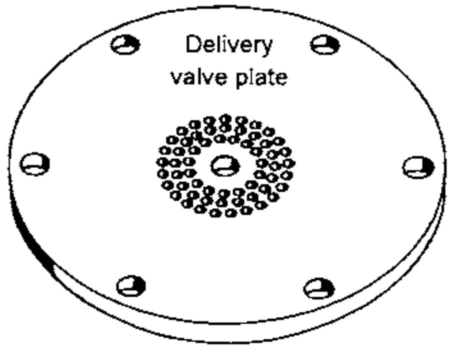
One edge of each valve disc must be chamfered with a 45° angle. The chamfer should only be 3mm deep, leaving 7mm of the edge straight.

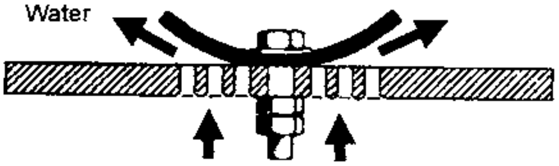


Making the S2 pump delivery valve

This is a simple flap valve. The delivery valve rubber is pushed up when the pump reaches delivery pressure, and flaps closed when the pressure drops. When the rubber is bent up, water flows through the small holes into the air vessel and into the delivery pipe.



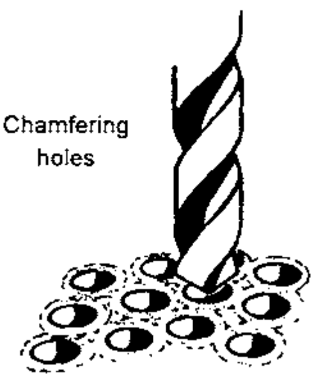




CROSS-SECTION THROUGH A DELIVERY VALVE WITH THE RUBBER OPEN

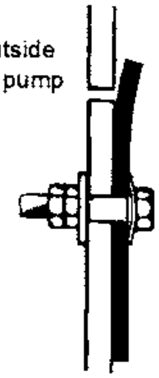
The delivery valve plate is cut from the same 10 or 12mm plate used for the flanges. You should have already chosen which of the design drawings numbers 5, 6 and 7 to use as a template. Punch through the template to mark out the holes. The central rings of holes allow water to pass through when the valve is open. To increase the flow through these holes, chamfer them using a larger drill bit (6 - 8mm) on one side of the valve plate.

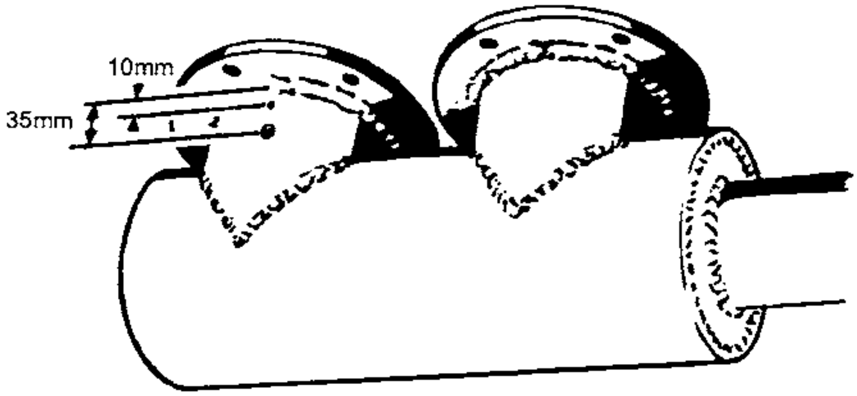
The chamfered side must be underneath when the valve is put together.



Making the S2 pump snifter valve

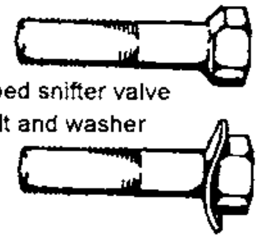
The snifter valve is a small flap valve in the riser furthest away from the drive pipe stub. When the pump is running, it allows a little air into the pump body. The air is pumped through the delivery valve with the water and keeps the level of air in the air vessel constant.





Drill a 1 or 2mm diameter hole in the riser 10mm below the bottom of the flange, (or 20mm below the top of the flange, which is the same thing). Drill a 10mm diameter hole 25mm below the first hole. The 1 or 2mm hole is the hole that air will come through.

The rubber flap inside the pump body must sit flat against the side of the riser. Because the riser is curved, you must file away parts of the bolt head and bend a washer as shown in the drawing. Then, when the bolt is tightened, the rubber flap will be able to sit flat. Be careful not to tighten the bolt enough to distort the rubber. Usually it is enough to tighten the nut with your fingers, then lock another against it using spanners.



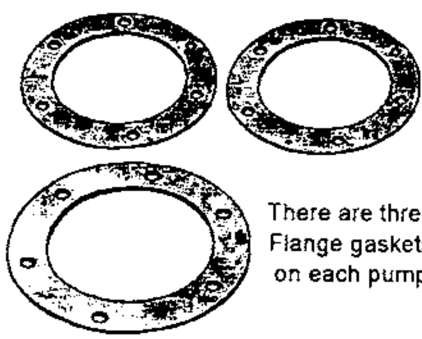
Shaped snifter valve bolt and washer

It is very important for the air in the air vessel to remain at a constant level, so it is essential that the snifter valve is fitted and working properly. If it does not work properly, the pump will be less efficient, and may even be damaged.

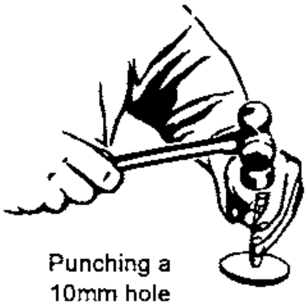
Rubber parts

You will need valve rubber and flange gasket rubber to complete an S2 pump.

Flange gaskets are usually made using old inner tube rubber. Make sure that it is not so old that it has started to perish, and try to select an area where it is more or less the same thickness. On some tubes, especially those made for big wheels, the rubber can be twice as thick in some places as others. Using the flange template as a guide, cut the big circles using a sharp knife. The bolt holes should be punched out using a 10mm hole punch. This leaves clean holes on which the threads of the bolts do not catch.



There are three Flange gaskets on each pump



Punching a 10mm hole

Delivery valve rubber

Impulse valve rubber

Inner tube rubber can also be used for the snifter valve rubber disc.

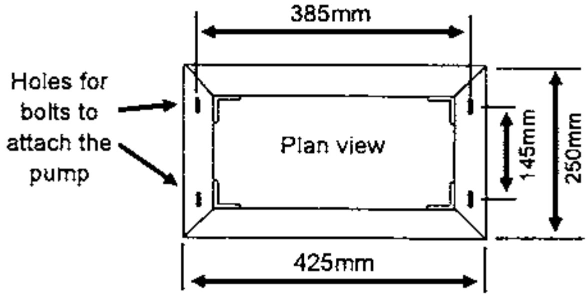
The large impulse valve rubber must be stiff but the delivery valve rubber has to bend easily. The impulse valve rubber should be about 6mm thick. Thicker rubber will probably be all right, but do not use thinner rubber. The delivery valve rubber should be about 3mm thick. Delivery valve rubber can also be used for the small impulse valve rubber washers above and below the impulse valve discs. We have used rubber made for shoe repairs and offcuts of conveyor belt when we cannot buy rubber sheet easily.

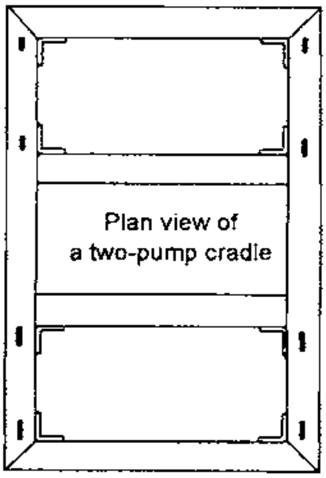
The pump cradle

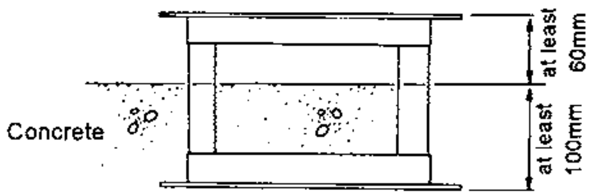
You should not make and sell a pump without including a pump cradle. If a ram pump is not securely fixed during use, it will break, and may break the connecting pipework too.

It is important that you use steel strong enough to hold the pump firmly, and that the cradle is buried in a strong concrete base. The pump tries to vibrate when operating and will soon shake itself loose from an insecure base.

Use 40mm angle-iron, about 5mm thick, to make the cradle. It can be extended to support two pumps when needed.







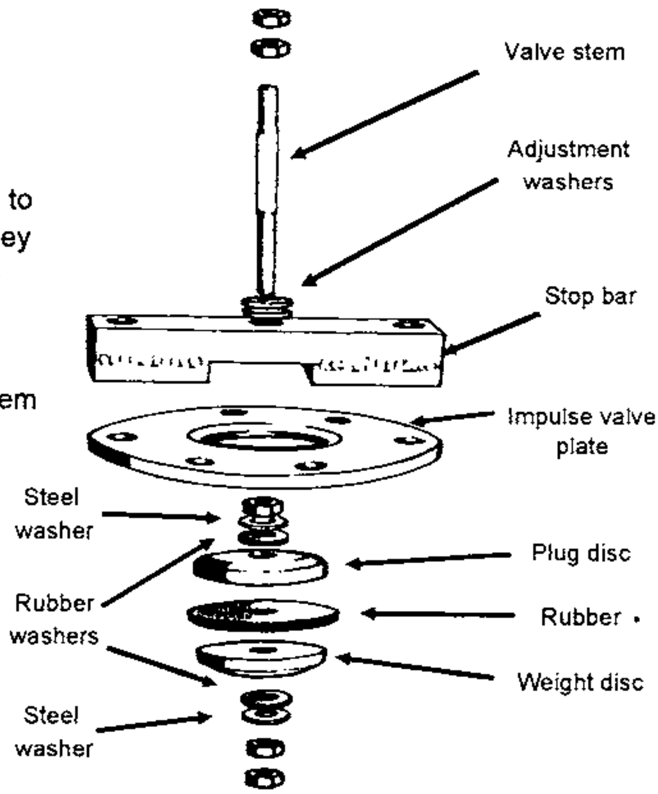
SECTION THROUGH A CRADLE INSTALLED ON A CONCRETE BASE

The pump is attached to the cradle by the angle iron feet that you have welded to the bottom of the body. Notice that the holes are slotted so that the pump can be moved from side to side slightly to allow for small mistakes in drive pipe alignment. The cradle must stand up from the concrete far enough to make it easy to reach the fixing nuts.

Assembly and testing

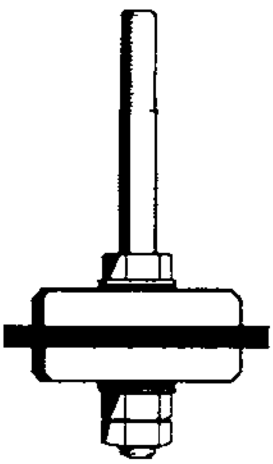
Putting the pump together properly is very important. The process of assembling the valves is described here, including some simple ways of testing them. Paint all the metal parts you have made before you assemble them for the final time. You may like to assemble them loosely before painting to check that everything is OK. To make the pump last longer, it should be painted inside and out with a metal primer, then a good enamel paint.

Assembling the impulse valve



The impulse valve design drawings, numbers 9, 19, 11 and 12, are also templates. Start by holding each part against the drawing of it on the template to check that the dimensions are right. If they are not right, either adjust them or make them again.

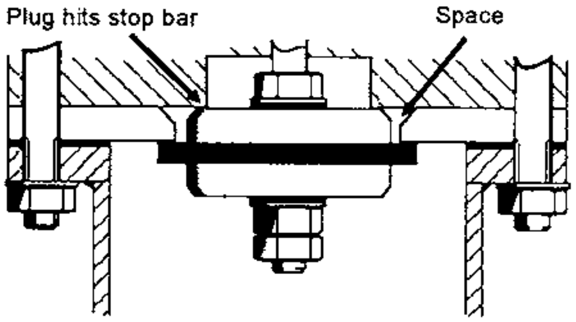
When the parts are all the right size, thread a nut onto the end of the valve stem that has a longer thread. This will be the bottom of the valve stem. Screw the nut to the end of the thread and use a spanner to lock it there. Then push a steel washer and a rubber washer up to the nut. Put the plug disk onto the stem, with the chamfered edge towards the nut and washers already there. Then push the impulse valve rubber over the stem up to the plug disc. Put the weight disc over the stem with the chamfered edge facing away from the valve rubber. Then push a rubber washer and a steel washer up to the weight disc. Thread on a nut up to the washer. Thread it on finger tight. If you use a spanner, do not tighten it so that it squashes the rubber washers. Hold the nut with a spanner and use another spanner to lock a second nut against it. The valve stem should look like the one in the drawing below.

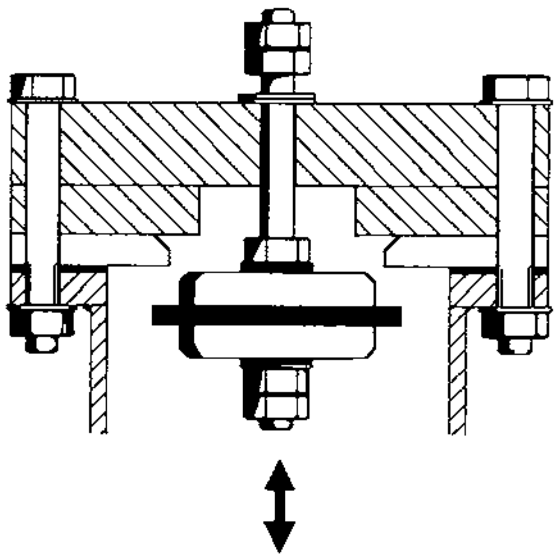


Push the stem up through the Impulse valve plate and through the stop bar. Drop two washers over it and thread on two nuts. Lock them lightly against each other. They should be adjusted when the pump is installed, so do not over-tighten them.

When the valve has been assembled, bolt it to the pump with a rubber gasket between the impulse valve plate and the flange on the pump. The impulse valve goes on the riser furthest away from the drive pipe stub. Tighten all the bolts on the flange except the two holding the stop bar in place. Put nuts on these but leave them finger tight.

Check that the impulse valve can move freely up and down without the plug disc catching on the sides of the hole in the Impulse valve plate. If it does catch, push the stop bar away from the side that catches. The stop bar has a small amount of movement between the bar and the threads of the bolts holding it.

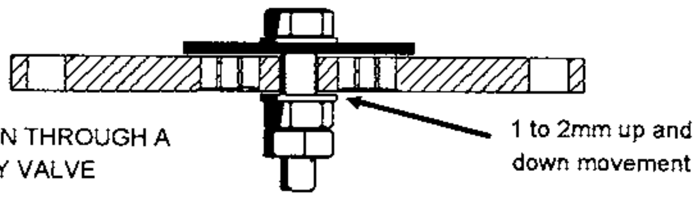




There should be a space all the way around between the side of the plug disc and the Impulse valve plate. If the pump has been made exactly to the measurements, the space will be 3mm. If it is less than 1mm, you should take the valve apart and check the parts against the templates. If the plug disc is too large you may be able to make it smaller. If the hole in it is not in the centre, you will probably have to make another. If the hole in the impulse valve plate is too small or not round, you may be able to file it out. Do not file it so that the hole is bigger than 66mm as shown in design drawing number 10. The plug disk must also hit the stop bar all the way around. Turn the plug disk to make sure that this is so.

Assembling the delivery valve

The delivery valve must be assembled so that the nuts are tight on the bolt, but the bolt has some up and down movement. This is shown on the drawing below. When the bolt head is pressed down against the washer and rubber on top of the delivery valve plate, there should be a gap on the underside of 1 to 2mm between the plate and the washer.

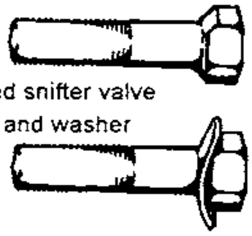


CROSS SECTION THROUGH A DELIVERY VALVE

To assemble the valve put a washer over a 40mm M10 bolt and push it through the delivery valve rubber. Make sure that the rubber moves freely on the bolt. It the hole in the centre was cut out with a hole punch, it should move freely up and down. If the rubber distorts when it is pushed over the bolt, you must make the hole in the middle bigger. This can sometimes be done with a round file or a stick with emery paper wrapped around it.

Check that there are no rough edges on the holes in the delivery valve plate then push the bolt through it. The chamfer on the delivery valve holes should be on the underside of the plate, away from the bolt head. Push on a washer and thread on a nut, leaving 1 to 2mm up and down movement in the bolt. Use a feeler-gauge if you have one, or do up the nut with your fingers until it starts to get tight, then unscrew it one full turn. Use spanners to lock a second nut against the first, then check that there is still enough up and down movement. It should be at least 1mm and not more than 2mm.

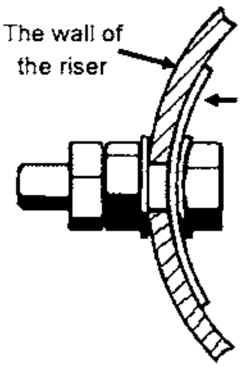
Assembling the snifter valve



Shaped snifter valve bolt and washer

The snifter valve rubber must sit flat against the inside curve of the riser below the delivery valve. To make this happen you must shape a nut and washer as shown on page 15.

Make sure that there are no rough edges on the inside of the two holes you have drilled through the riser on the pump body. Even a small burr can stop the valve working properly. Also make sure that the holes have not been blocked by paint.



CROSS SECTION of the snifter valve assembly from above

To assemble the valve, push the rubber over the bolt up against the shaped washer. Make sure that the rubber moves freely on the bolt. It the hole in the centre was cut out with a hole punch, it should move freely up and down. If the rubber distorts when it is pushed over the bolt, you must make the hole in the middle bigger. Then push the bolt through the riser on the pump body. Make sure that the rubber disc covers the small snifting hole in the riser. Be sure to use a disc of rubber rather than a smaller flap. If the disc turns it will still cover the snifting hole.

Push a washer over the thread outside the pump body and thread a nut onto it. Holding the head inside the pump, tighten the nut half a turn with spanner. Check that the rubber disc has not distorted. If it has, slacken the nut off until the rubber disc sits flat against the riser. When the disk sits flat and there is no play in the nut and bolt, use spanners to lock a second nut against the first.

Spare parts

It is important that you make the pump parts carefully to match the dimensions given on the design drawings. Then, if a part needs to be replaced, it can be made from the drawings and taken to the pump. If the parts are made carelessly, the pump may have to be brought to the workshop so that you can make a part that fits.

The DTU S2 ram pump costs much less than any commercial pump we have seen. It is made using materials and tools that are widely available. The disadvantage of this is that some parts will wear out or fail more quickly than they do on expensive pumps. The parts that have failed in the past are the rubber discs and the valve stem. You should make spares of these and supply them with the pump. A valve stem made from stainless steel usually lasts a lot longer than a stem made from mild steel. After the pump has been taken apart a few times it may also need a new flange gasket. The head or the thread on a bolt or nut may also get damaged, so the pump should be supplied with a few extra nuts, bolts and washers of the right size.

Provide these spares with each pump:

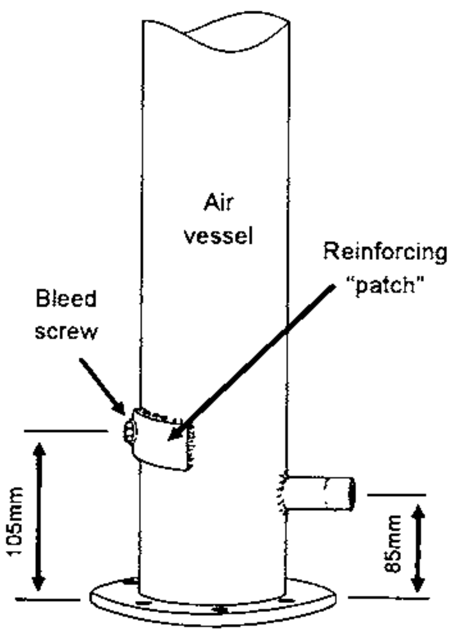
- a spare impulse valve stem;
- spare impulse and delivery valve rubbers;
- 2 spare flange gaskets.
- 1 spare 40mm M10 nut and bolt;
- 1 spare 80mm M10 nut and bolt;
- 2 spare 50mm M10 nuts and bolts;
- 4 spare M10 nuts and 6 spare washers.

If the impulse valve discs are not made carefully with their holes in the centre, the valve plug disk may not turn freely in the hole in the valve plate. It may not strike the stop bar on both sides all the time when the valve plug is turned through 360°. This may also happen if the hole in the middle of the stop bar is not drilled absolutely vertically through it. If you find these faults, you must make the parts again.

Optional addition

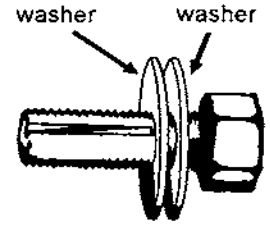
The addition of a "bleed" screw in the air vessel can make it easier to find out what is wrong with a pump when it does not perform properly. It can also make the pump easier to maintain.

Many commercially available pumps have a bleed screw on the air vessel. The screw is opened to check that there is enough air in the air vessel, and to let out the water when there is too much. It is also a useful way of letting the pressure out of the air vessel when you want to take it apart for maintenance.



The bleed screw should be position just above the delivery pipe stub on the other side of the air vessel.

The pressure in the air vessel can get very high, so the bleed screw and its thread must be made carefully to prevent it leaking. To make the thread longer and more secure, a "patch" cut from the same 4" pipe as the air vessel should be welded over the area first. Then you drill a hole through the patch and the wall of the air vessel. Cut a thread in the hole so that an M10 bolt will screw into it.



The thread on the bolt used should be 30mm long. Holding the head of the bolt in a vice, use a hacksaw to cut a shallow slot along the threads. Do not cut more than 1mm deeper than the bottom of the thread. When the hacksaw blade hits the bolt head, stop. The bolt should look like the one in the drawing alongside. You will need to use a steel and a fibre washer under the bolt head to make a good seal.

To bleed air or water from the air vessel, simply undo the bolt a few turns until air starts to hiss out, or water to spray out.

Ram Pump Programme

HOW RAM PUMPS WORK

TECHNICAL
15
RELEASE

How ram pumps work

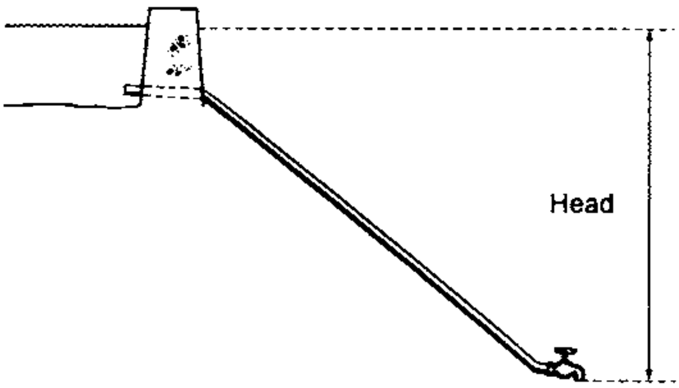
This Technical Release explains what is happening inside working ram pumps. It shows how changes in the design of a ram pump system can change its performance. It will be useful to anyone who is designing ram pump systems and to anyone who is tuning ram pumps to give the best performance.

This section begins with a few examples of simple systems and introduces the words that are used later. It also shows the way that the water flowing through pipes can be shown on a graph. Even if you are already understand terms such as *terminal velocity* in pipes, you should read all of this part so that you know the way that we are using the words.

Falling water

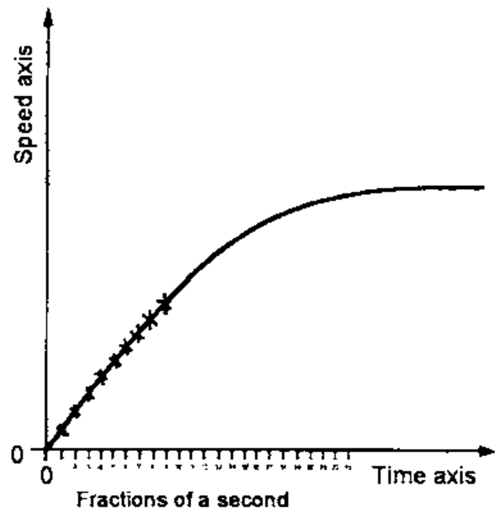
Head

In the drawing here there is a reservoir of water behind a dam. A small pipe passes through the bottom of the dam and runs down the hill. At the end of the pipe there is a tap which is closed. The height from the water level in the reservoir to the tap is called the *head*.



When the tap is opened, water starts to flow down the pipe and out through it. It flows slowly at first, but speeds up very quickly. After a short time the water reaches its maximum speed and the flow becomes steady. If the tap is left open, water will of course continue to flow steadily down the pipe from the reservoir and out through the open tap.

A graph can be drawn to show how the water coming out through the tap gets faster at first, and then flows at its maximum rate. The graph alongside shows what happens. Imagine that a stop-watch was started as soon as the tap was opened and the speed of the water in the pipe was measured every hundredth of a second. The graph has the speed of the water flowing through the pipe marked on the side axis. The time that has passed is marked along the bottom axis.

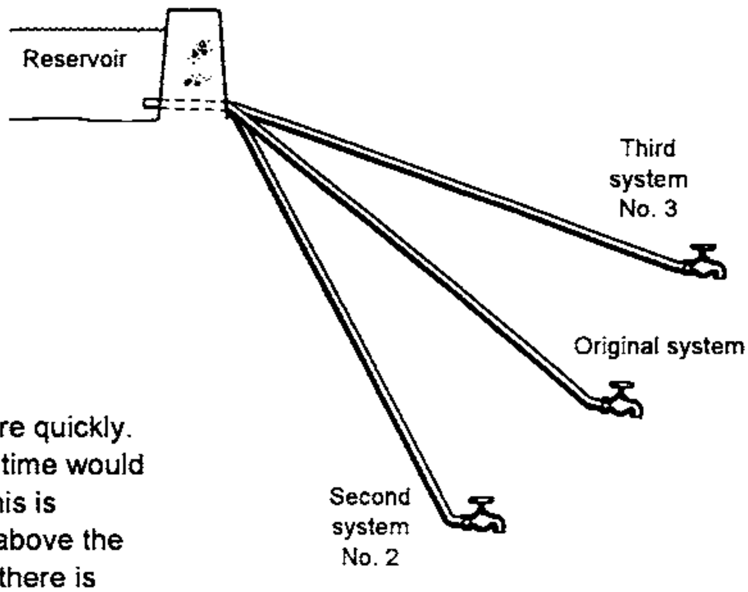


Before the tap was opened and the stop watch was started, there was no water coming through the tap. That is why the graph starts when the "Time" is zero and the "Speed" of the water in the pipe is also zero.

At first the line on the graph goes up very quickly. As the water flows it rubs against the sides of the pipe. This rubbing is usually called *friction*. As the water gets faster, the friction becomes bigger and stops the speed of the water from increasing as quickly. This is shown on the graph by the curve of the line getting flatter and flatter. After a while, the water is flowing as fast as it can and the line on the graph is flat. This shows that the water is continuing to flow out of the tap at the same speed.

A larger head

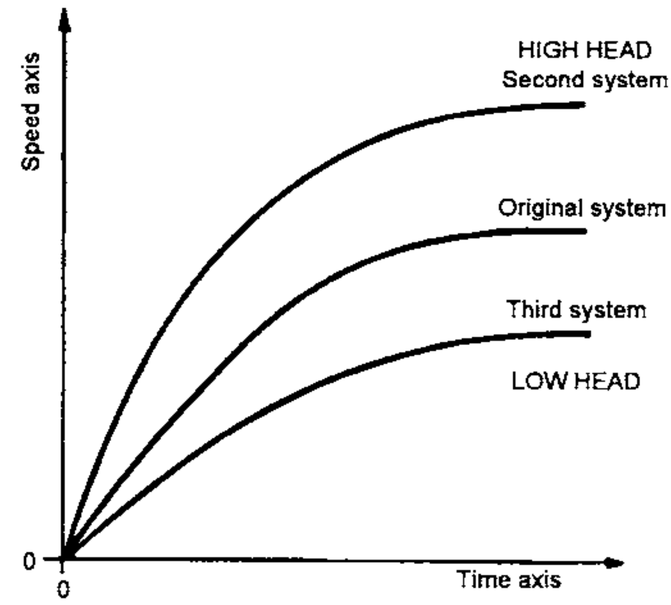
In this drawing there is a water supply with a reservoir and three pipes and taps. The pipes are labeled as the original, second and third systems. In the second system it is further downhill to the tap (the *head* is bigger than in the original system). When the tap on No.2 is opened, the water will flow down the pipe and out through the tap more quickly. The line showing speed against time would rise more steeply on a graph. This is because the reservoir is higher above the tap than it was on System 1, so there is more pressure pushing the water down the pipe and out through it.



As the water gets faster the friction between it and the wall of the pipe gets greater. The curve of the line on the graph begins to flatten out. When the water is flowing as fast as it can, the line on the graph is flat. Because the *head* in the second system is greater than the *head* in the first, the water flows faster in the second. This is shown on the graph at the top of the next page.

A smaller head

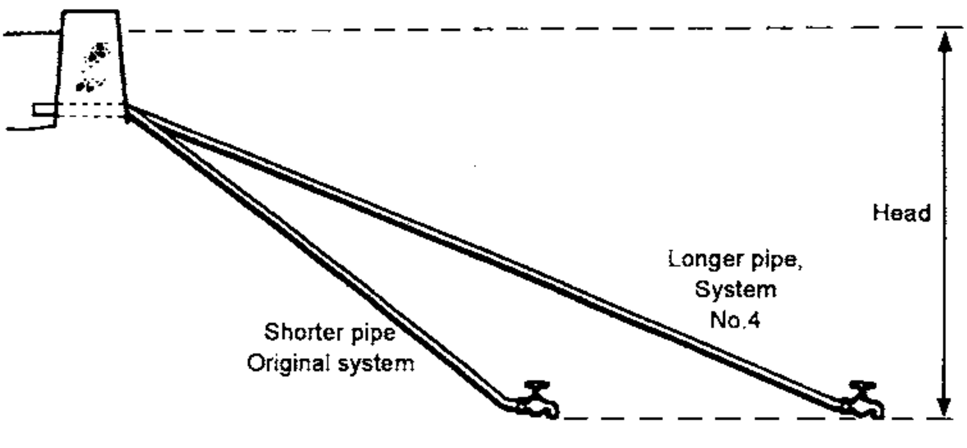
For the third system, the drop from the reservoir to the tap (the *head*) is much less than in the original system. When a graph of System number 3 is drawn, the line on the graph showing speed against time does not rise as sharply and flattens out at a lower speed. This is because there is less pressure pushing the water down the pipe and out through the tap. The speed of the water when it reaches a steady flow is the slowest of the three examples.

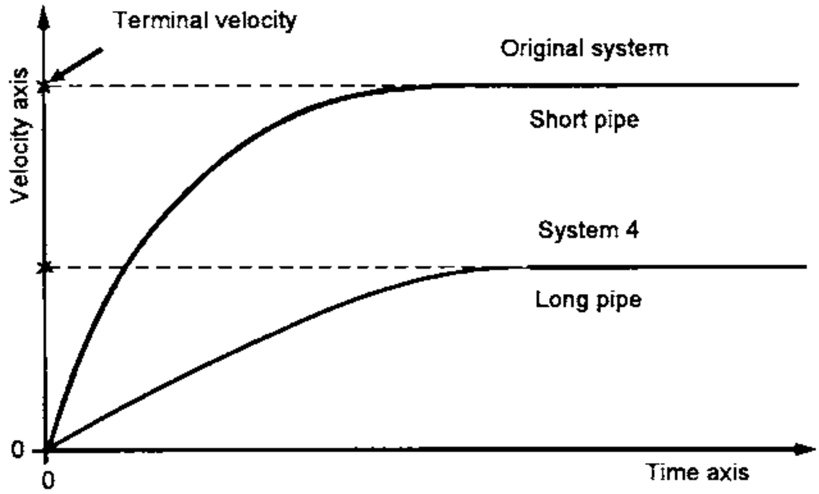


Acceleration

The rate of increase in speed is called the *acceleration*. When the tap is first opened, the speed of the water increases very quickly, so the *acceleration* is very high. As the water flows more quickly there is more friction and the line on the graph flattens out. This shows that the water is still accelerating but that the rate of acceleration is becoming lower. When the water is flowing as fast as it can, there is no more acceleration and the line on the graph is flat. This maximum speed is called the *terminal velocity*. In this case, the word *"terminal"* is used to mean *"as much as possible"*. *"Velocity"* is really just another name for *"speed"*. *"Terminal velocity"* just means *"top speed"*.

In the drawing below another pipe is installed from the reservoir. The new pipe is called System number 4. The pipe is the same diameter as the first one, but it is much longer. The height from the reservoir to the tap (the *head*) is the same. When the tap of this new system is opened, the water accelerates down the pipe and out through the tap. Because the water has to flow through a longer pipe there is more friction to slow it down, so its *terminal velocity* is not as fast.



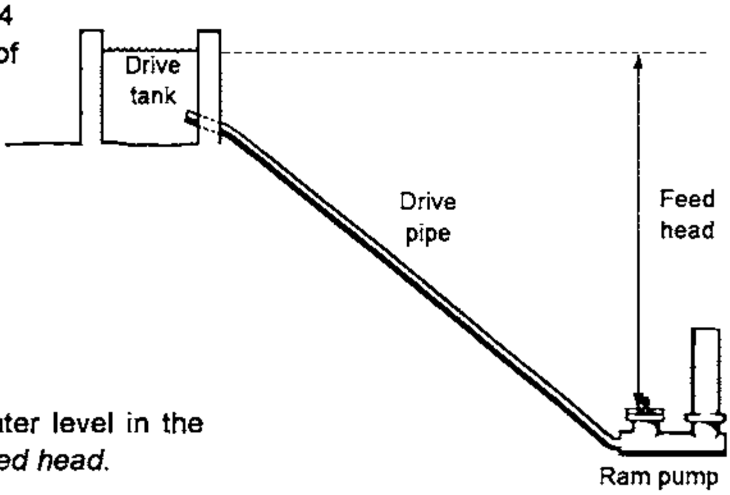


On the graph of this example above, the original system is also shown. The line on the graph flattens out at a lower speed and in a longer time.

If any one of the pipes in these systems was replaced by a pipe with a bigger internal diameter, the graph would change. This is true even if the bigger pipe were the same length and ran along the same route. When the acceleration of the water was measured again, you would find that the water reached a faster *terminal velocity*. This is because the larger pipe would have less friction. In a bigger pipe, there is more room for the water to pass through without touching the sides.

How ram pumps use the water

In the drawings of Systems 1 to 4 there was a reservoir at the top of a pipe with a tap at the bottom. From now on the reservoir is replaced by a tank and the tap on the end of the pipe is replaced by a ram pump.

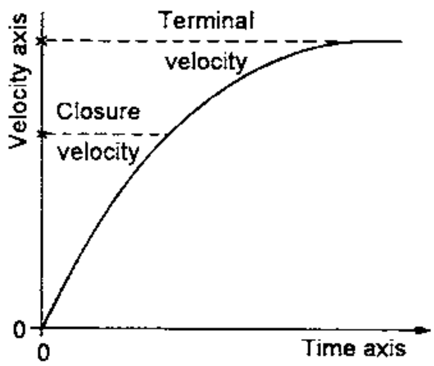


Feed head
The drop in height from the water level in the tank to the pump is called the *feed head*.

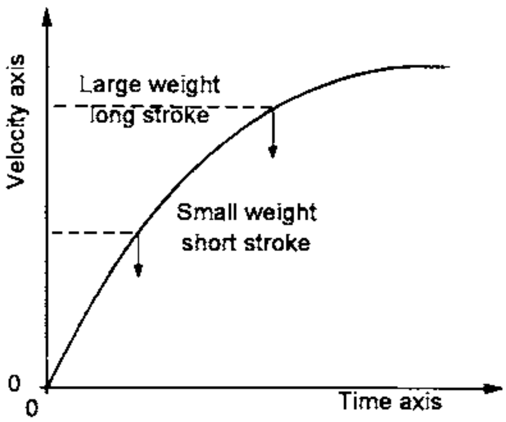
Closure velocity
When the ram pump is not working and the impulse valve is closed, there is no water coming through it. When the impulse valve is pushed down, water begins to come out through the open valve, getting faster as it accelerates down the pipe. The force of the water flowing around the impulse valve tries to lift it closed but the weight of the valve keeps it open. The force of the water trying to close the valve gets bigger and bigger.

When the force trying to close the valve becomes bigger than the weight, the valve starts to move upwards. All impulse valves will close when the drive water reaches the right velocity. What that velocity is will depend on how the impulse valve on the particular pump is tuned. The water accelerates down the pipe and out through the impulse valve until it reaches the *closure velocity* and the valve closes.

A graph can be used to show the increasing velocity in the system just as it was for the examples with the tap. If the impulse valve was held open and water allowed to flow out for a long time the graph would show it reaching a *terminal velocity* just as before. The shape of the line on this graph would depend on the feed head, the pipe diameter, the pipe length and the amount of friction through the pump. If the pump was operating normally, the impulse valve would close when the velocity reached the *closure velocity*. This point can be marked on the graph.

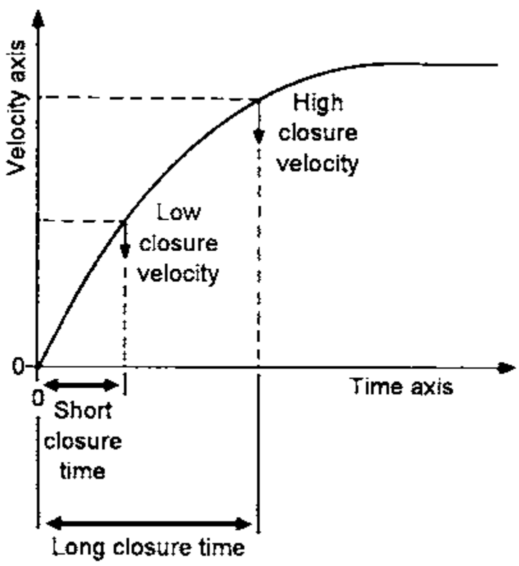


At any ram pump site the settings of the impulse valve (the stroke length and the valve weight) will decide how big the *closure velocity* is. A valve with a small weight and a short stroke has a low closure velocity. It will close when the water reaches only a low velocity. A valve with a large weight and a long stroke will need a much higher velocity to make the valve close. The *closure velocity* of the pump can be changed by making adjustments to the impulse valve — in other words, by *tuning* the pump.



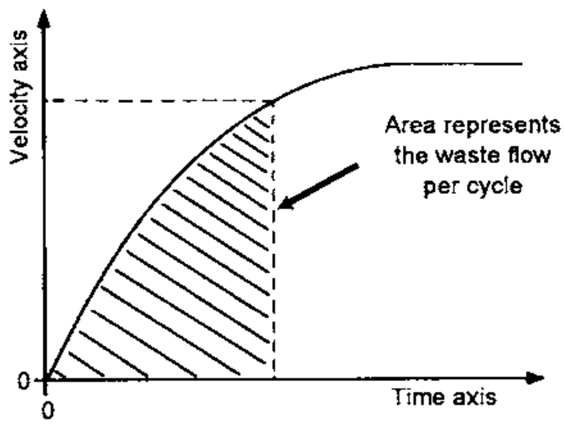
The time it takes for the water to reach the *closure velocity* can be worked out using the same graph. This is done by drawing a straight line across from the Velocity (Speed) axis at the *closure velocity* until it reaches the line on the graph. Another line is drawn from this point straight down to the bottom of the graph where it hits the Time axis. The scale on the Time axis can then be read to find out how long it takes to reach *closure velocity*.

You can see that if the pump has a high *closure velocity*, it will take a long time for the valve to close. If the stroke of the impulse valve was reduced, the velocity needed to close the valve would also be reduced and the time it would take to reach the new *closure velocity* would be less. So, reducing the length of the impulse valve stroke on a pump will make it work faster.

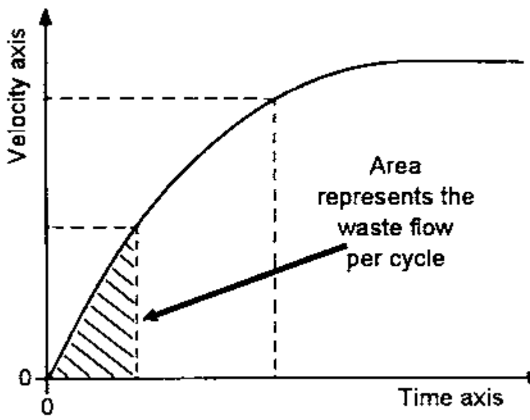


Closure velocity and waste flow

When a pump has a high *closure velocity* a lot of water will flow through the impulse valve before it shuts. This water is often called the *waste flow* for one cycle and can be represented by the area under the graph that has been shaded.

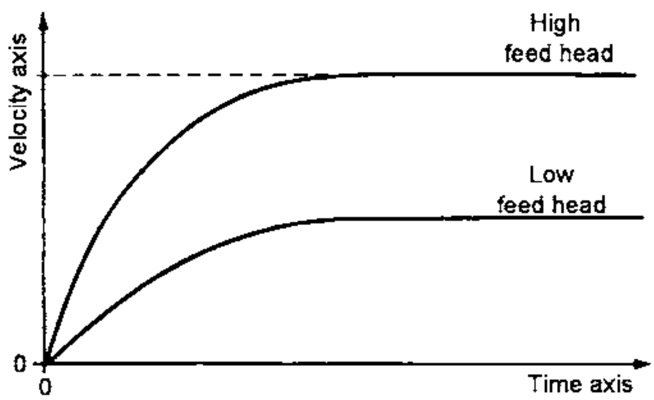


By shortening the length of the impulse valve stroke, the pump can be made to work faster and the *closure velocity* will be lower. The area representing the *waste flow* on the graph will be smaller, showing that the amount of water flowing through the pump (the *waste flow*) has gone down.

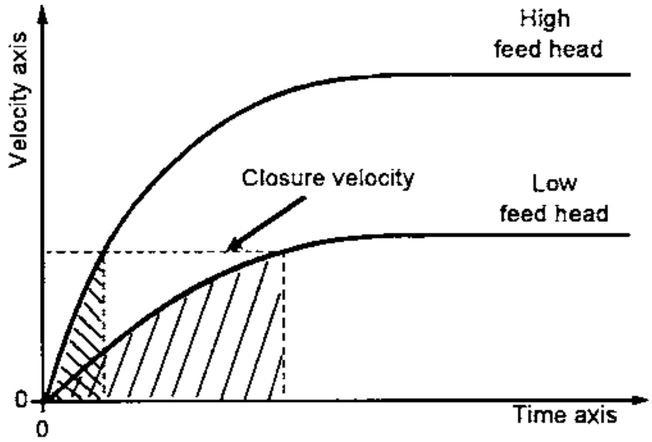


Closure velocity and feed head

You saw earlier with the reservoir, pipe and tap that when the head from the reservoir to the tap was increased, the acceleration was faster and the line on the graph rose more steeply. If the *feed head* of the ram pump system is increased, the line on the graph also rises more steeply.

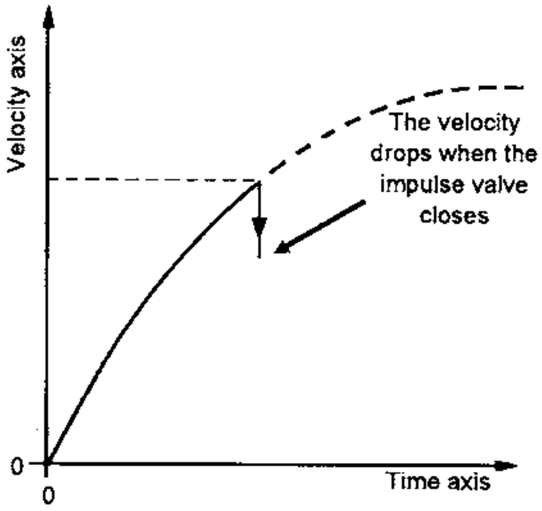


If the same ram pump system was given a different feed head, the *closure velocity* for the system would stay the same as long as the same pump was used and its tuning was not changed. The area under the line on the graph for the system with the higher feed head would be much less, showing that the waste flow was smaller. It would also take less time to reach the *closure velocity*, so the pump would work faster.



Water delivered from a ram pump

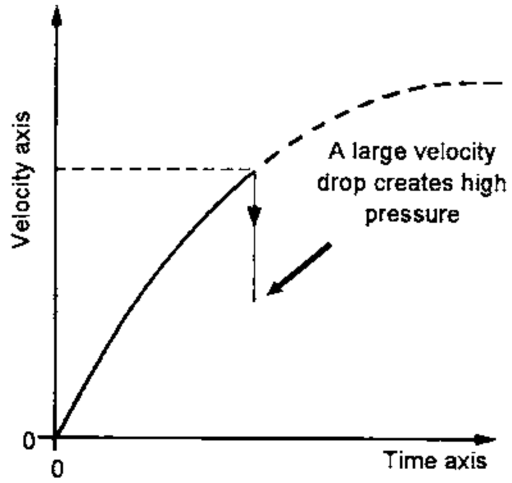
When the impulse valve on a ram pump closes, the water flowing down the drive pipe and through the pump has nowhere to go. The velocity of the water drops very quickly. As the velocity of the water drops, the energy of the moving water is turned into pressure energy. The more the velocity of the water drops the more the water pressure inside the pump rises.



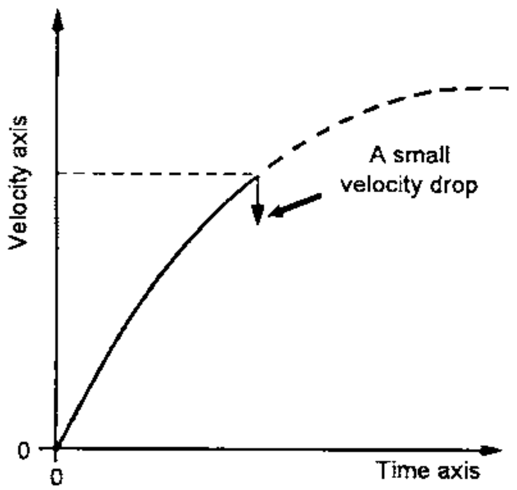
Delivery head

The velocity of the water continues to fall until the pressure in the ram pump is higher than the pressure in the air vessel. The pressure in the air vessel will depend on the height from the pump to the top of the delivery pipe. The height from the pump to the top of the delivery pipe is called the *delivery head.*

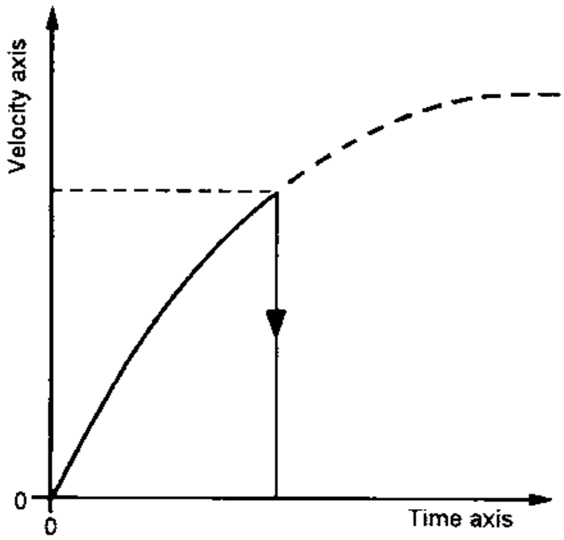
When the *delivery head* is high, there has to be a big drop in the velocity before the pressure in the pump is bigger than the pressure in the air vessel.



When the *delivery head* is small, the velocity only has to drop a small amount before the pressure in the pump is higher than the pressure in the air vessel.

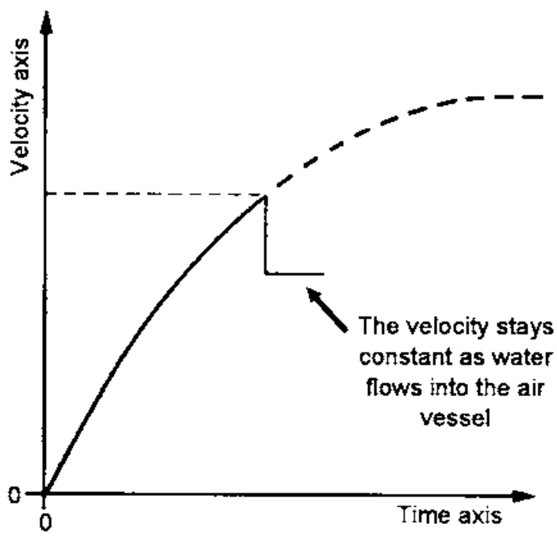


If the delivery head is very high, the closure velocity may be too small. When it is too small, there is not enough velocity to turn into pressure energy when the impulse valve closes. The pressure in the pump rises, but not enough to reach the delivery pressure. The water loses all of its velocity but the delivery valve does not open. The impulse valve may then open again and water flow through, allowing the velocity of the water to increase until the impulse valve closes again. When this happens a pump can work with the impulse valve opening and closing but without the delivery valve opening, so no water is pumped.



Delivery pressure

When the pressure in the pump is greater than the pressure in the air vessel, the delivery valve opens. Water flows through the delivery valve and into the air vessel. The water has lost velocity and gained pressure. It flows at the lower velocity into the air vessel. Water will continue to flow through the delivery valve at this velocity for a certain period of time. The amount of time will depend on the time it takes for a shock wave to travel up the water in the drive pipe to the drive tank and back down to the pump again.



This is more fully explained in the box on the next page. It is not necessary to understand all the details so you can miss out the box if it seems too complicated. All you need to know is that the water flows through the delivery valve at the reduced velocity for a certain period of time. The length of time will depend on the length of the drive pipe. If the drive pipe is short the period of time will be short. If it is long then the period of time that the water flows through the delivery valve will be longer. Remember that the pump is likely to be cycling every second or so, so the periods of time are all only fractions of a second.

More advanced explanation

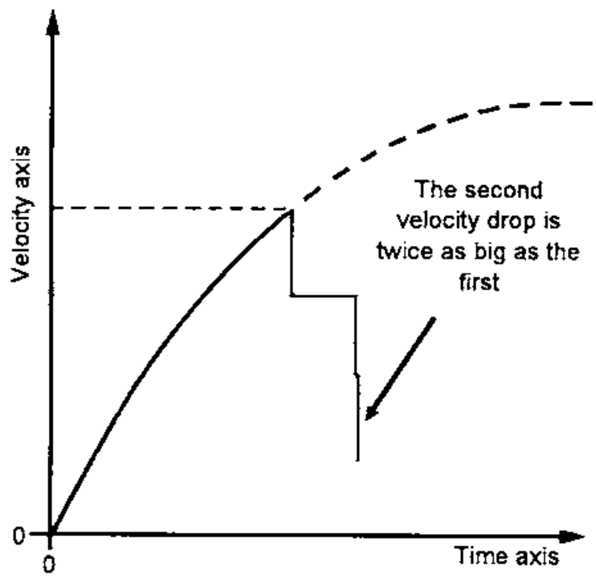
When the impulse valve closes, the water moving inside the pump suddenly slows down. When the first bit of water starts to slow down, its pressure rises. The water behind it also slows down and its pressure also starts to rise. Pressure rises along the drive pipe as all the water slows down and its pressure rises.

Try to imagine a line between the water in the pipe that has slowed down and the water that is still moving at full speed. This imaginary line travels very quickly from the impulse valve up the drive pipe to the drive tank. On one side of the line the water has slowed down and the pressure has risen. On the other side the water is still moving at closure velocity. This imaginary line is at the front of a "shock wave". The drop in velocity of the water across this shock wave is the same as the drop in velocity needed to open the delivery valve.

The shock wave travels at very high speed (usually over 1000 meters per second) up the drive pipe until it reaches the drive tank. The drive tank acts a bit like a mirror that turns things around and reflects them back. It is a low pressure shock wave which travels back down the drive pipe towards the pump.

The time taken for the shock wave to travel from the pump to the drive tank and back again will depend on the length of the drive pipe and the speed of the shock wave. The pressure in the pump, and the velocity of the water flowing through the delivery valve will remain constant until the shock wave has gone up the drive pipe, been reflected and come back down to the pump. The graph below shows that the velocity of water in the pump stays constant for a set period of time. The time will depend on how long it takes the shock wave to go up and down the drive pipe.

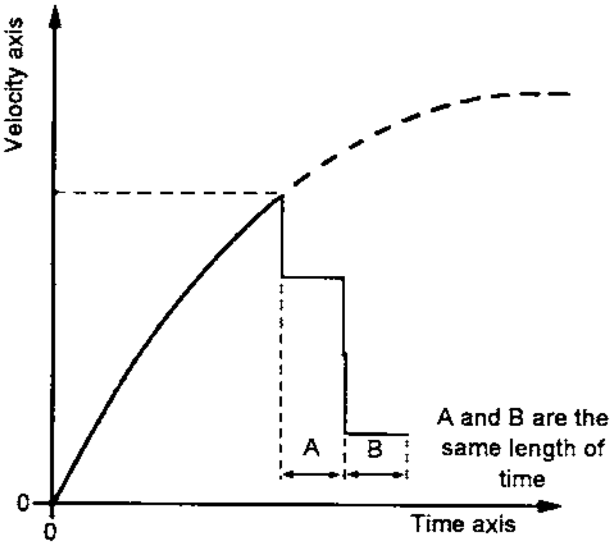
When the shock wave in the drive pipe has returned to the pump, the velocity of the water drops again. This keeps the pressure in the pump high enough to push water through the delivery valve into the air vessel. The second velocity drop is twice as much as it was the first time.



More advanced explanation

When the reflected shock wave reaches the pump the velocity there drops due to the lower velocity of the water *behind* the shock wave. It immediately drops again to recreate the pressure needed to keep the delivery valve open. Both of these drops in velocity are the same size as the first velocity drop when the impulse valve closed.

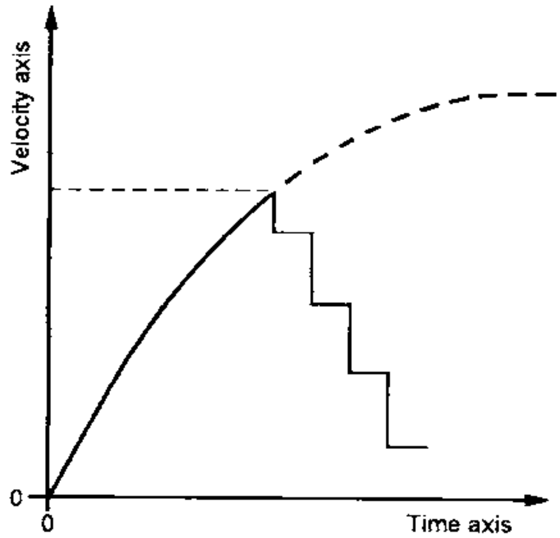
Water continues to flow through the delivery valve at the reduced velocity. It flows for the same amount of time as before, while the second shock wave travels up to the drive tank and back again.



More advanced explanation

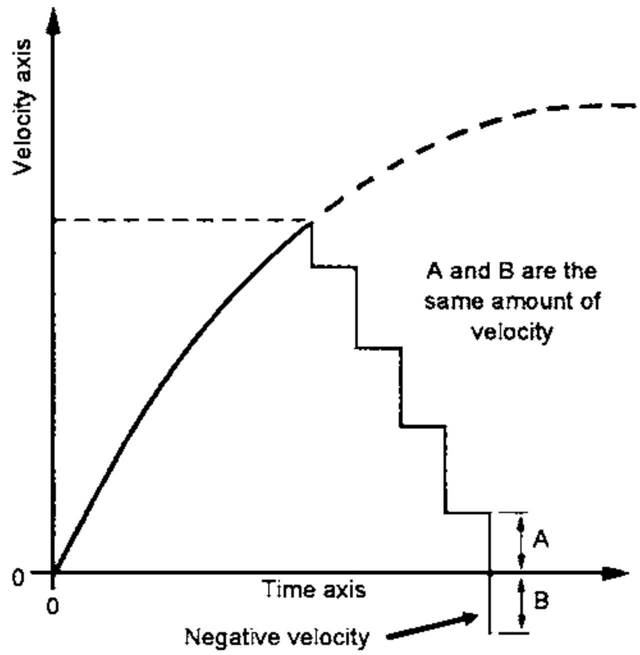
The second part of the second drop in velocity produces another increase in pressure that keeps the pressure in the pump greater than the pressure in the air vessel. Water flows through the delivery valve at the lower velocity. The increase in pressure starts another shock wave that travels up the drive pipe. The second shock wave is also reflected by the drive tank and another low pressure shock wave travels back down to the pump. Water continues to flow from the pump into the air vessel until the reflected shock wave reaches the pump.

Each time a shock wave comes back to the pump, the water's velocity drops again and a new shock wave travels up the drive pipe. Water continues to flow into the air vessel at the reduced velocity. The velocity in the pump continues to step down in this way until there is not enough velocity left to make another full step.



Recoil

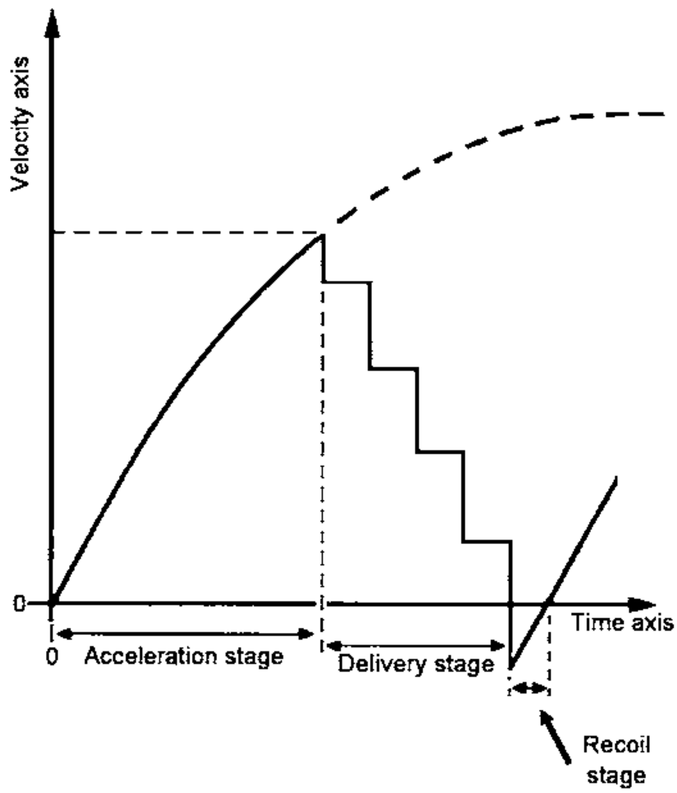
When there is not enough velocity left to make one complete step the pressure can no longer stay high enough to keep the delivery valve open, so it shuts. The water in the system is still moving with a low velocity down the drive pipe. The impulse and delivery valves are both closed so the water has nowhere to go. The water bounces back up the drive pipe towards the drive tank. The water is like a spring that is pushed against a wall so that it compresses and then is suddenly let go. It opens up and flies away from the wall.



As the water moves away from the pump it has a negative velocity, so the line on the graph goes under the base (under 0 on the Velocity axis). The negative velocity will be the same size as the positive velocity that was left when the delivery valve closed. When the water has a negative velocity it moves away from the pump towards the drive tank.

The negative velocity is shown where the line on the graph goes below 0 on the Velocity scale. The water flowing back up the drive pipe slows down and stops, then the line on the graph crosses back over the Time axis. After that, the impulse valve has reopened and the water begins to accelerate down the drive pipe. The line on the graph rises in the same way as before. The section of the graph below the line is called the "recoil" stage of the pump's cycle.

When the delivery valve closes and the water in the pump *recoils* back up the drive pipe, it is actually flowing away from the pump. This leaves a low pressure or vacuum in the pump. The low pressure lets the impulse valve drop open with its own weight.

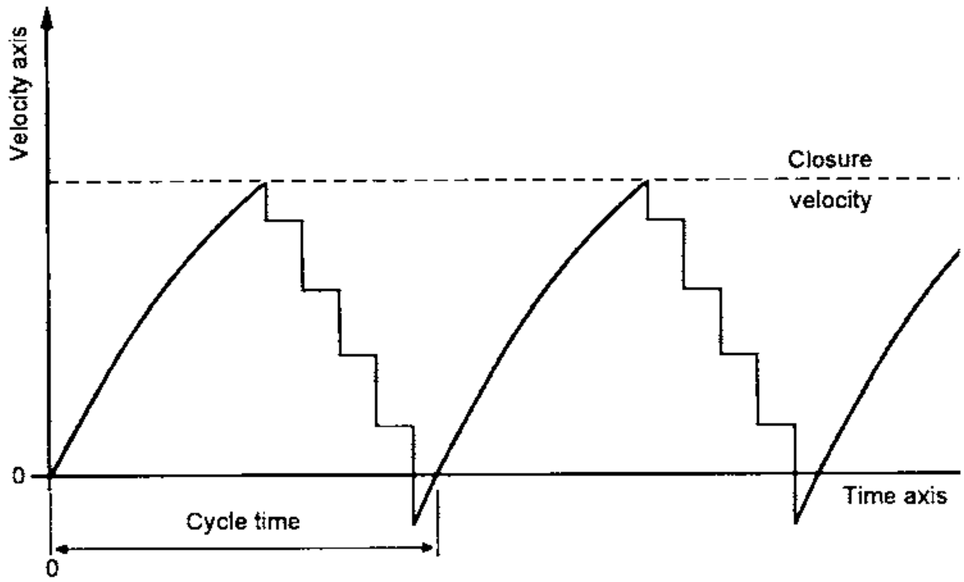


When the water has stopped recoiling, it starts to flow down the drive pipe and out through the open impulse valve again. It accelerates down the drive pipe and through the open valve as it did at the start of the pumping cycle.

The pump cycle

To make the operation of the pump easier to understand the pump cycle can be divided into three stages. They are called the *acceleration, delivery and recoil* stages. There is a very short pressurisation stage as well, but that can be ignored. The graph at the bottom of the previous page shows how these stages refer to different parts of the cycle.

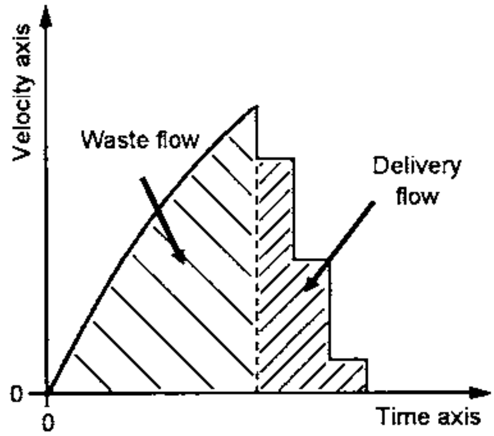
As the pump continues to operate, the same cycle is repeated. The water accelerates down the drive pipe and out through the impulse valve until the velocity of the water reaches closure velocity. Then the stages of delivery and recoil occur before the cycle starts again. The graph can be used to see the time taken for each cycle and work out how fast the pump is operating.



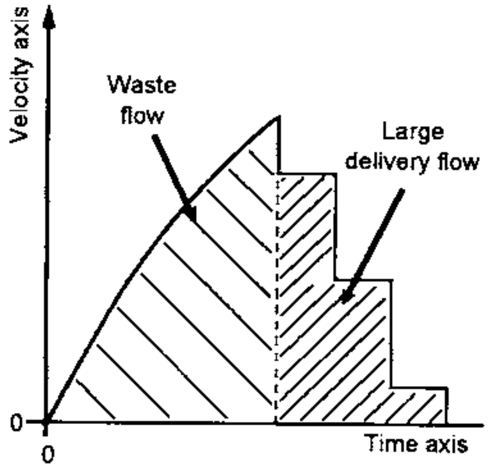
The impulse valve closes and the pump beats every time the line on the graph reaches closure velocity. For a pump working at 60 cycles a minute, the "cycle time" would be 1 second.

Delivery flow

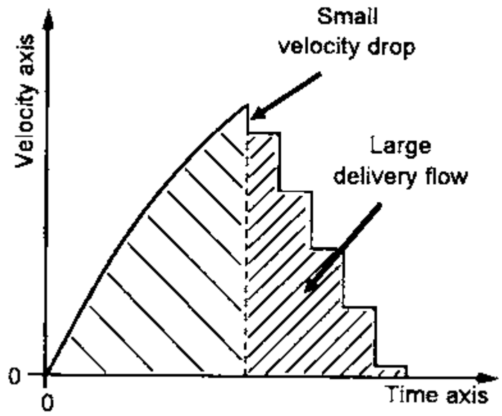
You saw on page 6 how the amount of waste flow could be represented by shading the area under the line on the graph. In the same way, the amount of water flowing from the pump into the air vessel can be represented by the area under the graph during the delivery stage. This is called the *delivery flow* per cycle.



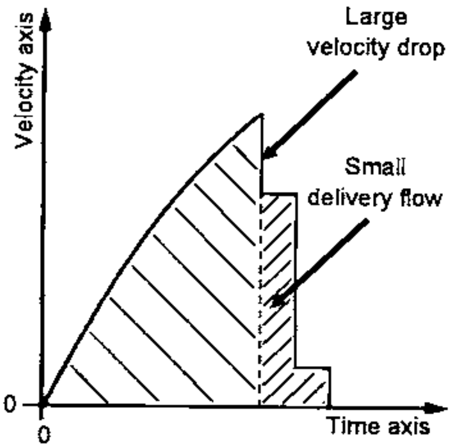
When the area under the falling part of the graph is large it means that there is a large *delivery flow*. Two things increase this area. One is increasing its height. The other is increasing its width either by having more steps or by having longer steps.



Systems with a low delivery head will only need a small drop in velocity to deliver water. The delivery stage will have many small drops in velocity before all the velocity is used up. The large area under the line on the graph shows that a large amount of water will be pumped with each cycle.



If the delivery head of the same system was increased, the acceleration of the water and the closure velocity would be the same but the drop in velocity required to reach the delivery head would be much higher. The graph shows that there would be a few large drops in velocity during the delivery stage of the cycle. The area under the graph during the delivery stage would be much smaller, showing that the flow through the delivery valve was small. Much less water would be pumped with each cycle.

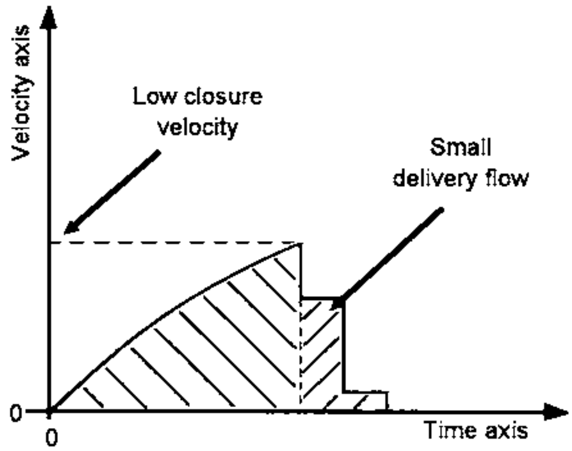


More advanced explanation

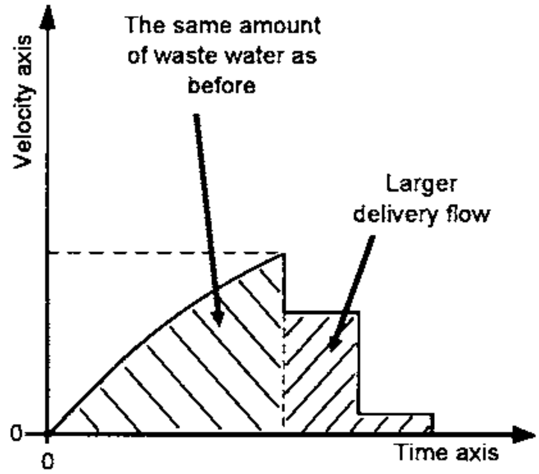
Because the drive pipe is the same length in both of the systems just described, the time taken for a shock wave to travel from the pump to the drive tank and back again would be the same. So the flat sections of the graphs, showing when the water is flowing at a steady velocity through the delivery valve, would each last the same length of time. The delivery stage of the pump cycle in a system with a low delivery head would be longer than it would be in the same system with a higher delivery head. The acceleration time would be the same in both cases and the time for the recoil stage would be very small. When the delivery head is increased, the length of the delivery stage is reduced and the pump operates faster.

Getting the best delivery flow

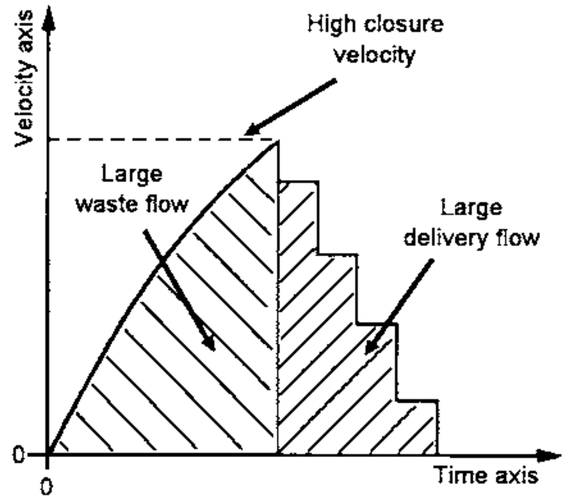
This is explained using an example. Suppose you are asked to design a ram pump site on a stream where the flow of water in the dry season is quite small. There is an obvious ram pump site but it only has a small drop, so the feed head would also be small. If a pump was installed there, the acceleration of the water would be quite low and so the graph would not rise very steeply. The impulse valve of the pump could be adjusted to use all the water available in the stream. With a low feed head, the acceleration and closure velocity would also be low. The pump would not deliver much water.



The owner of the site says that he needs more delivered water than the proposed site would give, so you have to look more carefully at the site design. Suppose that you find that you can double the feed head without too much trouble. Normally the drive pipe length will also double. By keeping the closure velocity the same, the feed flow will hardly change. The delivery head would be increased by an amount equal to the extra feed head, but this has little effect on the flows. Although the drops in velocity would be about the same as before, the steps are twice as wide and much more water would be delivered.



If the same site has plenty of water available in the rainy season, you could recommend changing the tuning of the impulse valve when the stream is full so that the closure velocity was increased. The valve would then take longer to close and much more water would flow through it. The delivery head would be the same as before so the drops in velocity would be the same size. Because the closure velocity would be higher there would be more drops in velocity during the delivery stage and more water would be pumped.



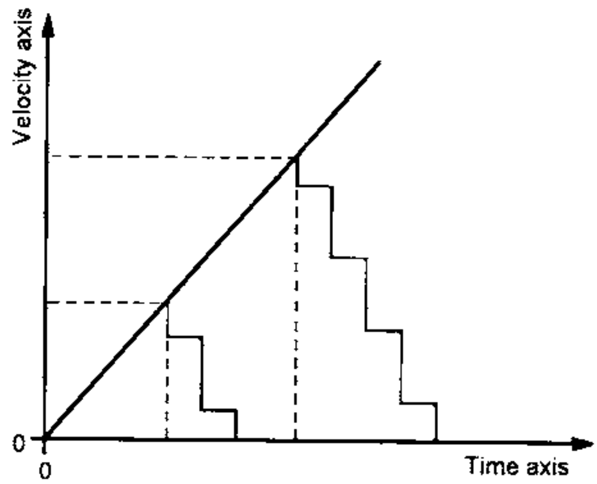
More advanced explanation

As the closure velocity is increased (by changing the settings of the impulse valve) three things happen:

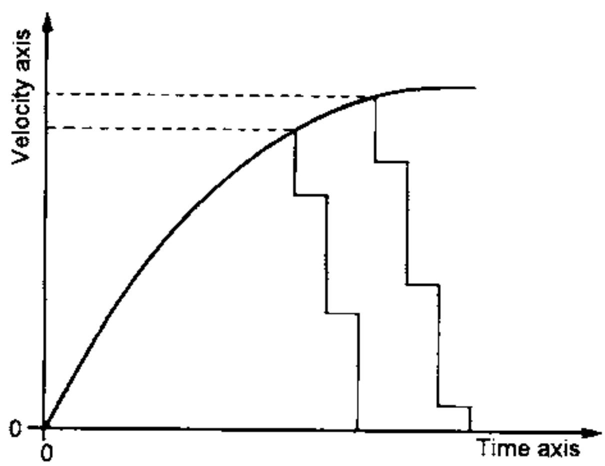
- the drive flow per cycle increases a lot
- the delivery flow per cycle increases a lot
- the pump works a little more slowly (fewer cycles per minute)

The overall effect is to increase both the delivery flow per minute and the drive flow per minute.

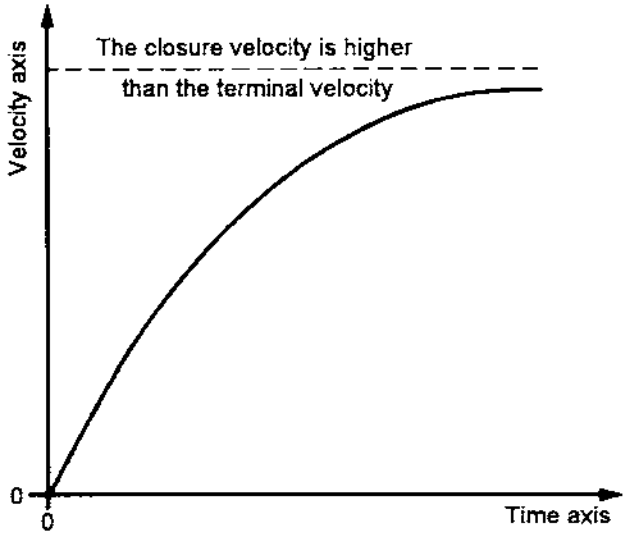
When the closure velocity is in the steep section of the line on the graph, increasing the closure velocity will increase the delivery flow per cycle and the total water delivered by the pump.



If the impulse valve was tuned so that the stroke was very long or the weight very heavy, the closure velocity would be in the flatter section of the line on the graph. The drive flow through the pump would increase a lot but the delivery flow would change very little. The time taken for each cycle would also increase so that there would be fewer cycles per minute. The pump would become less efficient and would actually pump less water per minute.



Increasing the weight and stroke of the impulse valve too much would stop the valve from closing at all. This is because the valve cannot close when the velocity needed to close it is more than the terminal velocity of the water through the pipe.



The following DTU Technical Releases give further information about ram pumps.

RELEASE

An introduction to hydraulic ram pumps

This Technical Release explains briefly what ram pumps are, how they work, and how you might select them. It finishes with a catalogue of the current DTU designs of pump for local manufacture in developing countries.

Contents

A much fuller description of how to design and install ram pumps systems can be found in the book *Ram pumps and the design of ram pump systems*, DTU, UK 1995, which is available from the DTU at the address on the back cover of this Technical Release. A list of Working Papers and other Technical Releases, several of which refer to ram pumps, can also be found on the back cover of this Technical Release.

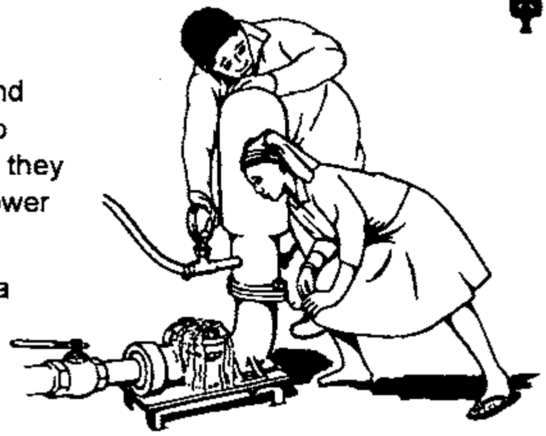
What a ram pump does

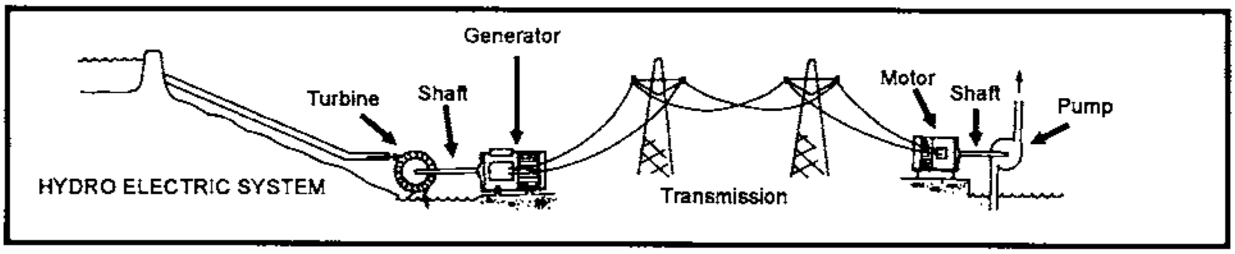


Some ram pumps are made from many parts and look very complicated. Others look too simple to work. Whether they look simple or complicated, they all work in the same way and they all get the power to run in the same way.

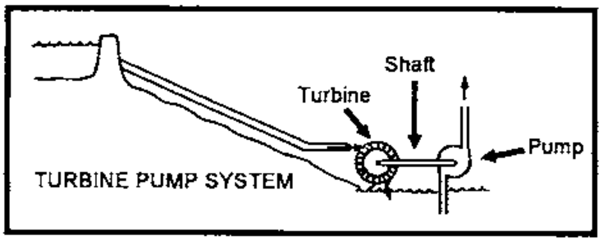
Many people are surprised when they first see a ram pump working. They think that it is driven by a hidden motor, or by magic. They watch it pumping and are amazed.

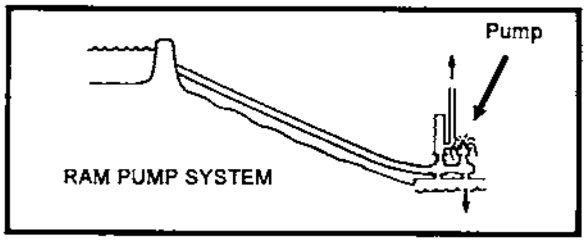
Every kind of pump needs a source of power. They can be powered by people or animals, the wind, falling water, electricity , or fuels such as diesel and petrol. The source of power is often separate from the actual water pump and the two can be joined together by, for example, a shaft. The ram pump uses the power of falling water and there is no separate motor or mechanism that turns the pump. This is why a well designed ram pump can look much simpler than some other pumps. It *is* a very simple machine, although the reasons for it working well are not simple at all.

The drawing below may help you to understand how much simpler a ram pump system is than other ways of using water power to pump water.



THREE DIFFERENT WAYS TO USE WATER POWER TO PUMP WATER

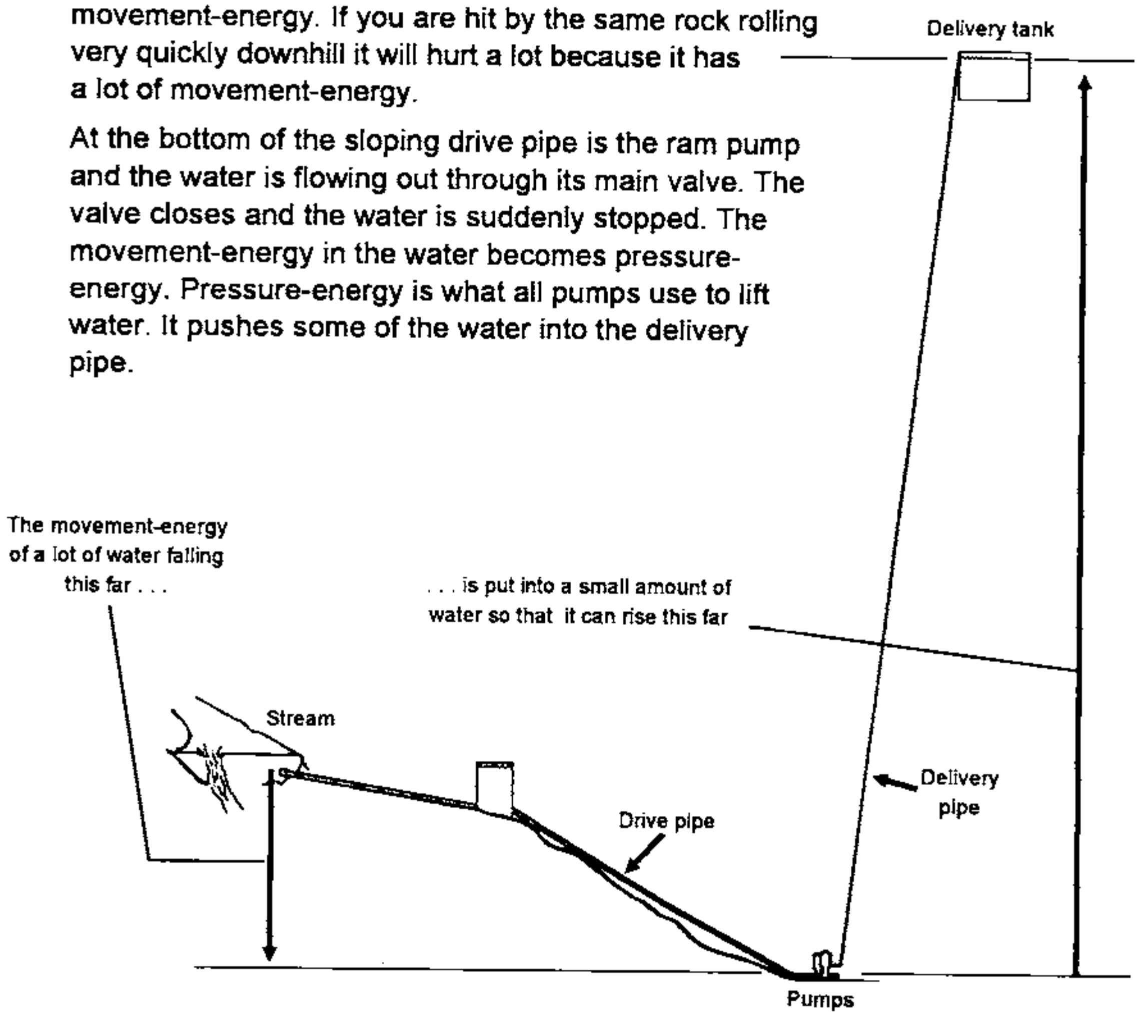




As far as we know, the ram pump was first discovered or invented 200 years ago. Since then it has been rediscovered many times.

Water is diverted from a spring or river and flows down a sloping drive pipe, gathering speed like a rock rolling downhill. As the water gathers speed it gathers energy. The faster it goes the more movement-energy it has. If you are hit by a small rock rolling slowly downhill it will stop without hurting you very much because it does not have much movement-energy. If you are hit by the same rock rolling very quickly downhill it will hurt a lot because it has a lot of movement-energy.

At the bottom of the sloping drive pipe is the ram pump and the water is flowing out through its main valve. The valve closes and the water is suddenly stopped. The movement-energy in the water becomes pressure-energy. Pressure-energy is what all pumps use to lift water. It pushes some of the water into the delivery pipe.



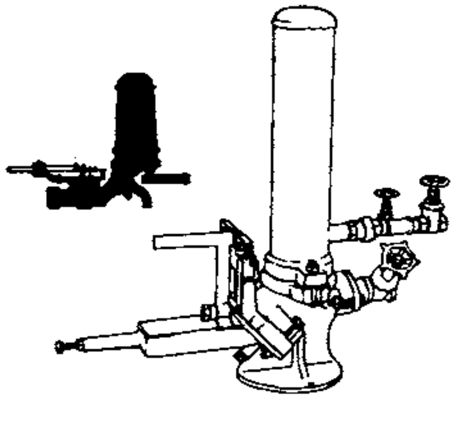
SKETCH OF A RAM PUMP SYSTEM

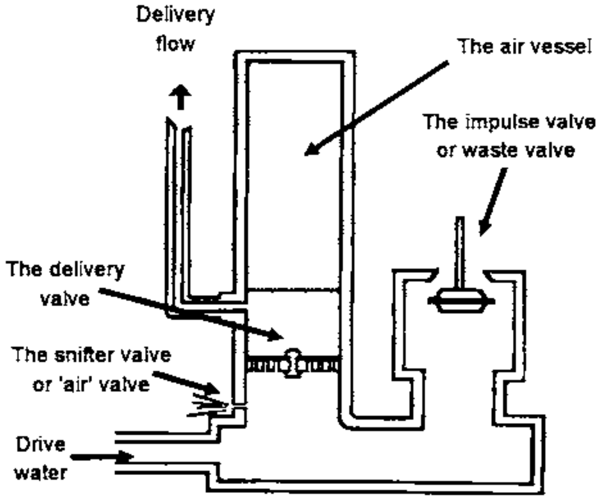
The movement-energy of all the water falling down the drive pipe is put into a small part of that water. The small part of water then has enough pressure energy in it to be 'delivered' to the place where it is needed.

All ram pumps need a lot of water falling down a pipe to provide the energy they use, and they only pump a small amount of the water. This is why they can only be used in places where there is more water than you need to pump. Usually, each pump will pump about 5 to 10% of its drive water. The rest goes back into the stream for other people to use.

The parts of a ram pump

Ram pumps come in many different shapes and sizes but they all have the same basic parts. They all have two main valves, which are an impulse valve and a delivery valve. They also have an air vessel of some kind.



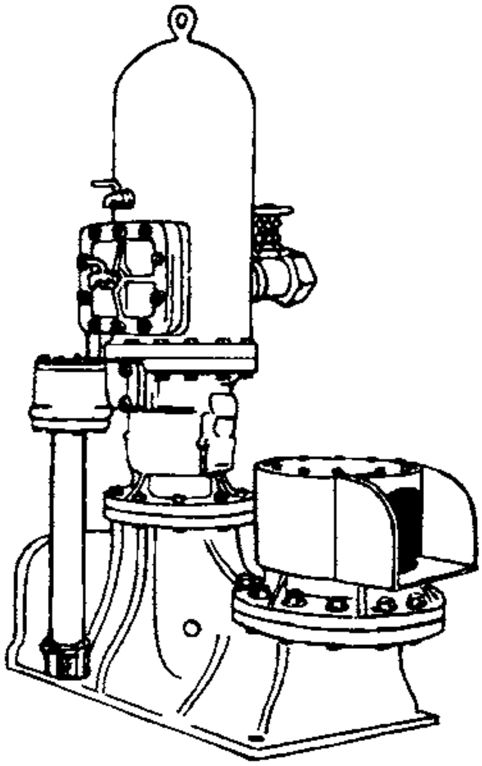


A DRAWING OF A RAM PUMP CUT IN HALF

Most pumps have an air vessel that is slowly filled with air by the snifter valve when the pump is started. The air acts as a shock absorber, absorbing the high pressure surges of the pump. A few modern pumps have an air vessel that is closed by a rubber diaphragm, like the Platypus pump shown on page 12. The pump operator pressurises the air vessel by pumping in air in the same way as you would pump up an inner-tube for a tyre. The diaphragm takes away the need for a snifter valve.

Some ram pumps have the air vessel and the impulse valve the other way around from the pump in the drawing so that the drive water reaches the impulse valve first. Some big ram pumps have more than one impulse valve working together to get the same effect.

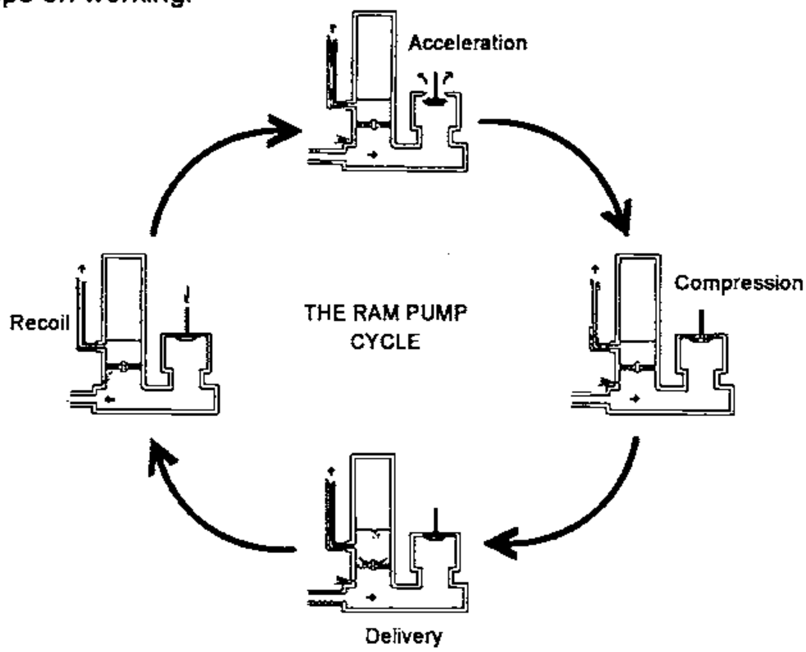
A few pump makers build ram pumps that keep the water that is pumped separate from the drive water. This allows you to pump clean water from a nearby spring while using the power of dirty water from a river or stream. These are sometimes called 'compound' rams. The pumps are more complicated and expensive than ordinary ram pumps, so they are not covered in this Technical Release.



A LARGE GREEN AND CARTER 'COMPOUND' RAM PUMP

The ram pump cycle

Ram pumps have a pumping cycle. The last part of each cycle is the first part of the next, so the pump keeps on working.



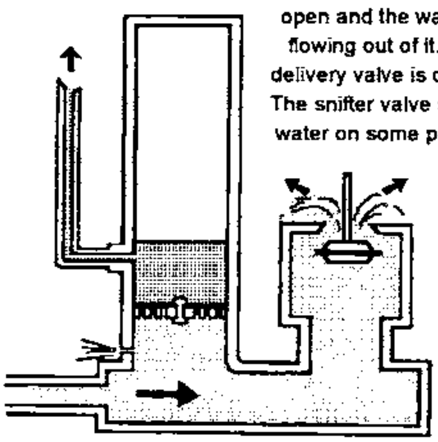
Each cycle happens very quickly, often about once a second. This means that there is no time to see what is happening. The time each stage takes is usually measured in 'milliseconds', which are thousandths of a second. A mosquito flaps its wings about 1000 times a second, so a millisecond is roughly the time it takes for a mosquito to flap its wings once.

It is easiest to explain how the ram pump cycle works by dividing it into four stages called ***Acceleration, Compression, Delivery*** and ***Recoil.***

In the explanation that follows the pump is cycling 60 times a minute, or once a second. The time that each stage takes is given in flaps of a mosquito's wings. Because the cycle takes one second, there are a total of 1000 flaps of the mosquito's wing.

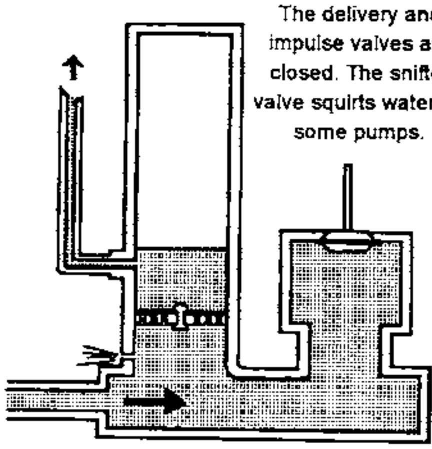
Acceleration (about 900 flaps of a mosquito's wing)
When the impulse valve on the pump is open, water flows down the drive pipe and comes out through the open valve. The water flowing past the open valve drags past it, trying to close it. The flow down the drive pipe and out through the impulse valve gets faster and faster. As it gets faster, it drags harder on the valve until it is strong enough to drag it closed.

The impulse valve is open and the water is flowing out of it. The delivery valve is closed. The snifter valve squirts water on some pumps.



ACCELERATION

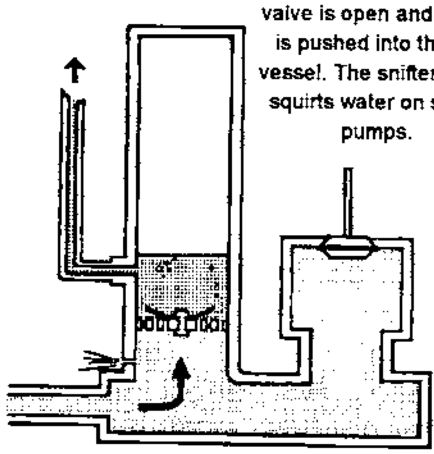
Compression (1 or 2 flaps of a mosquito's wing)
When the impulse valve shuts, the water flowing down the drive pipe cannot come out through it. At the moment the valve closes, the water is travelling very fast and suddenly it has nowhere to go. As it got faster, it gathered movement-energy like the rock rolling down a hill. The movement-energy changes to pressure-energy as it compresses the water in the body of pump. It is as if each small part of the water is bumping into the one ahead as they rush to come down the pipe and escape. As a result there is a sudden rise in pressure that is sometimes called "water-hammer". The pressure rises to a level much higher than the pressure in the pump's air vessel.



The delivery and impulse valves are closed. The snifter valve squirts water on some pumps.

COMPRESSION

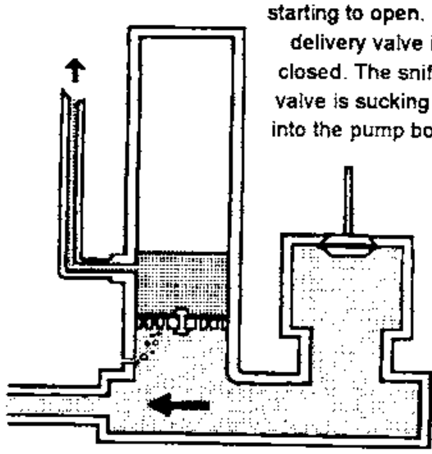
Delivery (about 50 flaps of a mosquito's wing)
Because the pressure rises higher than the pressure in the air vessel, the delivery valve is pushed open and water flows through it. The pressure in the pump body drops quickly to equal the pressure in the air vessel. The water coming down the drive pipe slows down and the pressure in the pump body drops. As soon as the pressure falls enough to be lower than the pressure in the pump's air vessel, the delivery valve closes. The delivery valve is a one-way valve, which stops water flowing back from the air vessel into the pump.



The impulse valve is closed. The delivery valve is open and water is pushed into the air vessel. The snifter valve squirts water on some pumps.

DELIVERY

Recoil (about 50 flaps of a mosquito's wing)
When the delivery valve closes, there is still some pressure in the pump body and drive pipe. The valves in the pump are closed, so the only direction in which the water can move is back the way it came. The water coming down the drive pipe has stopped, so the pressure-energy can be released by moving back up the drive pipe. The water in the pump body bounces back a little way up the drive pipe. This bouncing back makes the pressure in the pump body fall low enough for the impulse valve to reopen. On some pumps the impulse valve includes a spring to help it reopen, on some they reopen because of their own weight. The low pressure in the pump body means that a small amount of air is sucked through the snifter valve. The air waits under the delivery valve until the next cycle when it will get pushed into the pump's air vessel. This makes sure that the air vessel always stays full of air.



The impulse valve is starting to open. The delivery valve is closed. The snifter valve is sucking air into the pump body.

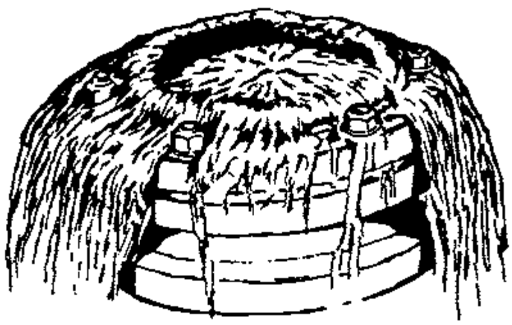
RECOIL

Very quickly, the pressure left in the pump body is released by bouncing back up the drive pipe. When the bouncing back is complete, water begins to flow down the drive pipe again. This is where the cycle started, and the water **Accelerates** down the drive pipe through the open impulse valve.

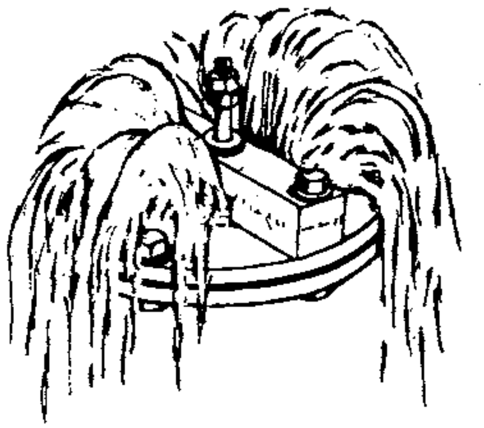
During each pumping cycle only a small amount of water is pumped. Most of the movement-energy harvested from a large amount of water is transferred into a small amount of water. The high pressure in the pump body pushes water through the delivery valve and into the air vessel. It provides the power to push the small amount of water much farther uphill than the big amount of water fell downhill.

Throughout each pumping cycle the pressure in the pump's air vessel is steadily forcing water up the delivery pipe. The air vessel smoothes the pulses of water coming through the delivery valve into a steady flow up the pipe to the delivery tank.

While a ram pump is working, water flows out of the impulse valve and splashes onto the floor of the pump house. This happens during the 'acceleration' phase of each cycle. It is the splashing water and the noise of the "water hammer" that people notice when they see a working ram pump. The water splashing out is often called 'waste' water. Although 'waste' water is not delivered by the ram pump, it is the movement-energy harvested from this water that pumps the water that is delivered. A better name for 'waste' water would be 'used' water. The noise varies from pump to pump. Pumps with impulse valves that have no moving metal parts are the quietest, but they can still disturb people who live nearby. This is because of the water hammer "drumming" in the drive pipe.



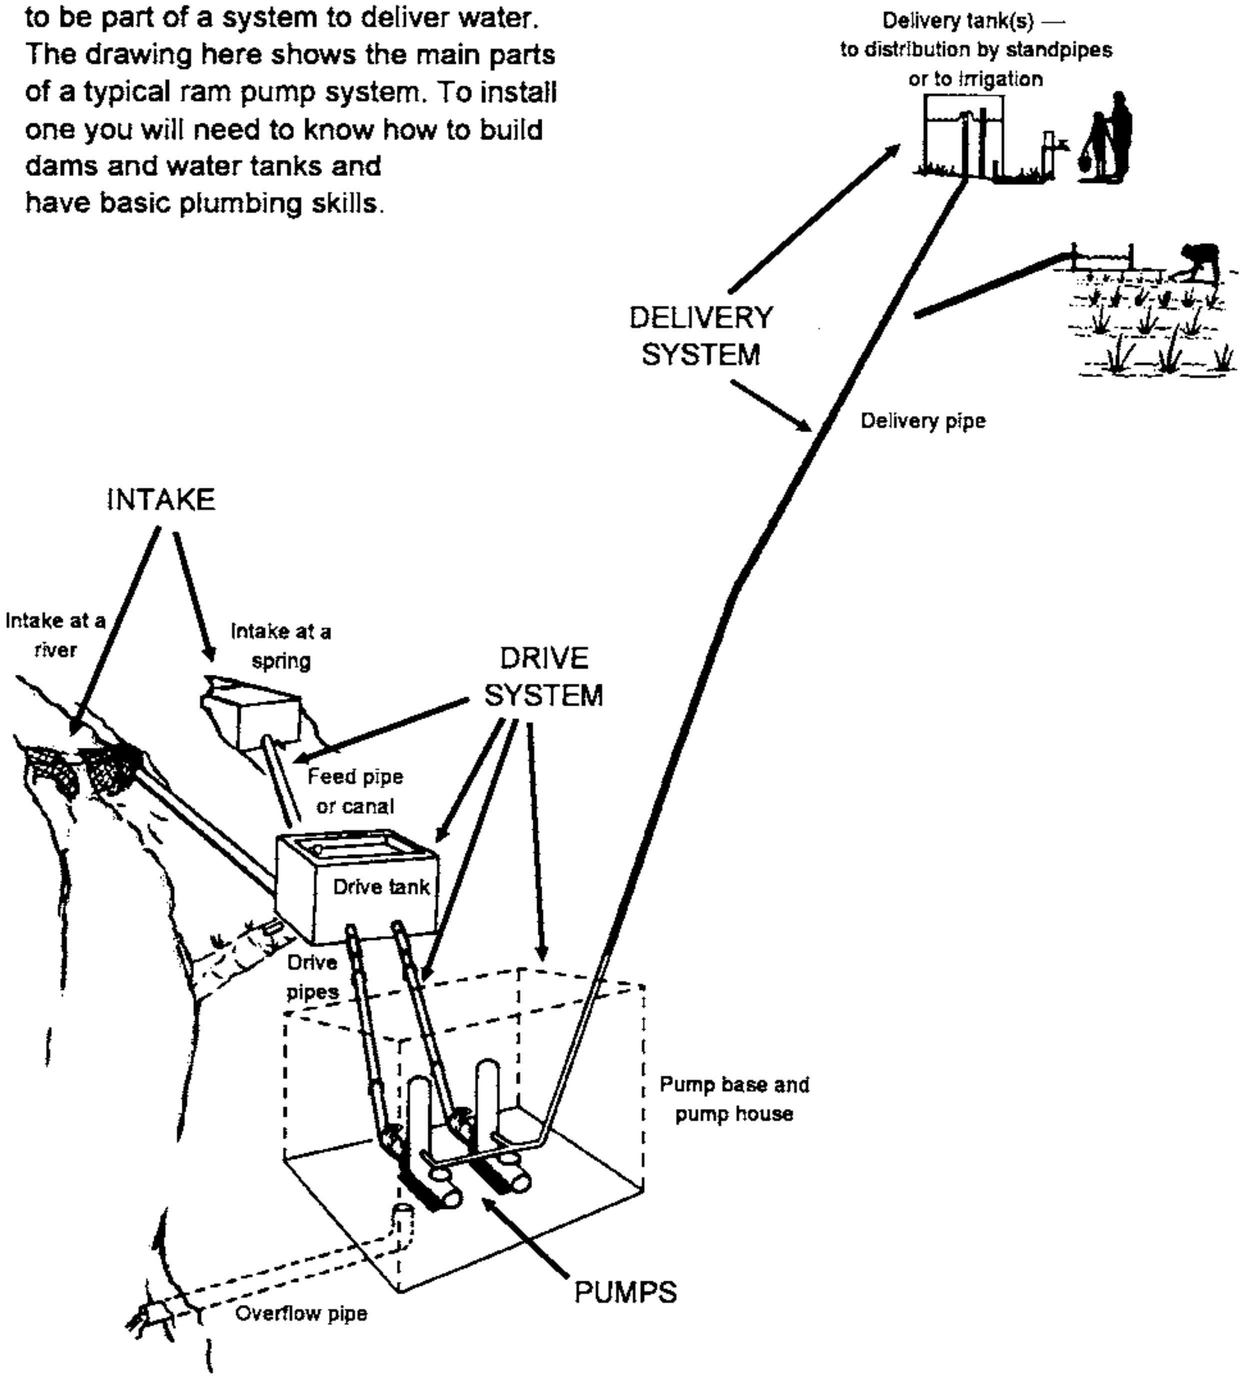
THE IMPULSE VALVE OF A BLAKES RAM PUMP
This has no moving metal parts. It pulses gently and is fairly quiet



THE IMPULSE VALVE OF A DTU M8 RAM PUMP
This splashes and is noisy.

The parts of a ram pump system

A ram pump does not work alone. It has to be part of a system to deliver water. The drawing here shows the main parts of a typical ram pump system. To install one you will need to know how to build dams and water tanks and have basic plumbing skills.



THE MAIN PARTS OF A RAM PUMP SYSTEM

As you can see, ram pump systems can have more parts than some other water pumping systems. This means that they may be more expensive to install. The main advantages of using ram pumps are that they can often be maintained by the users and cost little to maintain and nothing to run.

When to use ram pumps

Ram pumps can only be used where water flows downhill and where there is much more water flowing than you want to pump. They are usually used to lift water from springs or streams in hilly areas. Sometimes they are used for irrigation, but more often they are used for community water supplies.

There is a limit to how high a ram pump can lift. This varies from pump design to pump design. Some pump makers make unrealistic claims for their pumps. Generally, ram pumps with up to 4" drive pipes can deliver a useful amount of water to heights of up to 100 meters. Some pumps cannot pump this high, so check a pump's instructions before choosing which pump to use.

In most cases it is important that the pumps work all year round. They cannot do this if the springs or streams from which they get their water run dry or get very low in the dry season.

A ram pump system is very cheap to run but it does need care and maintenance. The people using the system must be committed to its maintenance and understand how to do it.

The water supplied by any water system to a community must be distributed in a way that meets the people's needs and is seen to be fair. The people must be involved in planning the system, especially the way the water is distributed. They must also be prepared and able to pay for occasional replacement parts.

So, ram pump systems can be useful when there are the following things.

- A flow of water that is dropping quite quickly. It does not have to be flowing steeply in the stream or river. The system designer can usually make the water do that.
- A source of water that has a much bigger flow than you want to pump.
- A source of water that does not get very low or dry up at some times of year. This applies especially to irrigation systems because the time they are needed is usually the time when the water is lowest.
- A place for the pumps that is not more than 100 meters below the place where the water must be delivered.
- A willingness for system care and maintenance to be provided by the community that uses the water.
- A community involved in planning and paying for the system.

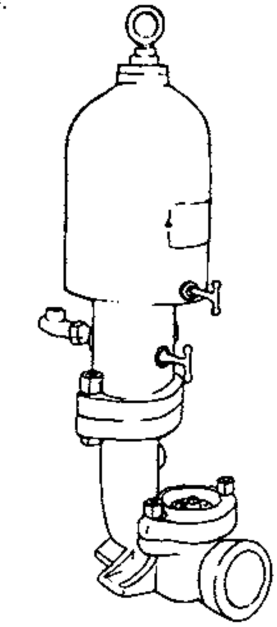
If a site meets these conditions, it is probably worth carrying out a site design survey. A design survey will give a good idea of the amount of water that can be delivered and how much a system will cost.

When you are installing a community supply, remember that many sources of water are not safe to drink. Springs are usually safe but water from streams and rivers is usually not safe to drink. The water must be filtered or boiled before you use it. Slow sand-filters that clean the water can add quite a lot to the cost of a system.

Choosing which ram pump to use

Ram pumps have been made for general sale for well over a hundred years. Many of the early designs were much stronger than they needed to be. Some were also more complicated than they needed to be. A few of the pumps made early in this century are still being used around the world. Many pumps made fifty years ago are still working even though the makers may have stopped selling them a long time ago.

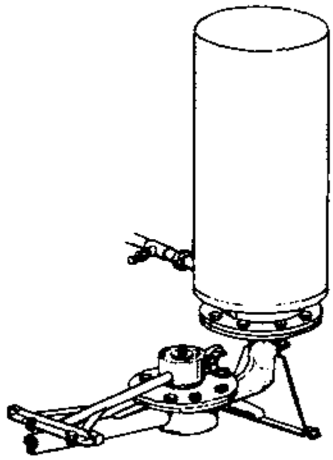
Some of the traditional ram pump makers are still in business at the time this is written. The most famous is perhaps John Blake in the UK. The basic design of their pumps has been so successful that it has been copied by a number of makers from China to Africa.



A SMALL 'JOHN BLAKE' RAM PUMP, UK

Buying ram pumps from traditional makers can be very expensive if they have to be imported. Although some run for years without needing spare parts, others need them frequently. It can be expensive and difficult to get the spare parts and advice you will need. The only way to avoid the spare parts problem is to buy pumps that are made locally or arrange to have your own pumps made. You are probably reading the Technical Release to help solve the problem of lack of advice.

Recently, a number of small engineering firms have started to make ram pumps to meet local demand. Be warned that some of these businesses do not understand ram pumps very well and their pumps can be poorly designed and made. Try to see an example of the pump installed and working before buying one.



A 'DCS' RAM PUMP
Nepal

If you want to make your own ram pumps, several designs are freely available from European organisations. The DTU believes that its own range of designs are the easiest to make in small workshops and give the best performance.

Ram pumps vary a great deal in size, but a single ram pump does not normally pump a lot of water. If a lot of water is needed, two or three pumps are usually installed and they are all left working constantly. For example, if a single pump delivered 5 liters of water a minute to a tank, it would deliver 7,200 liters of water each day. If three pumps were side by side in the system, they could deliver together 21,600 liters of water each day.

Some pump makers produce a range of pump sizes so that you can choose from it a single pump that will deliver enough water for your needs. If you know that the pumps are very reliable and easy to tune, it can be sensible to just use a single pump. If you are buying pumps that are locally made and do not have a well known reputation, it is better to buy two smaller pumps than one big one. Then, when a pump needs to be maintained or repaired, the other pump will keep working and some water will be delivered.

Buying a pump

Which pumps you buy will depend on which pumps you can get.
You will need to find out these things from the maker's instructions:

- The size of the pump's drive pipe. This is the pipe's internal diameter (ID).

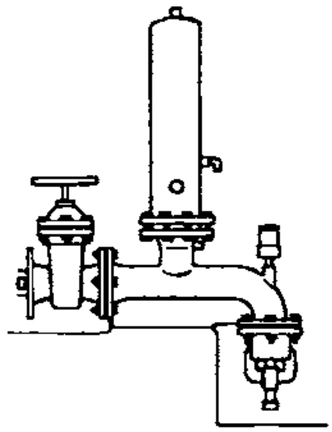
  ☛ *If you choose a pump with a drive pipe bigger than 4" you should get the manufacturers to help design the system.*

- The pump's maximum and minimum drive flow. This is the most drive water it can use, and the least drive water it can use.
- The pump's maximum "feed" or "drive" head. This is the highest feed head that it can use.
- The pump's maximum delivery head. This is the highest that it can pump to.

The instructions also tell you the pump efficiency. It is always useful to know a pump's efficiency but unfortunately pump maker's claims about efficiency are not often reliable.

Imported pumps

If you can afford to buy imported and well known pumps, that may be the best choice. They often cost five to ten times as much as a locally made copy, and between ten and twenty times as much as a pump you make yourself. There are so many ram pumps available for import that it is not possible to assess them here, but most well known names give good and reliable service. Remember that all pumps will need spare parts eventually, and some imported spares are very expensive. If you are installing a system for someone else, remember to make sure that *they* will be able to get the spares when they need them. There are many ram pumps around the world that no longer work because the people who installed them have left the area. After some time the pumps needed parts and the users had no idea how to get them.

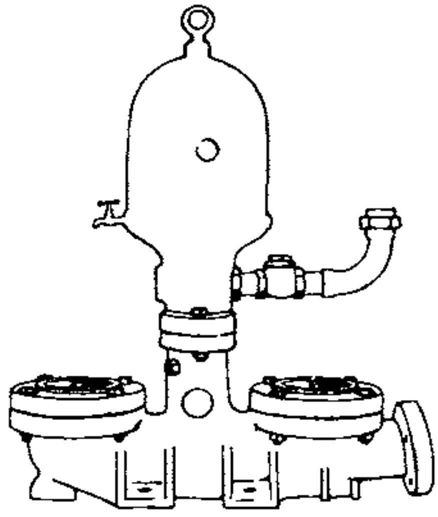


A PFISTER AND LLANGHAUS RAM PUMP, Switzerland

Locally made pumps

There are advantages if you buy from a maker that can be contacted easily when spare parts are needed. Try to make sure that the maker has been in business for some time so that they are still likely to be in business when the spares are needed. Locally made copies of pumps may need a spare part much more frequently, but if the spares are cheap and easy to get, that is not usually a problem. Check any pump that is locally designed very carefully.

The drawing on the right is of a pump made by Jandu plumbers in Tanzania. It is based on a heavy cast-iron John Blake design. Notice that it has two impulse valves so that it can use more drive water and harvest more energy to pump the delivered water.



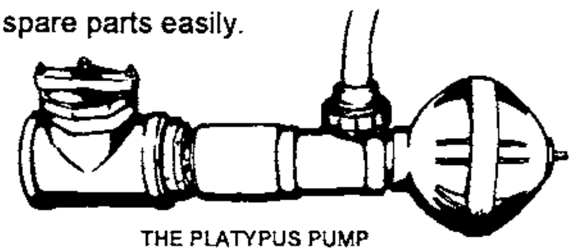
A JANDU PLUMBERS
TWIN-IMPULSE RAM PUMP
Tanzania

What to look for in a pump

With any make of pump, the first thing to check is that the makers give the pump's operating ranges. Do not buy pumps that do not include some instructions that tell you the operating ranges. Even if the pump is good, you will not know how to design the system properly and it may let you down.

- Look at the whole pump. If it looks very complicated with lots of small parts, it is probably more likely to break down.
- Check that the pump is well made. Inspect any welds carefully to see if they are fairly regular and not lumpy.
- Look at the hole or holes around the impulse valve where the water comes out. The combined area of those holes should be at least as big as the hole inside the drive pipe. If it is not, the drive pipe is bigger than it need be and the pump is badly designed. Some pumps with a body that is screwed together from pipe fittings have this problem. Surprisingly, some of the best known pumps also have it. If it is the only thing wrong with a pump it can be ignored.
- Look for any parts that look as if they may bend or break easily and avoid these designs if you can. Pay special attention to the impulse valve arrangement, which has to open and close millions of times a year.
- Check that the impulse valve moves up and down freely and appears to seal. If it has a spring or lever arrangement, make sure it is protected against rust.
- Check that the air vessel is made from thick steel. Usually 3mm is thick enough. If possible, check that the air vessel has been painted or galvanised inside and out.
- Avoid pumps that have already started to rust. They may be old stock, or carelessly made. If the nuts and bolts are rusty it may make the pump hard to maintain. When a pump is being used, the water will wear paint away from some parts very quickly. Those parts will not rust much because the moving water will keep them clean.
- Check that the pump includes a way to attach it firmly to a base or cradle. Pumps made from cast iron often have feet with holes for bolts. Pumps made using pipe fittings may use "U" bolts.
- Look at any rubber parts carefully. If the rubber is starting to perish the pump may be old stock and the rubbers will need to be replaced soon.
- Check that the pump has a snifter valve. It may be a small hole or a valve and is usually in the body of the pump just below the delivery valve. Very rarely the air vessel is made with a diaphragm inside like the Platypus pump shown below. These can be pumped up like a car tyre and do not need a snifter valve. All other pumps must have one. If they do not they can be dangerous.
- Make sure that you can buy spare parts easily.

The Platypus pump has an inflatable air vessel and is designed to run completely under water.



THE PLATYPUS PUMP
Australia

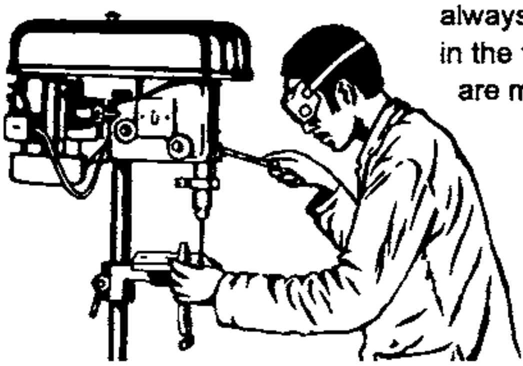
Using an old ram pump

If you have found an old pump that you want to use, contact the makers before deciding to do so. If the makers do not make the pumps any more, you may not be able to get spare parts. Also, you may not be able to find out the operating ranges of the pump.

Engineers may be confident that they can make any part that needs to be replaced. Be warned that the rubber parts on European ram pumps are nearly always made from a very special compound and the pump will not work reliably with anything less.

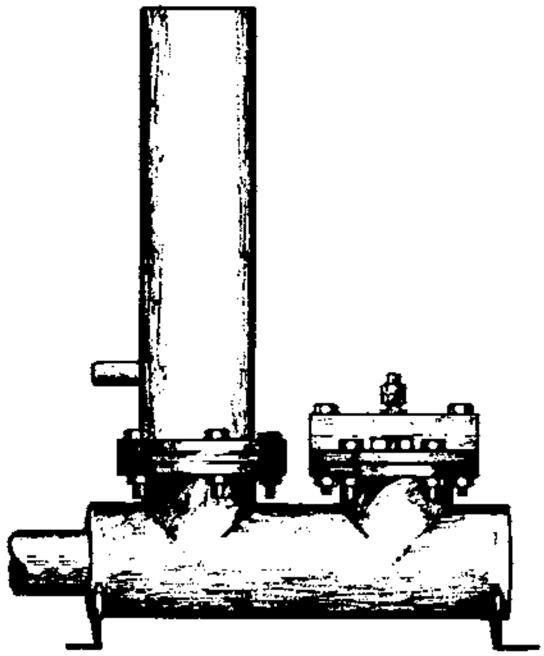
Making a ram pump in a small workshop

There are two big advantages in making the pumps or having them made in a local workshop. The first is that spare parts are easily made and so always available. The second is that the pumps cost so little in the first place. In the case of the DTU designs, the pumps are made from materials that are cheap and easy to get, so the spare parts are also cheap.



There are also disadvantages in making the pumps or having them made in a local workshop. The workshop must have a skilled metalworker to make the pumps or they will almost certainly be unreliable. Also, using cheap and available materials means that some small parts wear out and need to be replaced quite often.

The DTU S2 pump shown in this drawing is built from steel pipe and plate that is widely available around the world. This pump has a high efficiency. It can be made in a small workshop that has welding facilities, a gas cutting torch and a pillar drill.



THE DTU S2 RAM PUMP

The DTU range of ram pumps

Since 1988 the Development Technology Unit has been developing designs for ram pumps. These have been intended to enable small industries in developing countries to manufacture reliable pumps using commonly available materials. The pumps are much cheaper than imported ones but their lives are shorter. Indeed, it is assumed that they will need and get some maintenance over their working lives. Parts most likely to wear out have been made easy to copy and replace.

Three pumps are described briefly here. All are latest versions of pumps used in Africa and Asia for some years. Two are of steel (for respectively 1" and 2" galvanised iron drive pipes) and one is of plastic the P90 (for use with 90mm plastic pressure pipe) The P90 could be made entirely with hand tools. The S1 and S2 require simple power tools (welder, pillar drill) and the skills to go with them. Whilst a lathe or gas cutter are also required to make the steel pumps, the operations involving these machines are so few and simple that they could be sub-contracted to an urban machine shop at little expense.

TABLE OF PUMP CHARACTERISTICS

	S1	S2	P90
Material (mainly piping)	Steel	Steel	PVC or ABS
Drive flow range (in liters per minute)	20 — 60	40 — 120	100 — 360
Drive pipe size (high drive flows)	1"	2"	90mm
Drive pipe size (low drive flows)	¾"	1½	90mm
Maximum delivery head in meters	80	100	20
Maximum drive head in meters	15	15	3
Typical delivery flow in liters per minute	½ — 10	1 — 20	3 — 40
Typical life (assuming minor repairs)	5 years	5 years	2 years

Note that if two pumps are used in parallel, the drive flow and delivery flow of the system will be doubled

S1 pump. This small pump is normally used to supply drinking water to a house or small group of houses. The drive flow is usually taken from a spring.

S2 pump (formerly M8). This medium size pump can be used for water supply to a village or institution, or to irrigate gardens or to water cattle. Its drive flow is usually taken from a large spring or a small stream.

P90 pump. This large pump is mainly used for irrigation, drawing its drive water from a (diverted) stream or drop-structure in a canal.

For full details of each pump see other DTU Technical Releases:
TR 11: The DTU S1 ram pump
TR 12: The DTU P90 ram pump
TR 14: The DTU S2 ram pump.

RELEASE

STEEL FOUR FRAME CART FOR ONE DONKEY

Development Technology Unit, Department of Engineering, University of Warwick, Coventry, CV4 7AL UK, tel: +44 (0)203 523523 extn 2339, fax: +44 (0)203 418922, email: esceo@eng.warwick.ac.uk
KENDAT, PO Box 61441, Nairobi, Kenya, tel/fax: +254 2 766939, email: kendat@africaonline.co.ke

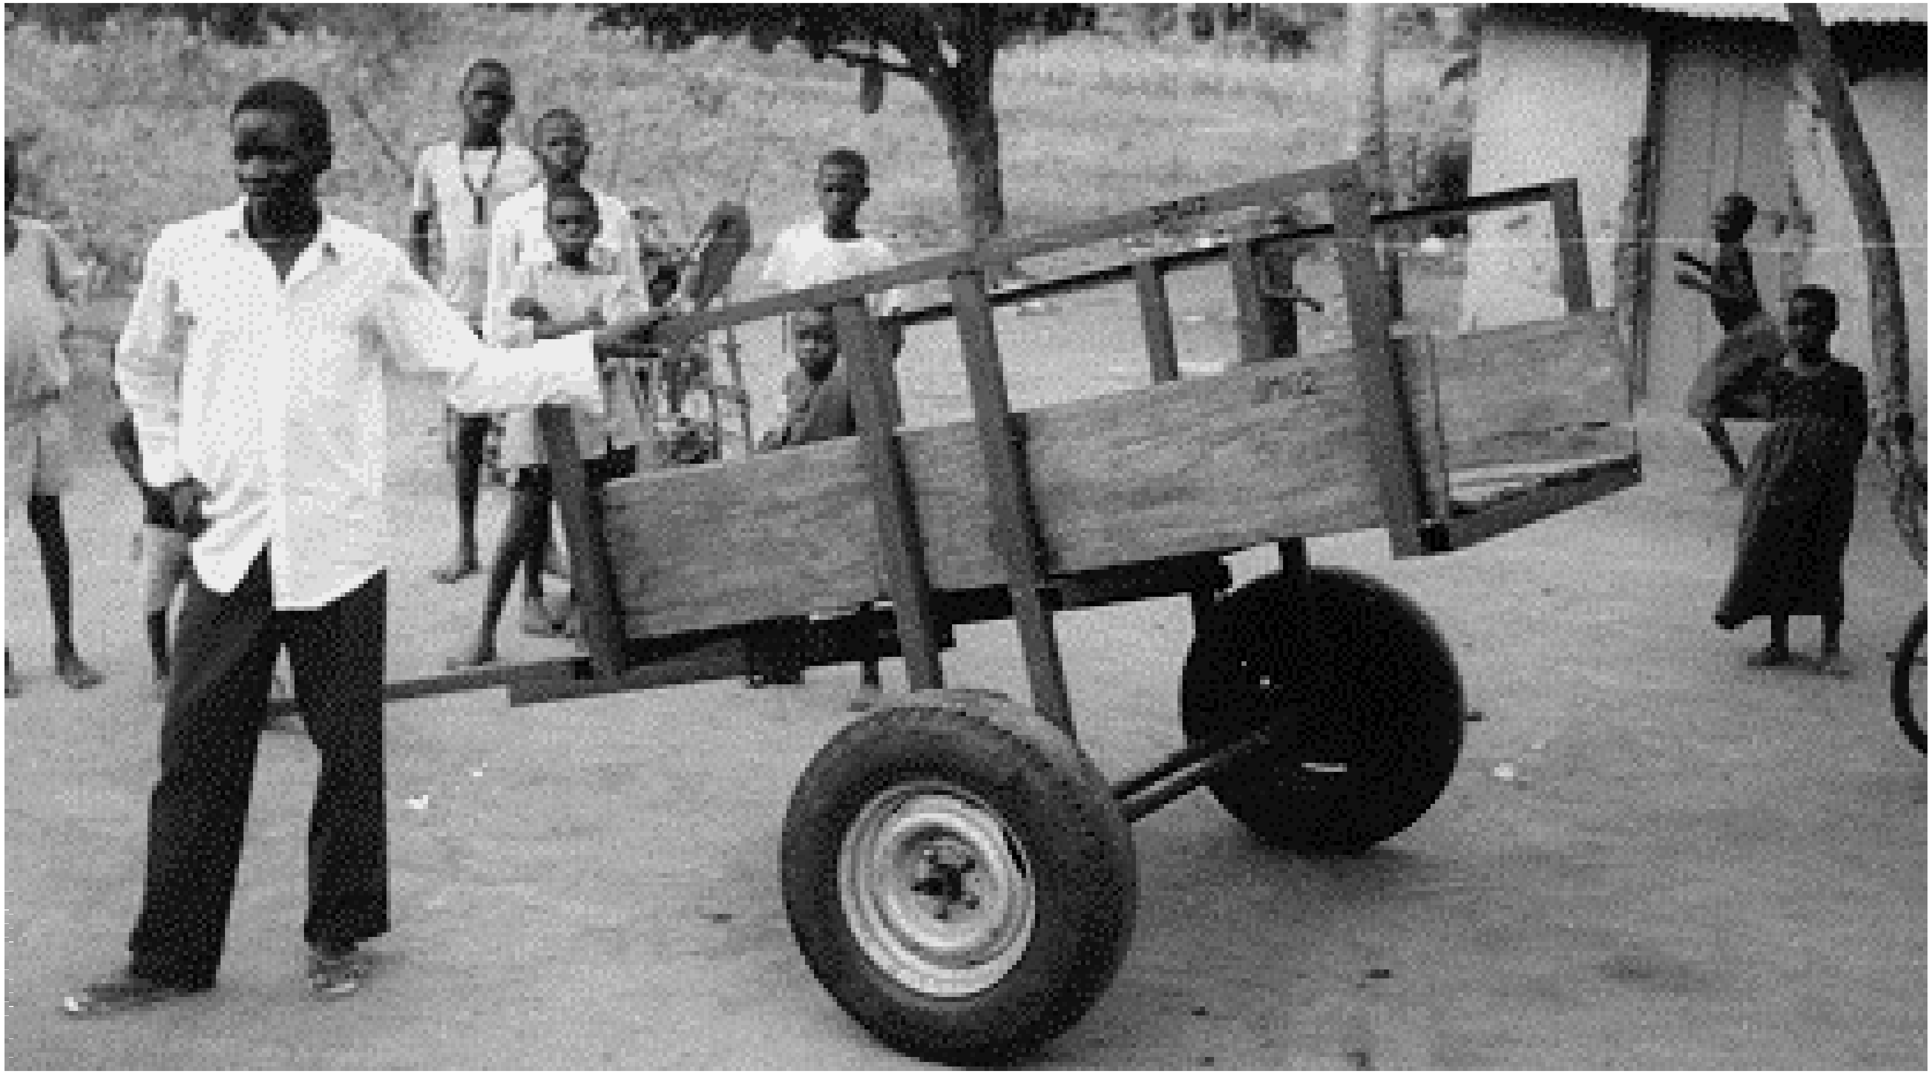

Figure 1: four frame cart with extended frames and twin live axles.

Steel four frame cart for one donkey

This is a light cart for one donkey or for use as a handcart. It is made from square steel tube welded together and timber planks fixed with clenched studs. The planks are part of the structure of this cart and so must be fitted.

Suitable axles

We recommend that you use the PVC plain bearing fixed axle described in Technical Release 28 with this cart, or one of the twin offset axle systems described in Technical Release 36, 37 or 41. An alternative is the needle roller bearing axle described in Technical Release 21, but this is more difficult to make.

You should find that you can make the body for about £$_{UK}$50, depending on the cost of the materials and labour. Once you get organised, two men can probably make one body in a day. We've designed these carts to be easy to make.

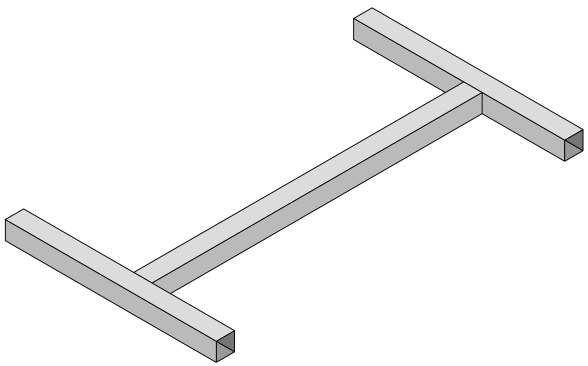

Figure 2: an H shaped centre frame.

To make this cart you must have a simple welder, a woodsaw, a hacksaw, and a hammer.

Construction step by step

Table 1 shows a cutting list for a complete cart body. Recent (1998) prices of materials in Kenya are shown converted into £$_{UK}$.

1) Start by getting all the material together and clear a space to work. Ideally you will be able to work on a flat area of concrete.
2) Cut the 50 × 50 box section steel into the right lengths, as in the cutting list, then cut the bottom and side planks. Lastly cut the 6 mm or 8 mm diameter re-bar for the fixings ie studs.

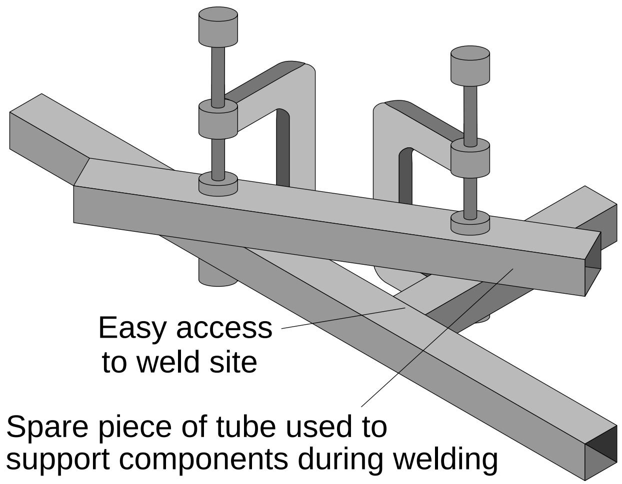

Figure 3: supporting components during welding.

3) Next make up the two H shaped central frames which will support the axle. Figure 2 shows one of these. Figure 3 shows how two pieces of square tube may be held in the right place when welding. Once you have made one frame, make the other the same by welding it on top of the first.

4) Then make up the U shaped end frames as shown in Figure 4. Again, make them as accurately as you can by building them on top of the H frames.

5) Now stand the H frames on the two axle support beams, tack or spot weld them and check that all the joints are square. Figure 5 shows what the finished centre frame assembly should look like.

Table 1: materials and costs.

component	material	# lengths & length reqd [#*mm]	total material in cart [mm]	materials cost in Kenya [£UK]
animal shafts	50×50 RHS	2×2200	4400	8.80
body frame bottoms	50×50 RHS	4×1000	3000	6.00
body frame sides	50×50 RHS	4×325	1300	2.60
axle struts	50×50 RHS	4×625	2500	5.00
axle beams	50×50 RHS	2×400	800	1.60
shaft strengtheners	8mm to 12mm round bar1	8×600	4800	1.52
draw pole loop	12mm round bar	2×500	1000	0.32
axle strut braces	8mm to 12mm round bar	2×600	1200	0.38
axle fixing studs	M12 threaded rod or bolts	2×100	200	2.00
axle fixing loops	6mm dia re-bar or similar	2×200	400	0.04
plank fixing staples	6mm dia re-bar or similar	30×250	7500	1.25
tray bottom planks	1"×6" or similar timber	6×1800	10800	3.54
tray side planks	1"×6" or similar timber	4×1800	7200	2.36
tray ends	1"×6" or similar timber	4×900	3600	1.18
TOTAL				36.59

6) Now you can fit the side and the bottom planks to the end frames and then the middle frame. Figure 6 shows how to position these studs and how they can be tightened with a hammer and a weight or another hammer.

7) Fix the axle to the axle support beams as described in the Technical Release on the axle you have chosen.

8) Nearly there! Now you need to fix the draw poles or 'shafts'. It is best to fix them to the body so they can be taken off and replaced if they get damaged. Figure 7 shows how they can be fixed using short lengths of round bar.

9) Figure 8 shows how you can make the ends of the load tray easily removable.

10) Paint or creosote the cart. You've finished it!

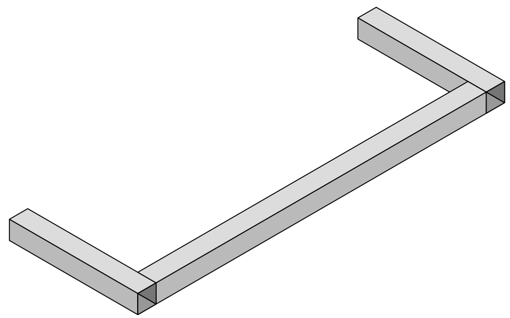

Figure 4: a U shaped end frame.

Modifications

You can try longer or shorter carts and you can make them wider or narrower. When you do this, check the length and width of the planks of wood that you will use to avoid waste. Figure 1 shows a cart made in Uganda with axle support struts extended upwards to carry light foliage.

Cart Drawings

You will find two drawings on the next pages, the first one gives a general view of the cart, and the second gives a view of the main components. As we have said you can vary the size of the cart quite a bit.

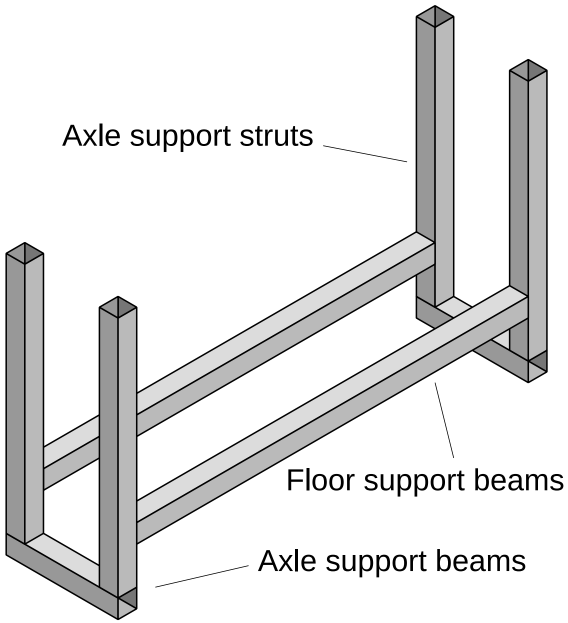

Figure 5: finished centre frame assembly.

Other DTU cart developments

The DTU has been working on a range of cart body types for use with both donkeys and oxen. It has designs for both wooden and steel framed types. The wooden types are cheaper in material terms, but the steel framed ones are easier to make because the joints are more straightforward - but you can make either type of cart in only a day or two.

The DTU has also been working on new designs of wheels, hubs and bearings to bring down their costs and make things more locally manufacturable. We have developed easily made wooden bearings, bearings from PVC pipe, axles using old ball races and axles where you make your own roller bearings.

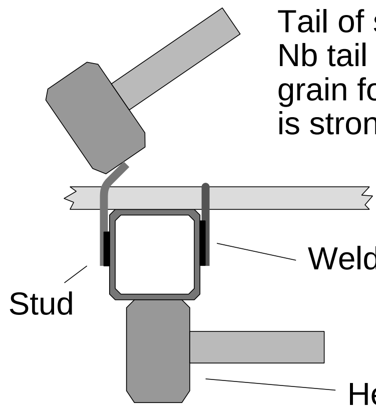

Figure 6: fixing planks to frame with clenched studs.

Technical releases for all these are available.

Acknowledgements

The DTU is grateful to the DFID (British Government) for the financial support necessary to carry out the research and development project under which this product was developed.

The DTU would also like to thank Dr Pascal Kaumbutho of KENDAT in Kenya and Mr Joseph Mugaga of TOCIDA in Tororo, Uganda for their very considerable help with this project. A large number of other people and organisations have contributed to the success of the project, most notably Mr Anthony Ndungu in Kajiado Kenya, Mr JD Kimani in Kikuyu Kenya and Mr Joseph Gitari in Wanguru Kenya in whose workshops most of the development work of this project was performed. Thanks are due also to Mr Stanley Lameria in Kajaido, Mr Patrick Gitari in Wanguru and Mr Mathew Masai in Machakos for their assistance.

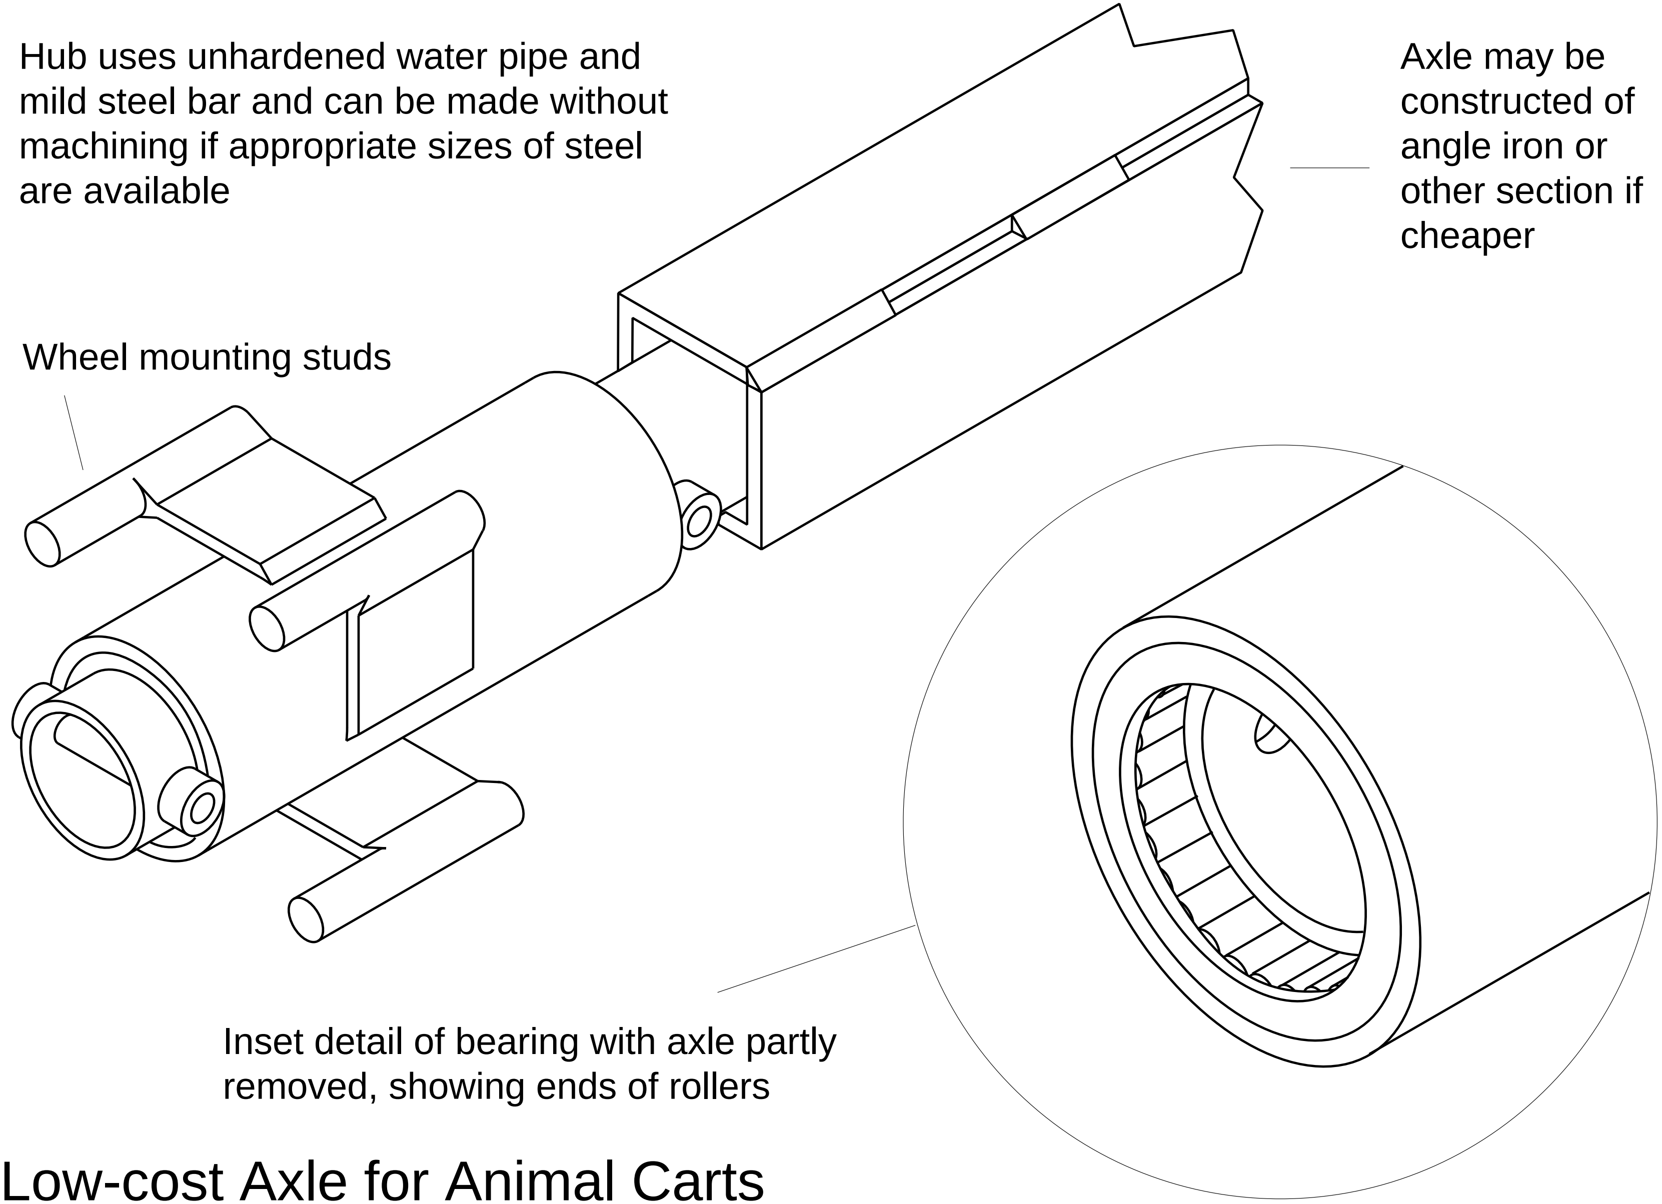
PIPE AND ROLLER DONKEY CART AXLES

Development Technology Unit, Department of Engineering, University of Warwick, Coventry, CV4 7AL UK, tel: +44 (0)1203 523523 extn 2339, fax: +44 (0)203 418922, email: esceo@uk.ac.warwick.eng



Low-cost Axle for Animal Carts

TR21: 1st August 1994

Pipe and Roller Donkey-Cart Axles

Introduction

Not enough farmers in Africa have animal carts. Those who have carts can take their produce to places where they can get the best prices. They can also get into town and buy fertilizer and better seeds and move stuff around their farm easier. The trouble is that carts are too expensive for many farmers. The question is what can be done about it?

Carts are made in many different places. Some carts are made in factories in industrial countries and some are made in factories in Africa, but most are made by local blacksmiths or carpenters using scrap car and Land-Rover axles. These people cannot get enough axles to meet the demand so the price is high. Another problem is that the axles are often so worn that they do not last long. Lots of farmers take the diff (differential) unit out of the axle too, which makes it break sooner and lets the dirt in.

What you need is an axle which blacksmiths and fabricators can make with fairly simple tools - without having to get parts machined. There are usually blacksmiths and fabricators in the small market towns used by the farmers. Experts think that having the cart maker close to the farmer is a good thing because they can talk to each other easily and sort out any problems. And of course if the cart is made locally, it can be repaired locally, so there will not be problems with spare parts.

Idea behind design

The idea behind the design of axle described in this technical release is to allow construction without the use of machine tools (lathes and milling machines), and using materials which should be readily available. The materials can be used 'as bought' - no hardening of any of the components is needed. The only tools which you must have are a hacksaw, a file and a drill able to drill a 13mm hole in steel. Having a vice is also very handy.

Of course if you do have power tools - especially a power hacksaw or cutoff wheel - things can be made much faster. This axle is suitable for a wide range of production methods.

The long thin needle rollers in this design have been used so that the hubs will usually fit scrap car wheels. Most wheels have a hole in the middle for the axle. This hole is usually about 60mm diameter, or a bit bigger. Sometimes they are smaller and the wheel will not fit. You can sometimes saw or file the hole bigger. Putting the fixing studs on struts like you see in the drawings means that you might be able to bend the struts a bit to fit a different wheel. Or if that does not work you can even cut nearly through the welds and then weld them in the right place. You could even cut the struts right off and weld on a different number if your wheels have a different number of holes.

Performance

We have tested axles like these for more than 10 000km in the laboratory and some axles have been ok for 30 000km. Usually we set the load at 200kgf per wheel, but we have used them at 400kgf for thousands of km. Sometimes you need to clean them out and regrease them. Some of the axles we have tested have not been very round at all - one was more than 1mm out, but they have still worked. We have tried rollers made out of 6" nails with the heads cut off. They still worked even though they were slightly bent. (The symbol " means inches so 6" means about 150mm since there are 25mm in one inch.)

component	material	number & lenghth required [no.×mm]	total material in axle [mm]	materials cost in Nigeria [$us]
central axle	2" angle iron[1]	2×1200	2400	3.94
hub stub axles	1¼" BSP malleable iron pipe	2×350	700	4.71
hub tube	2" BSP malleable pipe	2×164	328	1.47
rollers	5 mm or 3/16" dia BMS[2]	60×152	9120	2.49
roller retaining rings	5mm or 3/16" dia BMS	4×167	668	0.20
axial thrust rollers	16 mm dia BMS[3]	4×8	32	not used
hub restraint bolts	M8 or M10 bolts ×70mm	70×4	280	1.28
wheel studs	12mm studding	8×70	560	2.55
wheel stud struts	6×40 black steel strip	4×37	148	0.68
stud washers	3×40 BMS strip 4	4×40	160	not used
TOTAL COST =				17.32

1 Axle could be one piece of pipe with the stub axles - see text.

2 BMS = bright mild steel round bar.

3 Thrust rollers can be made from a stack of washers. They are not essential but give better performance.

4 Backing washers, placed on the stud before the wheel, make the wheel more secure if it has large stud holes.

Cutting list and costs

The table shows a cutting list for a complete axle - two wheel hubs and stub axles joined by an angle iron section in the middle. We did this because angle iron was much cheaper than pipe. But if it is not where you are then make the whole axle out of one piece of pipe. Recent prices of materials in Nigeria are shown in $\$_{US}$. The 2" BSP (British Standard Pipe) is about 60.8mm outside diameter, or a bit less, with a wall thickness of about 3.6mm. The 1¼" BSP is about 42.9mm outside diameter, with a wall thickness of about 3.2mm.

Construction step by step

These instructions deal with making an axle to the design shown in the drawings. If you find that you cannot get the right sizes you might still be able to make an axle with other sizes. See the **Modifications** section on page 6.

1. The first and probably most difficult job, is to get some suitable pipes and roller material. Obviously the axle has to be strong enough to carry the cart, so it should **not** be made from pipe smaller than about 40mm outside diameter. You must make sure that the pipe has a wall thickness of more than 2.5 mm.

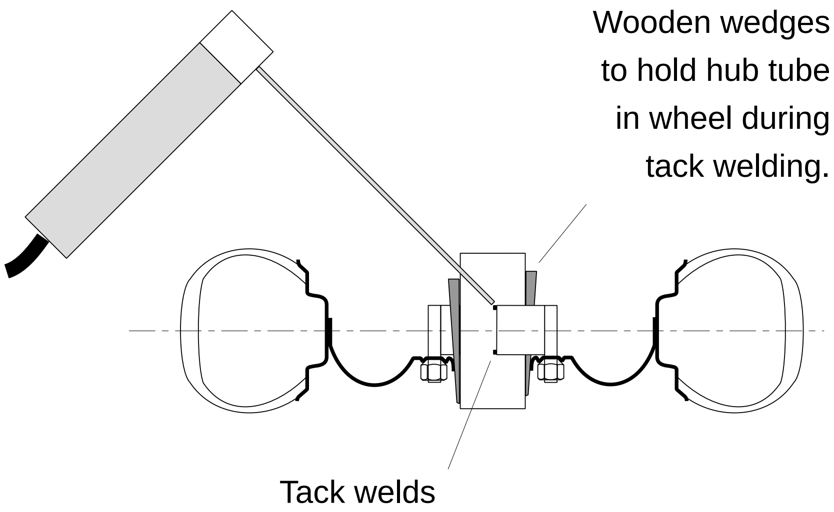
   The hub pipe must also have a wall thickness of 2.5mm or more. And it must have a bore (or inside diameter), which goes over the axle with enough room for rollers all the way around between it and the axle. Rollers must be 4.5mm, 3/16" or 5mm diameter (if they will go in). There can be quite a lot of play (slackness, looseness or clearance) between the rollers and the axle (say 1mm) - it does not have to be tight like an ordinary ball race.

2. When you have worked out how to get the right pipe and roller sizes, then you can cut the two hub pipes 164mm long and the two stub axles 300mm long. You also have to cut enough rollers to fill up between the stub axle and the hub pipes. You will probably need about 25 or 27 for each hub and the rollers must be about 152mm long. Do not try to squeeze the hub full of rollers - the best way to find out how many you need is to put as many in as you can and then take one or two out. You should clean up the ends of the rollers with a file after you have sawn them.

3. The next step is to weld the stud bolts or bits of threaded rod onto the struts. When you've done this you can put the studs into the wheels, put the nuts on, and get everything even and straight with the hub pipe in as well. You might find that holding the hub tube in with some wedges as shown in Figure 4 is a good way to do it. You also want to get the middle of hub pipe level with the middle of the tyre, as is shown in Figure 5. Most car wheels need the studs to be about 40mm offset and this is what is on the drawings. When you are happy, tack weld the struts to the hub pipe, remove the wheel and wedges so you've got room and weld the stud supports to the hub tube. Repeat this for the

other hub. If you are going to make several axles you can make up a simple jig, rather than the wedges, to hold everything for welding. We have used a piece of plywood with a central hole to fit snugly over the hub tube and four holes for the studs. In other words its a bit like a dummy wheel. Its best to check that the hubs, rollers and stub-axles still go together when you've finished welding - sometimes weld contraction can pull it all out of shape and make it all too tight. You might need to file off some high spots inside the hub. If you can get it together without a hammer you'll be ok because it will wear to the right shape.

Figure 5: CROSS SECTION OF TYRE WHEEL AND HUB TUBE DURING TACK WELDING OF STUD SUPPORT STRUTS



4. Now take the wheels off the hubs and make up four rings (called roller restraint rings on the drawing) from the same material as you used for the rollers. The rings have to be welded just inside the ends of hub pipes to stop the rollers falling out. When they're welded in you need to use a half round file to open the hole in the middle where the axle pipe will go so that it's got plenty of room - you do not want it rubbing on the axle.

5. Next drill the four holes for the cross bolts. Put the end ones about 15mm from the end of the axles. At the other end you need to make them just far enough away from the end of the hub so that you can turn the nuts to get them on. Again about 15mm seems to do the trick. It does not matter of they are a bit loose.

6. Nearly there! Now you need to cut two bits of angle iron and weld them together to make the center axle to join the stub axles. You must put the stub-axles in position when you weld - the contraction of the angle iron when the weld cools down clamps everything (if you are lucky). Otherwise

just put a few tack welds on to hold it in place.

7. Now put it together! Put some grease into the hub and put the right number of rollers in so that they are in place against the inside of the hub tube. You can hold them in with a bit of rag or a plastic bag if the grease does not stick them. Then just slide them onto the stub axles and fit the cross bolts. (If a plastic bag or rag was used to hold the rollers it should be pushed out by the axle.)

8. You've done it!

Modifications

If you cannot get suitable sizes of pipe and round bar, then pipes can be made slightly bigger (up to 1mm bigger) by forcing a short piece of round bar of the right diameter through them with a press. Another way to do it is to saw the pipe along its length and open to the right size and then weld it. You can also make it a bit smaller like this by cutting a wider slot and squashing the pipe down. Do not worry about the rollers rolling over the groove - as long as you clean the weld back flush with the tube it will be ok.

If you find that you cannot get anything like the materials talked about in the cutting list then maybe you can adapt the design a bit. If the hole in the middle of the wheels is big then you stand a better chance of finding a combination of pipes and rollers that will fit. You can often cut a bit out of the middle of the wheel to make the hole bigger. The hole in Land Rover wheels is big and you can get 4" pipe into them. You may find that you can use small pipe say 1/2" pipe to make the rollers for example. Of course the shaft does not have to be a pipe - it could be solid and then it could be a bit smaller, say 30mm diameter if the steel is high quality.

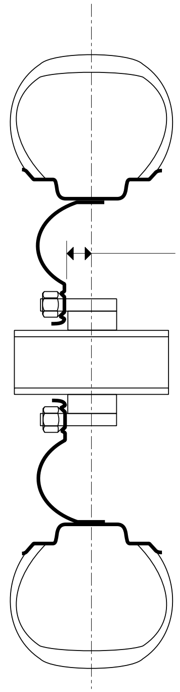


Figure 5: CROSS SECTION OF TYRE WHEEL AND HUB TUBE SHOWING CENTERING OF HUB TUBE IN WHEEL

This distance must be set to get the hub tube in the middle of the tyre.

Hub tube.

Getting the hub in the middle of the wheel and tyre means that the bearings in the hub are evenly loaded.

Another idea that we have tried is to use a hardwood as the hub and even the wheel. If you think about it, the wear on something which is rolling must be less than when something is sliding over it, so a wooden bearing should be better than a sliding one. Some bearings we have tried have had a steel ring fitted inside so that the rollers roll on this steel. We have also tried making these rings from round bar like wire so that it's like the rollers roll on the inside of a spring. This seemed to work quite well.

The main thing to remember with these bearings is that the rollers must be long compared to the diameter of the axle. In the axle and hub shown in this technical release the rollers are about four times as long (150mm) as the diameter of the axle (43mm). Also bigger rollers work better. In our design for Land-Rover wheels on bullock carts we use 3/8" or 10mm diameter rollers and we have successfully used rollers over 20mm diameter in some experiments.

Other ways of making the thrust bearings

We have tried some other ways of making the thrust rollers at the ends. You can have just one roller on each cross bolt and this one can have a countersunk hole in its end so that the

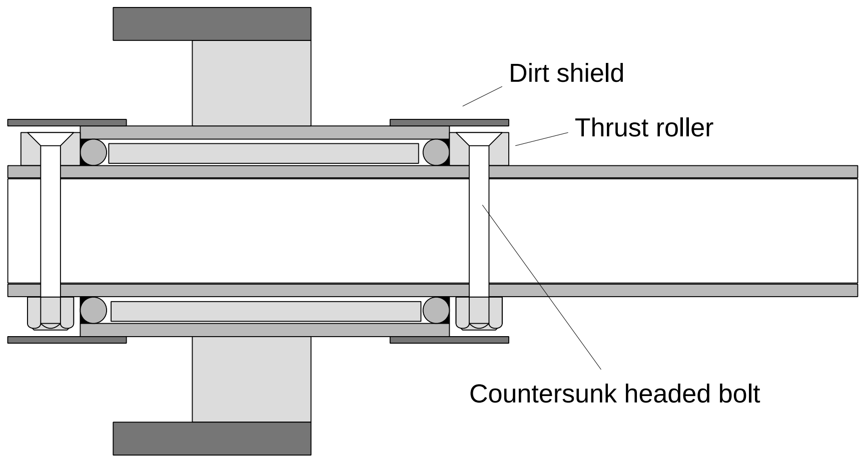

Figure 6: axial restraint rollers on countersunk head cross bolts.

cross bolt head (if its countersunk) can fit in and not stick out. This makes it easier to put dust shields on. You can see this arrangement in Figure 6.

Another way that we have used rollers is to put them inside the dirt shields without any bolts. You can see this in Figure 7. The rollers have no holes - they are just plain pieces of rod. You need to use big rod so that its diameter is a bit bigger than its length. If you do not do this the rollers can turn over and jam.

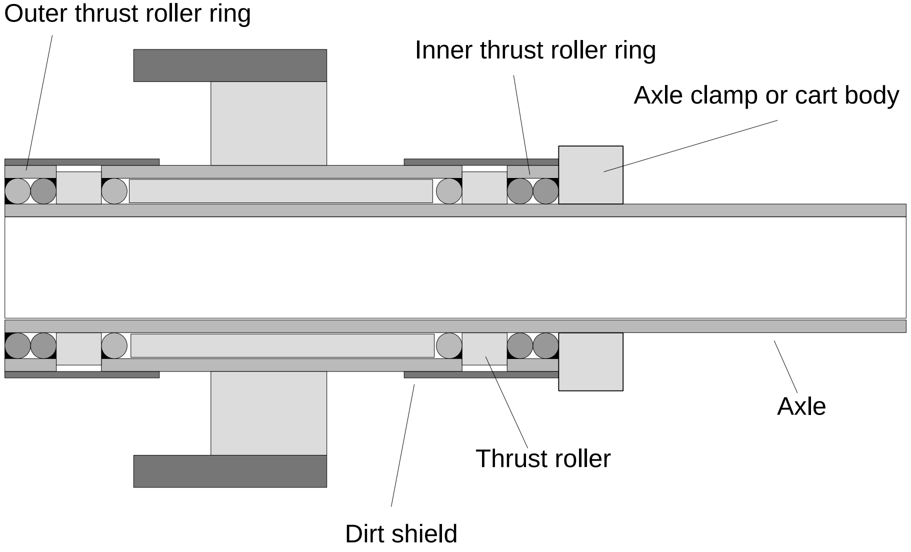

Figure 7: axial restraint rollers held inside dirt/ oil shields.

You must clean up the ends of the rollers with a file and round off the corners a bit so that they can slide inside the dirt shield and not catch on anything. The rollers roll against thrust roller rings made of the same pipe as the hub tube is made from and the same rod as the rollers. The outer thrust roller ring should be welded to the axle. The inner one is held on by the cart body or the clamps which hold the axle to the body. You can put one or more thrust rollers in.

One more advantage of this method of axle construction is that you do not need to drill any holes.

Other DTU cart developments

Other methods of hub design using aluminium castings, for example, which might need no machining, are under development at Warwick and wheel designs in steel sheet, cast aluminium and timber are also in manufacture or under development. A range of designs for donkey and ox carts made of steel and wood, is also available, some of which are in production in Nigeria.

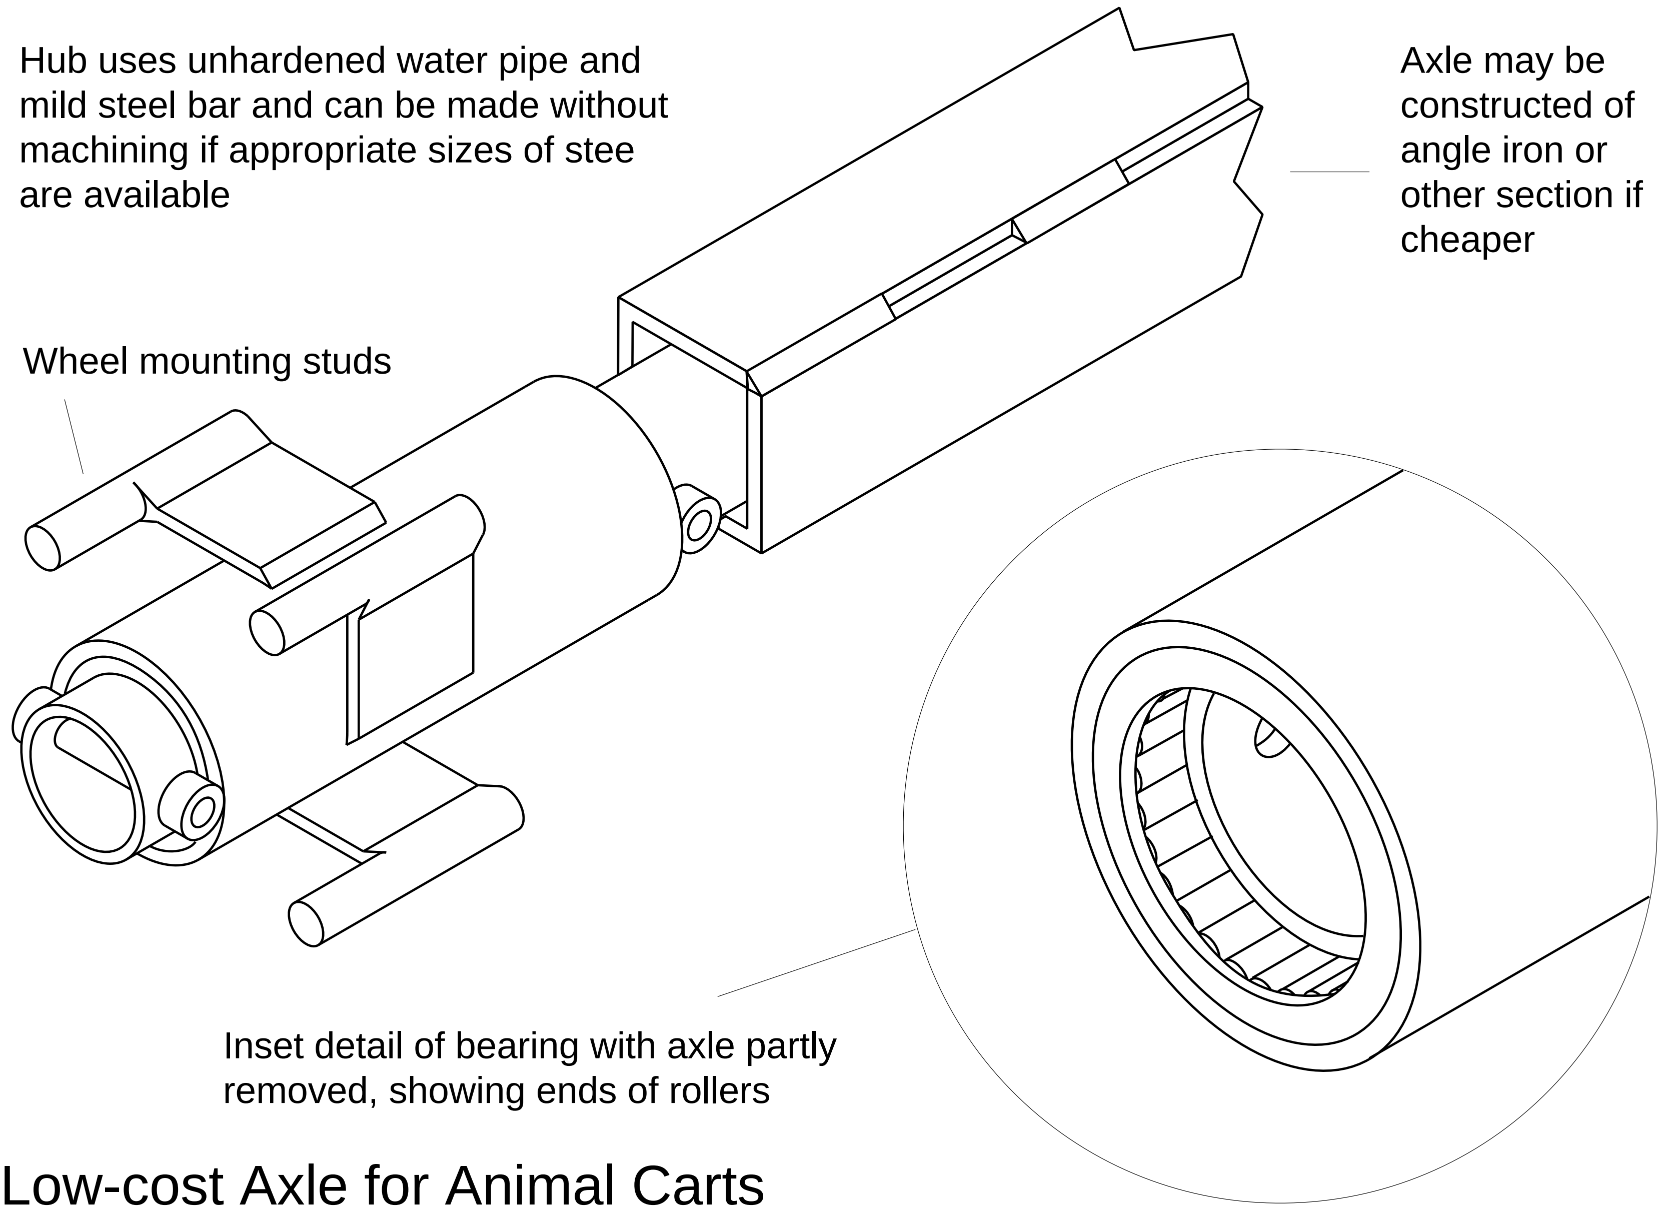
RELEASE

PIPE AND ROLLER AXLE FOR OX CARTS

Development Technology Unit, Department of Engineering, University of Warwick, Coventry, CV4 7AL UK, tel: +44 (0)203 523523 extn 2339, fax: +44 (0)203 418922, email: esceo@uk.ac.warwick.eng



Low-cost Axle for Animal Carts

Pipe and Roller Ox-Cart Wheel Hubs

Introduction

Not enough farmers in Africa have animal carts. Those who have carts can take their produce to places where they can get the best prices. They can also get into town and buy fertilizer and better seeds and move stuff around their farm easier. The trouble is that carts are too expensive for many farmers. The question is what can be done about it?

Carts are made in many different places. Some carts are made in factories in industrial countries and some are made in factories in Africa, but most are made by local blacksmiths or carpenters using scrap car and Land-Rover axles. These people cannot get enough axles to meet the demand, so the price is high. Another problem is that the axles are often so worn that they do not last long. Lots of farmers take the differential unit out of the axle too, which makes it break sooner and lets the dirt in.

What you need is an axle which blacksmiths and fabricators can make with fairly simple tools - without having to get parts machined. There are usually blacksmiths and fabricators in the small market towns used by the farmers. Experts think that having the cart maker close to the farmer is a good thing because they can talk to each other easily and sort out any problems. And of course if the cart is made locally, it can be repaired locally, so there won't be problems with spare parts.

Idea behind design

The idea behind the design of axle described in this technical release is to allow axle construction without the use of machine tools (lathes and milling machines), and using materials which should be readily available. The materials can be used 'as bought' - no hardening of any of the components is needed, and you do not need to be super accurate - good hand working is good enough. The only tools which you must have are a hacksaw, a file and a drill able to drill a 13mm hole in steel. Having a vice is also very handy!

Of course if you do have power tools - especially a power hacksaw or cutoff wheel - things can be made much faster. This axle is suitable for a wide range of production methods - you could even tool up for manufacture with some specially made tools!

The long thin needle rollers in this design have been used so that the hubs will usually fit scrap Land-Rover and Japanese four-wheel-drive vehicle wheels. These wheels have a hole in the middle for the axle which is 115mm diameter (ie 4½") on a

Land-Rover wheel, but is smaller on the Japanese vehicles. If the wheel won't fit you can sometimes saw or file the hole bigger. Putting the fixing studs on struts like you see in the drawings means that you might be able to bend the struts a bit to fit a different wheel. Or if that doesn't work you can even cut nearly through the welds and then weld them in the right place. You could even cut the struts right off and weld on a different number, if your wheels have a different number of holes.

Performance

We have tested smaller versions of axles like these for more than 10 000km in the laboratory and some axles have been ok for 30 000km. With the smaller axles we usually set the load at 200kg per wheel, but we have used them at 400kg for thousands of km. With these big axles we expect double the load capacity - say up to 800kg on each wheel. You will probably find that the axles need to be cleaned and regreased every six months or year depending on how much they are used. The materials that you use do not have to be perfect - some of the axles we have tested have not been very round at all - one was more than 1mm out, but they have still worked. We have tried rollers made out of 6" nails with the heads cut off on the small version of the hub. They still worked even though they were slightly bent. Another material which might work for small rollers is welding electrode with the flux knocked off. Of course none of these axles are as good as axles with proper bearings in them, but they are a lot cheaper and easier to make and they should still last many years.

Cutting list and costs

Table 1 shows a cutting list for a complete axle - two wheel hubs and stub axles joined by an angle iron section in the middle. We did this because angle iron was much cheaper than pipe. But if it isn't where you are, then make the whole axle out of one piece of pipe. Recent prices of materials in Nigeria are shown converted to $\$_{US}$. The 3"BSP (British Standard Pipe) is about 89mm outside diameter with a wall thickness of up to 5mm. The 2"BSP is about 61mm outside diameter with a wall thickness of about 4.5mm.

Construction step by step

These instructions deal with making an axle to the design shown in the drawings. If you find that you can't get the right sizes you might still be able to make an axle with other sizes. See the Modifications section on page 6.

1. The first and probably most difficult job, is to get some

Table 1 Cutting list and costs for pipe and roller ox cart axle

4 Backing washers, placed on the stud before the wheel, make the wheel more secure if it has large stud holes.				

suitable pipes and roller material. Obviously the axle has to be strong enough to carry the cart, so you must make sure that the pipe has a wall thickness of more than say 3.5 mm.

The hub pipe must also have a wall thickness of 3.5mm or more. It must also have a bore (or inside diameter), which goes over the axle with enough room for rollers all the way around between it and the axle. Rollers must be 9mm, 3/8" or 10mm diameter (if they will go in). There can be quite a lot of play (looseness, space or clearance) between the rollers and the axle (say 1mm) - it does not have to be tight like an ordinary ball race.

2. When you have worked out how to get the right pipe and roller sizes, then you can cut the two hub pipes 250mm long and the two stub axles 450mm or so long. You also have to cut enough rollers to fill up between the stub axle and the hub pipes. You will probably need about 20 or 21 for each hub and the rollers must be about 228mm long. Do not try to squeeze the hub full of rollers - the best way to find out how many you need is to put as many in as you can and then take one or two out. You should clean up the ends of the rollers with a file after you have sawn them.

3. The next step is to weld the stud bolts or bits of threaded rod onto the struts. When you've done this you can put the studs into the wheels, put the nuts on, and get everything even and straight with the hub pipe in as well. You might find that holding the hub tube in the wheel with some wedges, as shown in Figure 2 makes things easier. Also don't forget that you want to get the middle of hub pipe level with the middle of the tyre, as is shown in Figure 3. Most wheels need the studs to be about 40mm offset and this is what is on the drawings. When you are happy, tack weld

the struts to the hub tube, take the wheel off so you get at the tube easily and weld the stud support struts to the hub tube. Repeat this for the other hub. If you are going to make several axles you can make up a simple jig to hold everything for welding. We have used a piece of 18mm plywood with a central hole that fits the hub tube tightly and has a hole for each of the studs. Really this is like a dummy wheel. After welding its best to check that the hubs, rollers and stub-axles still go together - sometimes weld contraction can pull it all out of shape and make it all

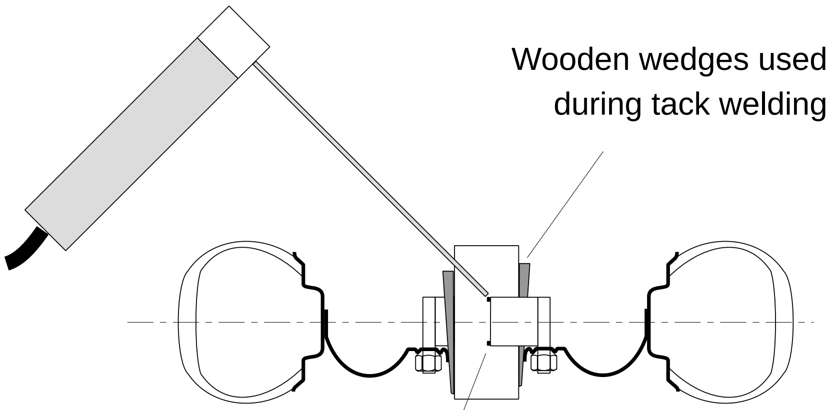

Figure 2: CROSS SECTION OF TYRE WHEEL AND HUB TUBE DURING TACK WELDING OF STUD SUPPORTS

too tight. You might need to file off some high spots inside the hub or you may even have to use smaller rollers. If you

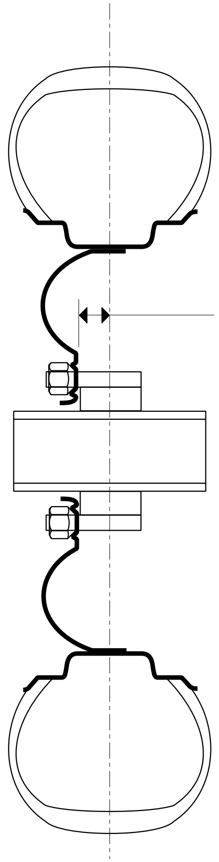

Figure 3: CROSS SECTION OF TYRE WHEEL AND HUB TUBE SHOWING CENTERING OF HUB TUBE

can get it together without a hammer you'll be ok because it will wear to the right shape.

4. Now take the wheels off the hubs and make up four rings (called roller restraint rings on the drawing) from the same material as you used for the rollers. Bend them in a vice if you have it, and cut the rod so that there is say a 4mm gap between the ends when they are the right diameter. Then you can push them into the end of the hub tube and weld the ends together. It's best to remove them then from the tube and clean up the weld with a file. The rings have to be welded just inside the ends of hub pipes to stop the rollers falling out so do this next. When they're welded in you need to use a half round file to open the hole in the middle where the axle pipe will go so that it's got plenty of room - you don't want it rubbing on the axle.

5. Next drill the two holes in each stub axle for the cross bolts. Put the end ones about 20mm from the end of the stub axles. You need to make the holes for the other two bolts just far enough away from the end of the hub so that you can just get the thrust rollers on. Probably the best way to do it is to assemble the hubs on the axles after you've drilled the first holes, offer up the other roller and mark the position. It doesn't matter of the hubs are a bit loose on the axles.

6. Nearly there! Now you need to cut two bits of angle iron and weld them together to make the center axle to join the stub axles. You must put the stub-axles in position when you weld - the contraction of the angle iron when the weld cools down clamps everything (if you are lucky). Otherwise just put a few tack welds on to hold it in place.

7. Now put it all together! Put some grease into the hub and put the right number of rollers in so that they are in place against the inside of the hub tube. You can hold them in place with a bit of rag or a plastic bag if the grease does not stick them. Alternatively you can put the hub a little way onto the shaft and then just ease the rollers into place one by one. Then just slide the whole thing onto the stub axles and fit the cross bolts. (If a plastic bag or rag was used to hold the rollers it should be pushed out by the axle.)

8. You've done it!

Modifications

If you cannot get suitable sizes of pipe and round bar, then pipes can be made slightly bigger (up to 1mm bigger) by forcing a short piece of round bar of the right diameter through them with a press. Another way to do it is to saw the pipe along its length and open to the right size and then weld it. You can also make it a bit smaller like this by cutting a wider slot and squashing the pipe down. Don't worry too much about the rollers rolling over a groove, but you will need to clean any flash or weld bead off from the bore.

If you find that you cannot get anything like the materials talked about in the cutting list then maybe you can adapt the design a bit. If the hole in the middle of the wheels is big then you stand a better chance of finding a combination of pipes and rollers that will fit. You can often cut a bit out of the middle of the wheel to make the hole bigger. The hole in Land Rover wheels is big and you can just get 4" pipe into them. You may find that you can even use small pipe say 1/2" BSP pipe to make the rollers for example, but you must make sure that it has a thick wall. Of course the shaft does not have to be a pipe - it could be solid and then it could be a bit smaller, say 38mm diameter or bigger if the steel is high quality.

Another idea that we have tried is to use a hardwood as the hub and even the wheel. If you think about it, the wear on something which is rolling must be less than when something is sliding over it, so a wooden bearing should be better than a sliding one. Some bearings we have tried have had a steel ring fitted inside so that the rollers roll on this steel. We have also tried making these rings from round bar like wire so that it's like the rollers roll on the inside of a spring. This seemed to work quite well.

The main thing to remember with these bearings is that the rollers must be long compared to the diameter of the axle. In the axle and hub shown in this technical release the rollers are about four times as long (228mm) as the diameter of the axle (about 60mm). Another rule is that bigger diameter rollers work better.

Other thrust bearing arrangements

We have tried some other ways of making the thrust rollers at the ends. You can have just one roller on each cross bolt and this one can have a countersunk hole in its end so that the

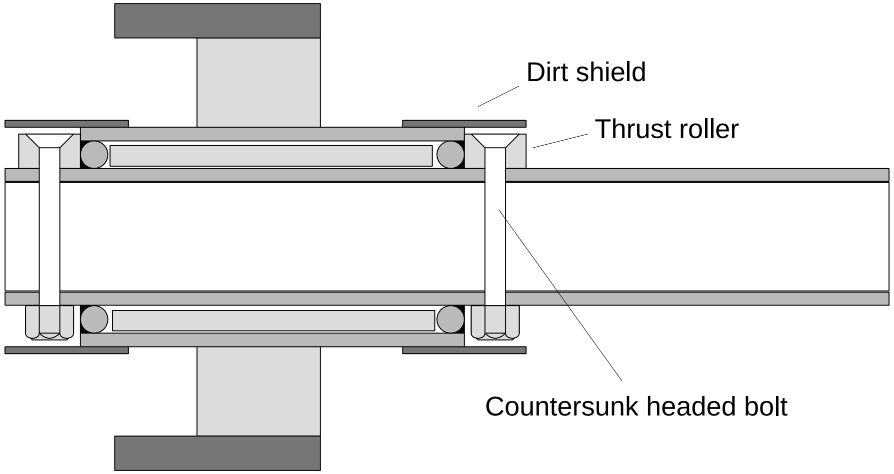

Figure 6: axial restraint rollers on countersunk head cross bolts.

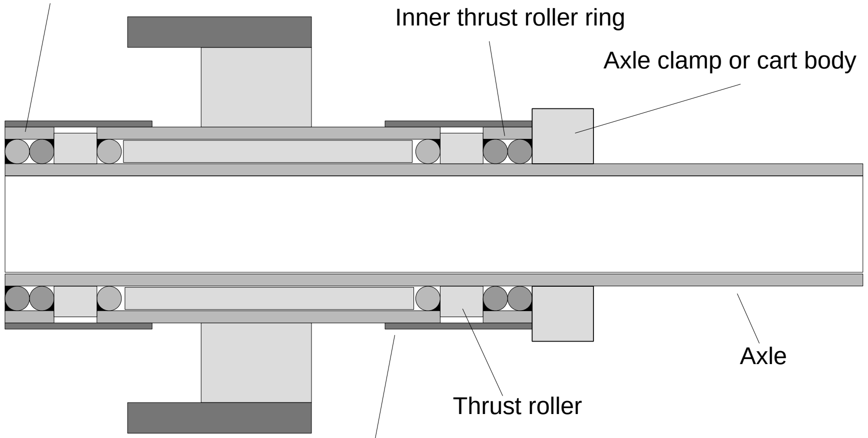

Figure 7: axial restraint rollers held inside dirt/ oil shields.

cross bolt head (if it is countersunk) can fit in and not stick out. This makes it easier to put dust shields on. You can see this arrangement in Figure 6.

Another way that we have used rollers is to put them inside the dirt shields without any bolts. You can see this in Figure 7. The rollers have no holes - they are just plain pieces of rod. You need to use big rod so that its diameter is a bit bigger than its length. If you do not do this the rollers can turn over and jam. You should clean up the ends of the rollers with a file and round off the corners a bit so that they can slide inside the dirt shield and not catch on anything. The rollers roll against thrust roller rings made of the same pipe as the hub tube is made from and the same rod as the rollers. The outer thrust roller ring should be welded to the axle. The inner one is held on by the cart body or the clamps which hold the axle to the body. You can put one or more thrust rollers in.

One more advantage of this method of axle construction is that you do not need to drill any holes.

Other DTU cart developments

Other methods of hub design using aluminium castings, for example, which might need no machining, and others which need only limited machining are under development at Warwick and wheel designs in steel sheet, cast aluminium and timber are also in manufacture or under development. We have also been working on a variety of other bearing types including pressed cup-and-cone ball bearings. A range of designs for donkey and ox carts made of steel and wood, is also available, some of which are in production in Nigeria.

If you are interested we can send you more information.

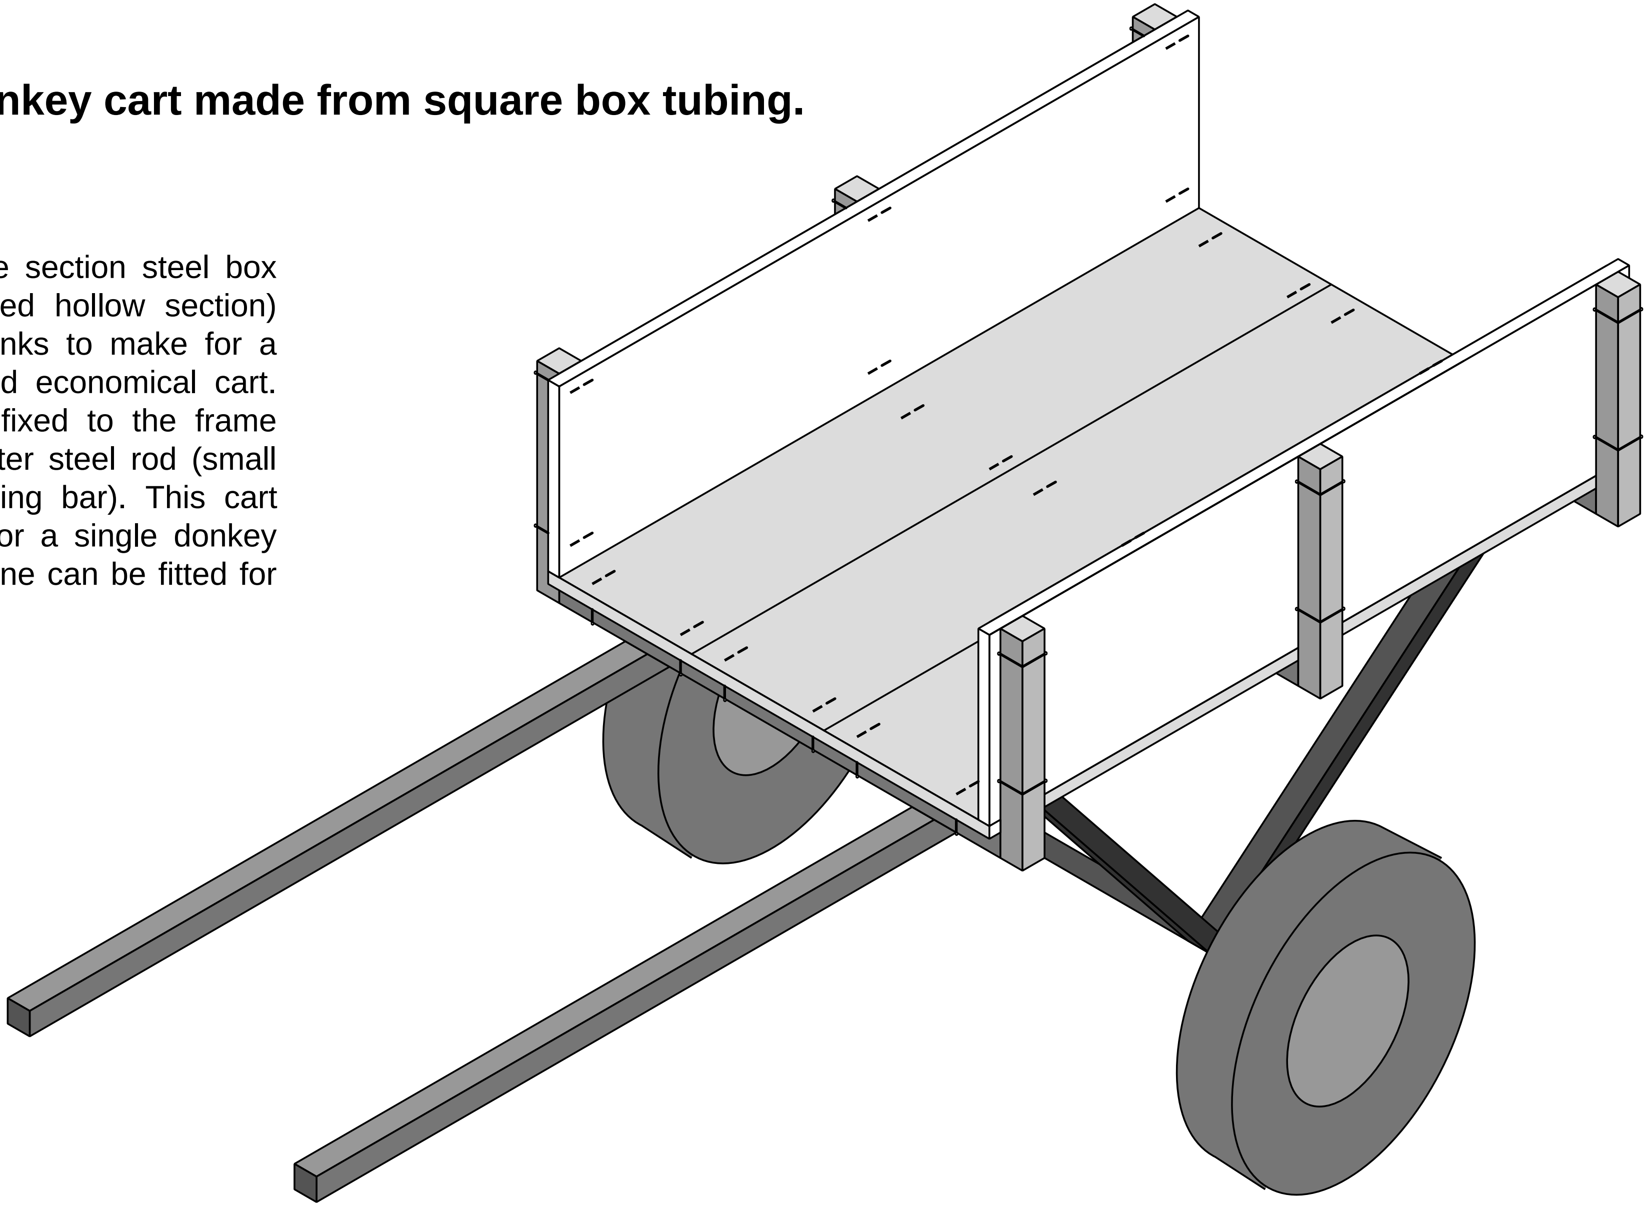
STEEL FRAME AND WOOD DONKEY CART

Development Technology Unit, Department of Engineering, University of Warwick, Coventry, CV4 7AL UK, tel: +44 (0)203 523523 extn 2339, fax: +44 (0)203 418922, email: esceo@uk.ac.warwick.eng

Figure 1: donkey cart made from square box tubing.

Cart uses square section steel box tubing (RHS rolled hollow section) plus wooden planks to make for a quickly made and economical cart. The planks are fixed to the frame with 6mm diameter steel rod (small concrete reinforcing bar). This cart has two shafts for a single donkey but one central one can be fitted for two animals.



Donkey Cart Body Made From Square Box Tubing and Timber Planks

Introduction

Not enough farmers in Africa have animal carts. Those who have carts can take their produce to places where they can get the best prices. They can also get into town and buy fertilizer and better seeds and move stuff around their farm easier. The trouble is that carts are too expensive for many farmers. The question is what can be done?

Carts are made in many different places. Some carts are made in factories in industrial countries and some are made in African factories, but most are made by local blacksmiths or carpenters using scrap car and Land-Rover axles. These people cannot get enough axles to meet the demand so the price is high. Even if they did have the axle, they still end up building heavy bodies that take ages to make. In another booklet in this series we have told you how you can make simple low-cost axles; in this booklet we tell you about a simple steel and timber body. You should find that you can make the body for about $\$_{US}$ 35 depending on the cost of the materials and labour. Once you get organised, two men can probably make two bodies per day.

What you need is a body which carpenters and fabricators can make with their simple tools. These people will probably be in the small market towns used by the farmers and they will have an electric welder and some basic handtools like a hacksaw. Experts think that having the cart maker close to the farmer is a good thing because they can talk to each other easily and sort out any problems. And of course if the cart is made locally, it can be repaired locally, so there should not be any problems with spare parts.

Idea Behind Design

The idea behind the design of donkey cart described in this technical release is to allow construction without lots of special tools and jigs, and without any hard-to-get materials. The only tools which you must have are a welder, a hacksaw, and a drill able to make a 6mm hole in wood. In fact you can make the drill yourself. You might find that a couple of 4" or a 5" G clamps (or something like it) are useful too. (The symbol " means inches here, so that 4" is about 100mm since there are about 25mm in an inch.)

You will see that there are no mitres and funny angles to cut in the square tubing so you save time when making the cart. Also the exact lengths of the components are not very fussy - again it saves a little time. But you will find that the carts look better if you take trouble to get things square and even etc.

These carts have been tested a bit in Nigeria, but we have not tested them enough. The only problems which we have found so far have been breaking of the animal shafts and we have cured this by welding some strengtheners (bits of 8mm, 10mm or 12mm round bar or re-bar) to the top and bottom of these shafts. (Re-bar means concrete reinforcing bar). The construction tends to be a bit light in Nigeria, because they sell very thin wall square tubing (much less than 1mm thickness) there. If you used tubing with a wall thickness of 2.5mm or more you probably would not need to put these strengtheners on. Really to get a cart at a reasonable cost you need to experiment a bit to see how the farmers treat their carts and what they expect them to stand. It's no good saying it must be strong enough so that they cannot ever break it - somebody will always break anything - and it will be very expensive to make it nearly unbreakable. At least like this you can repair it easily and cheaply.

Cutting list and costs

Table 1 shows a cutting list for a complete cart. Recent prices of materials in Nigeria are shown converted to $\$_{US}$. The square box tube (sometimes called rolled hollow section or RHS) is nominally 2" or 50mm on one side. You can often buy it in a variety of wall thicknesses. It's best with a with a wall thickness of 2.5mm (12 gauge) or more, but we have used wall thicknesses down to 1.6mm (16 gauge) as we mentioned earlier.

Construction step by step

1) The first job, is to get all the material together and clear a space to work. Ideally you will be able to work on a flat area of concrete. Start by cutting the square box tube into the right lengths, as in the cutting list above. Then cut the various bits of re-bar or whatever you are going to use. You could cut the timber also at this stage, but it might be easiest to leave it till last.

2) Next weld the three U-shaped frames together. You might find the method shown in Figure 2 the easiest way to support the components during welding. It's quick and if you do not tighten the clamps too tight to start with, you can tap the bits with a hammer until everything is square and

TABLE 1: cutting list for steel framed donkey cart.

component	material	number of lengths and length required [no.×mm]	total material in cart [mm]	materials' cost in Nigeria [$us]
animal shafts	50×50 RHS	2×3150	6300	8.94
body frame bottoms	50×50 RHS	3×1100	3300	4.68
body frame sides	50×50 RHS	6×300	1800	2.55
axle struts	50×50 RHS	4×600	2400	3.40
shaft strengtheners	8mm to 12mm round bar[1]	8×600	4800	1.02

tray side planks	1"×12" or similar timber	2×1800	3600	2.13
tray ends	1"×12" or similar timber	2×1100	2200	1.30
TOTAL->				30.12

1 The round bar can be anything actually - it doesn't even have to be round, so deformed or high-yield re-bar is fine. You could even use flat strip as long as its more than say 8mm thick.

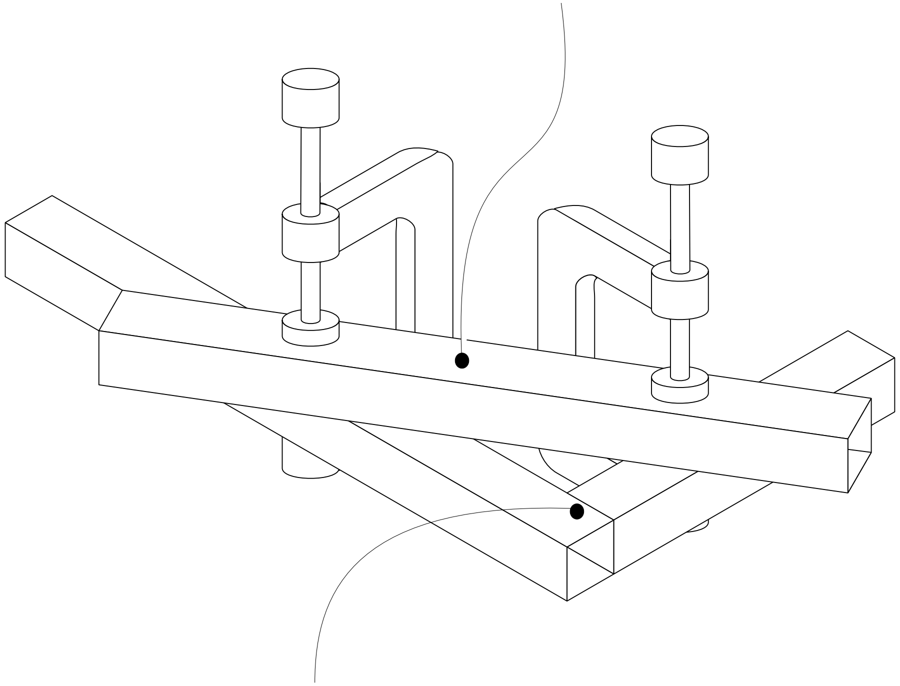

Figure 2: supporting components during welding.

straight. Then tighten the clamps before you weld.

3) Then take two axle support strut pieces and weld them together to make an L shape. When you do this you need to weld only two edges together to leave a space for the axle as Figure 3 shows. You can then weld this L piece to an animal shaft.

Repeat the process using the first sub assembly as a pattern for the second, but remember that the second assembly must be a mirror image of the second. In other words you will need to put the first assembly upside down on the ground and assemble the second one on top of it, as shown in Figure 4. make sure you do not weld the two assemblies together!

4) It may be easiest to fix the axle retaining bolts and loops on at this stage so that you can use them in the next stage.

5) Now you can weld the three U-frames on top of the animal shafts after you have checked for squareness etc.

6) Nearly there! Now you need to bend the staples to hold the wood onto the square tube. You could make up a jig for this with some bolts in a piece of wood or you can just bend them in a vice. They do not have to be very accurate, but as usual the more accurate the better. To fit them, drill a hole both sides of the tubing and push both legs of the U through the wood using a hammer if necessary. When it's through, hold a hammer against the bottom of the U whilst you knock the protruding legs over with another hammer. You might find this easier with someone to help you. Then clench the legs by knocking them into the surface of the wood to leave the surface flush. Once you are happy that

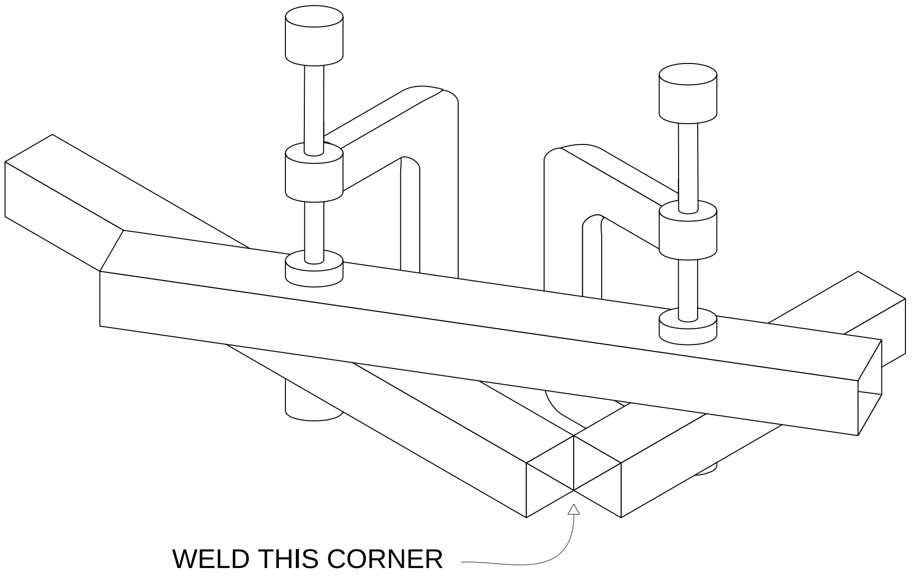

Figure 3: welding axle supports.

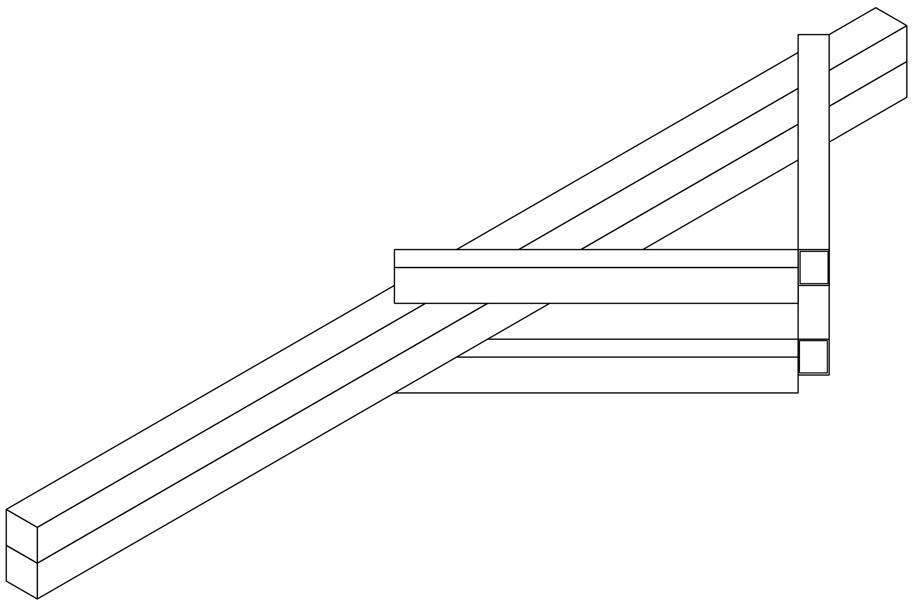

Figure 4: welding animal shaft and axle support struts assemblies.

all is in the right place, weld the staple to the square tubing with a couple of substantial tack welds, as shown in Figure 5. Then put the rest of the staples in in the same way.

7) Paint the cart. You've finished it!

Modifications

There are many different versions of this cart. This one has sides, for example, but you could make these removable by not using staples to fix the sides. A good way to fix the side planks might be to leave the steel uprights in place and tie the planks to the inside of these with bits of truck inner tube as giant bungees or elastic bands. This is an appropriate way because it is cheap and very easily repairable, but the farmers may want some flashy looking thing which will be very expensive to make. You will probably find that things like latches take as much time as the basic parts of the cart.

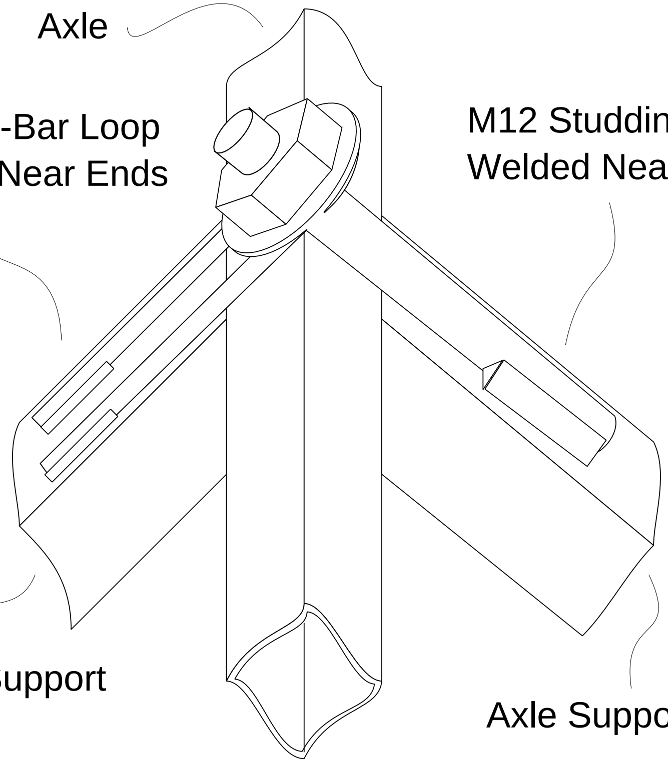

Figure 5: method of fixing axle to axle supports.

You can try longer and shorter carts and you can make them wider or narrower. When you do this, check the length and width of the planks of wood that you will use - you do not want to find that you are two inches short of being able to get two

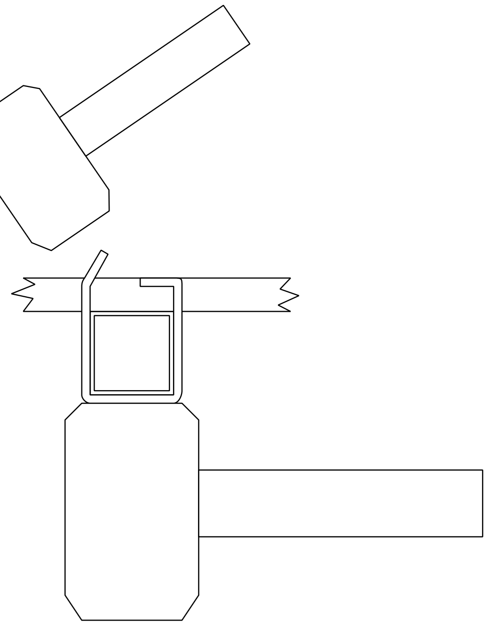

Figure 6: Using two hammers to clench wood fixing staple.

runs of plank out of one piece of timber, or that its just too narrow and you have to fiddle about and waste time filling the gap with an extra little strip.

Another thing is the height of the cart. No-one seems to know why some carts are made high and others low. Its better for the animals if the load tray is low particularly if the carts will be operated a lot over rough ground. But you may find that farmers want a high load tray to keep loads dry if they are fording rivers a lot, or it may be a status thing (if you are wealthy enough to own a cart, your eye level must be above a pedestrian's). Or it may be that it's too tiring to load a low cart - if, for example, you have to bend your back twice for each bundle - once to pick it up off the ground and again to put it down onto a low load tray. We have found that farmers usually want the body to come out over the wheels so they can load on lots of straw or light materials.

Other DTU cart developments

The DTU has been working on a range of cart body types for use with both donkeys and oxen. It has designs for both wooden and steel framed types. The wooden types are cheaper in material terms, but the steel framed ones are easier to make because the joints are more straightforward - nevertheless you can make either type of cart in only a few hours, if you are reasonably set up with tools and materials.

The DTU has also been working on new designs of wheels, hubs and bearings to bring down their costs and make things more locally manufacturable. For example it has pioneered a system of hubs using water pipe which do not need machining to make a roller bearing hub. Obviously friction is very low with these hubs and they usually give good milage before being worn out too - we usually get 15 000 km before they are very badly worn, but they may need cleaning and relubrication several times before they get this far. Still they are reasonably cheap - we can make them in Nigeria for about $\$_{US}20$, they only take one man a day to make, and they do not need any special tools.

Other hub designs using, for example aluminium castings, are in production in Nigeria and we are trying to reduce or eliminate the machining in these. Also wheel designs in steel sheet, cast aluminium and timber are in manufacture or under development.

Cart Drawings

Two drawings of carts are shown in the following pages. The first one is simple, but quite strong and easy to make, and is the one for which we have shown the list of materials. The second cart is lighter and even easier to make. You can use this cart with small donkeys.

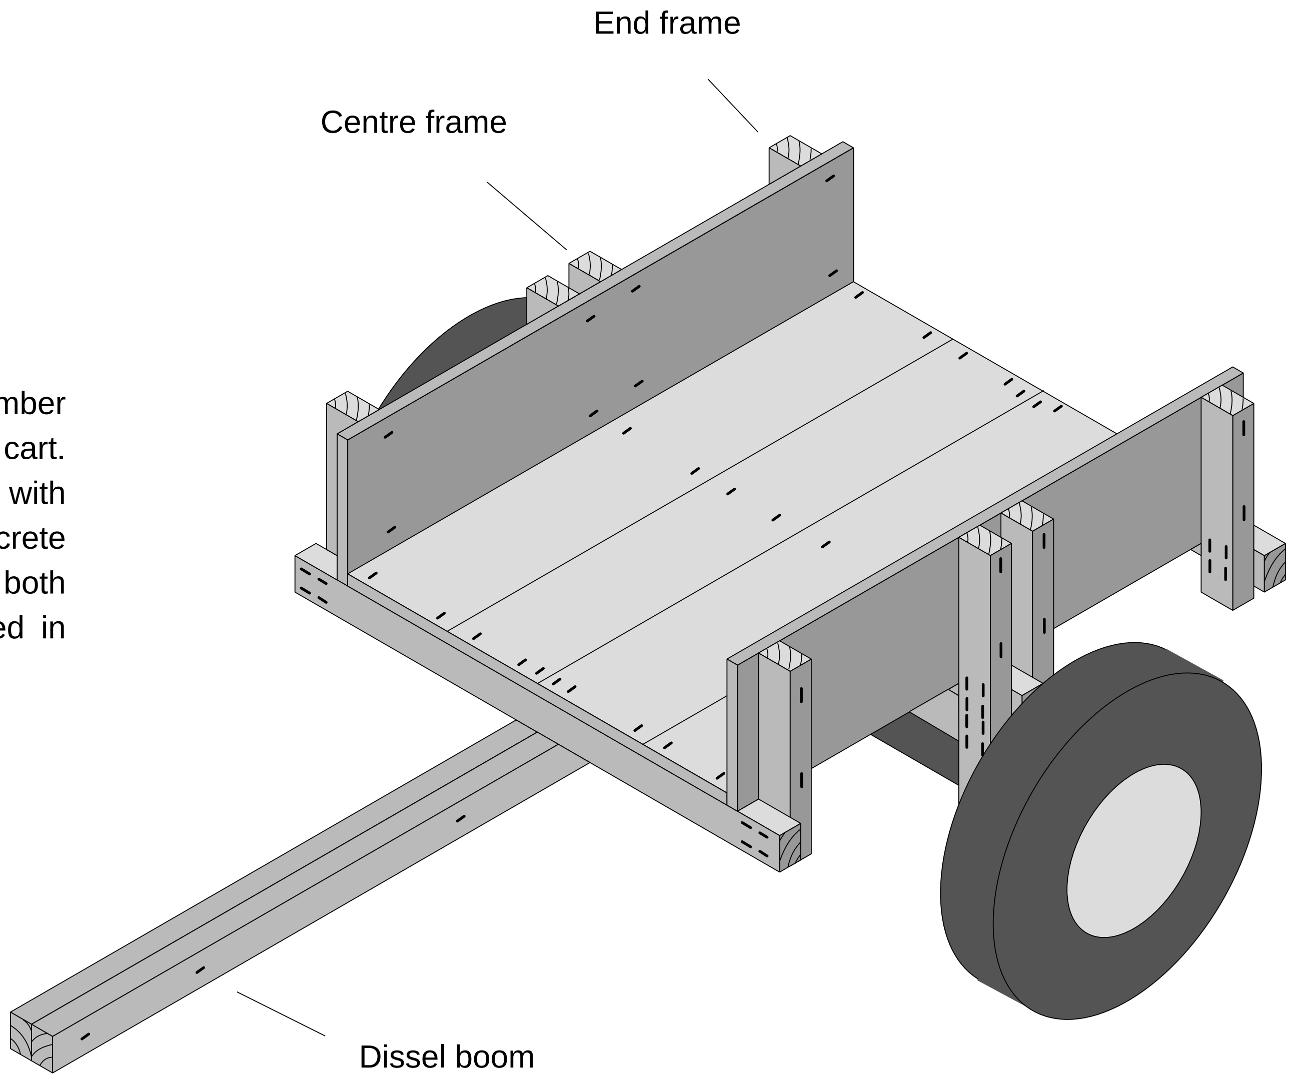
SIMPLE LOW-COST WOODEN OX CART

Development Technology Unit, Department of Engineering, University of Warwick, Coventry, CV4 7AL UK, tel: +44 (0)203 523523 extn 2339, fax: +44 (0)203 418922, email: esceo@uk.ac.warwick.eng

Figure 1: wooden oxcart



This cart uses wooden planks and timber for a quickly made and economical cart. The planks are fixed to the frames with 6mm diameter steel rod (small concrete reinforcing bar) clenched over at both ends a bit like copper nails are used in boat building.

Ox Cart Body Made From Timber

Introduction

Not enough farmers in Africa have animal carts. Those who have carts can take their produce to places where they can get the best prices. They can also get into town and buy fertilizer and better seeds and move things around their farm easier. The trouble is that carts are too expensive for many farmers. The question is what can be done about it?

What you need is a body which carpenters can make quickly with their simple tools. These people will probably be in the small market towns used by the farmers. Experts think that having the cart maker close to the farmer is a good thing because they can talk to each other easily and sort out any problems. And of course if the cart is made locally, it can be repaired locally, so there should not be any problems with spare parts.

Carts are made in many different places. Some carts are made in factories in industrial countries and some are made in factories in Africa, but most are made by local blacksmiths or carpenters using scrap car and Land-Rover axles. These people cannot get enough axles to meet the demand so the carts are expensive. Even if they did have the axles, they still end up building heavy bodies that take ages to make. In another booklet in this series we have told you how you can make simple low-cost axles; in this booklet we tell you about a simple timber body. You should find that you can make the body for about $\$_{US}20$, depending on the cost of the materials and labour. Once you get organised, two men can probably make two bodies per day. This is quite a lot faster than most carts can be made and it follows from the simplifications which we have made to the design. We've designed it to be easy to make.

Idea Behind Design

The idea behind the design of oxcart described in this technical release is to allow construction without lots of special tools and jigs, and without any hard-to-get materials. The only tools which you must have are a woodsaw, a hacksaw or cold chisel, a hammer and a drill able to make a 6mm hole in wood. In fact you can make the drill yourself if you have to. If you need to make a drill read the section **Making a flatbit** below - it's not too difficult, and its quite handy sometimes to be able to make very long drills. You might find that a couple of 4" or a 5" G clamps (or something like it) are useful too. (The symbol " means inches so 4" means about 100mm because there are about 25mm in an inch.)

The way that all the parts of this cart are joined together is like the one that used to be used to fix small boats together. It's called clench nailing and is a bit like riveting. What you do is make a hole right through the wood to be joined, and then put a straight piece of 6mm diameter re-bar (concrete reinforcing bar) right through so it sticks out about 25mm both sides. Then you just knock one end over with a hammer so it lies on the surface of the wood. Next you bend the other end over. Then you put a big hammer or something hard and heavy like a piece of steel against one of the ends and then hit the other with another hammer. What happens is that you tighten the two bits of wood together and you get quite a strong joint. If you put some washers or something like them made from sheet steel on the re-bar before you bend it over it will make the joint a bit stronger still. It does not make a very rigid joint, but you might find that the flexibility gives the cart some resilience so that it takes knocks better.

You will see that there are no mitres and complicated angles to cut in the timber so you save time when making the cart. Also the exact lengths of the components are not very critical - again it saves a little time, but you will find that the carts look better if you take a little trouble to get things square and even etc.

These carts have been tested a bit in Nigeria, but we have not tested them enough. We think that they are strong enough, but we cannot be sure. Really to get a reasonable price you need to experiment a bit to see how the farmers treat their carts and what they expect their carts to stand. It's no good saying it must be strong enough so that they cannot ever break it - somebody will always break anything - and it will very expensive to make it nearly unbreakable. At least you can repair these carts easily and cheaply.

Cutting list and costs

Table 1 shows a cutting list for a complete cart - Recent prices of materials in Nigeria are shown converted into $\$_{US}$.

TABLE 1: cutting list for wooden oxcart.

component	material	number of lengths & length required [No.×mm]	total material in cart [mm]	materials cost in Nigeria [$us]
animal shaft/ boom	75×50 or bush pole	2×3700	7400	2.39
body frame bottoms	75×50 roughsawn timber	3×1100	3300	1.06
body frame sides	75×50 roughsawn timber	6×300	1800	0.58
axle struts	75×50 roughsawn timber	4×600	2400	0.77
tray bottom planks	25×300 or similar timber	4×1800	7200	4.64
tray side planks	25×300 or similar timber	2×1800	3600	2.32
tray ends	25×300 or similar timber	2×1100	2200	1.42
plank fixing staples	6mm dia re-bar or similar	30×250	7500	0.80
body frame staples	6mm dia re-bar or similar	12×150	1800	0.19
axle fixing studs	M12 threaded rod or bolts	2×100	200	0.64
axle fixing loops	6mm dia re-bar or similar	2×200	400	0.04
TOTAL->				14.86

Construction step by step

1) The first job, is to get all the material together and clear a space to work. Ideally you will be able to work on a flat area of concrete. Start by cutting the 75×50 timber into the right lengths, as in the cutting list, and then you can cut the bottom and side planks. Then cut the 6mm dia re-bar for the fixings.

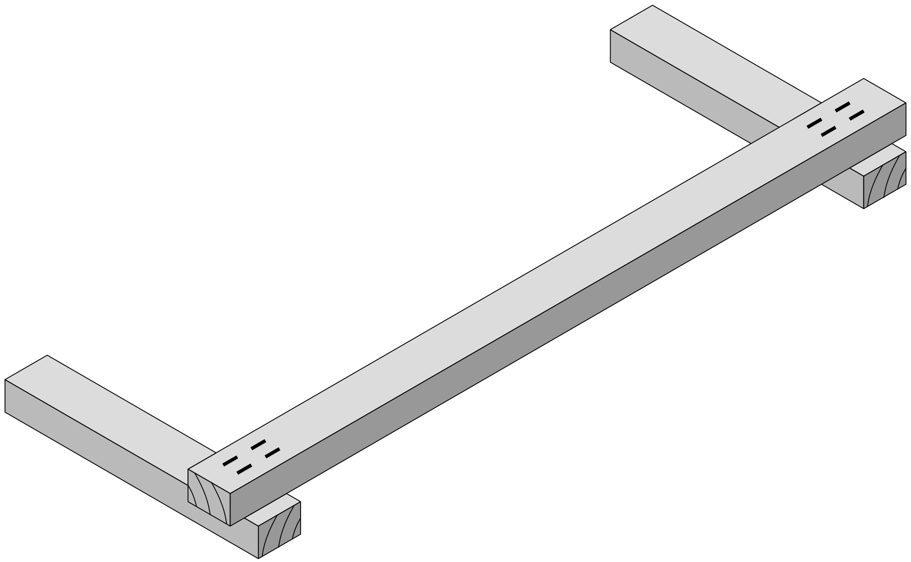


Figure 2: a finished end frame.

2) Next make up the two U-shaped front and back frames (endframes). If you have a G clamp you can use it to hold two pieces of the frame together during drilling and clenching. It's quick and you can tap the bits with a hammer until everything is square and straight and then drill the holes. You might also find that leaving the G clamp on makes it easier to get the re-bar fixings through.

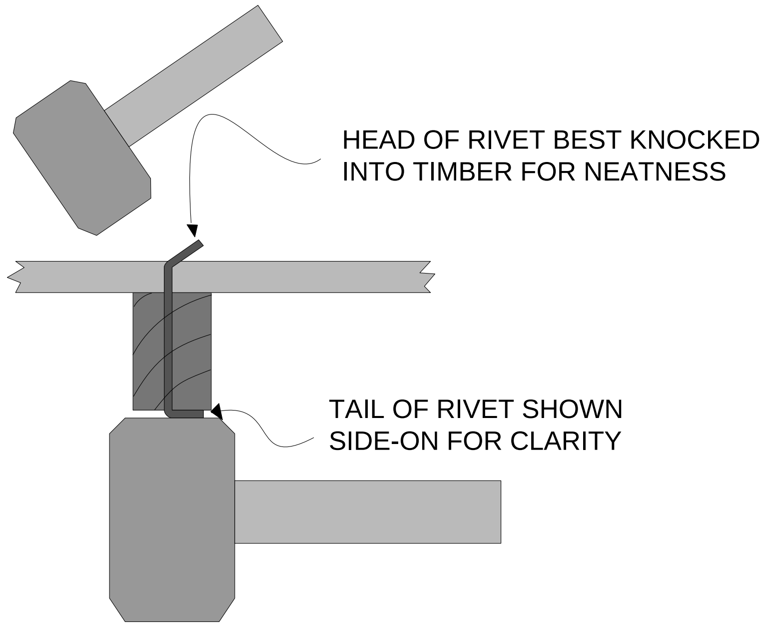

Figure 3: Using two hammers to clench rivet.

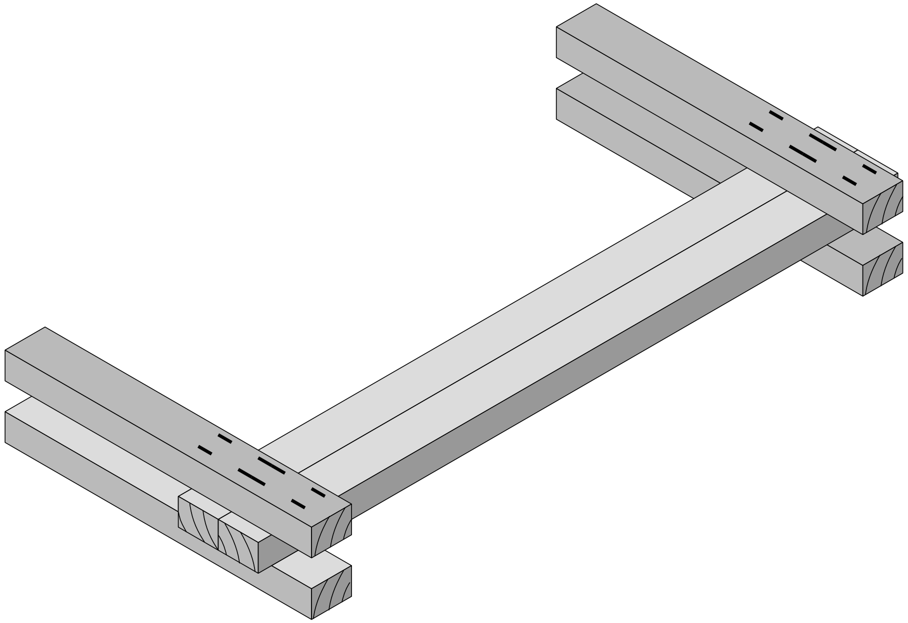

Figure 4: a finished midframe/ axle support frame including spacer.

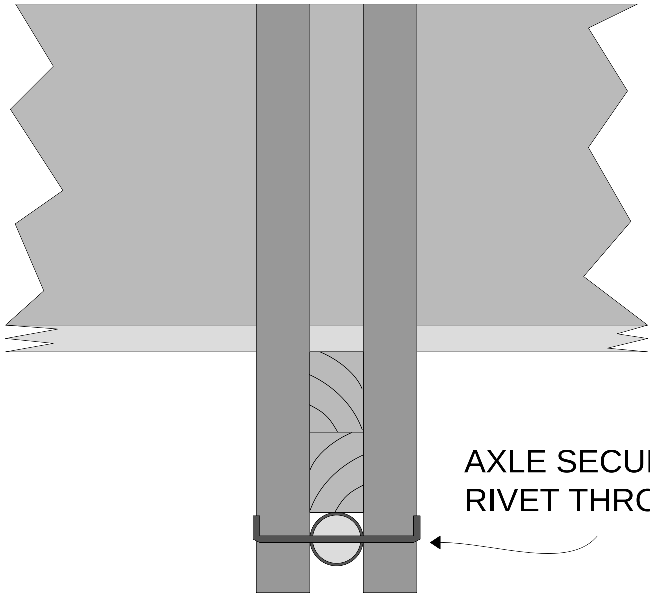

Figure 5: method of fixing axle to axle supports.

3) Then you can make up the frames that go in the middle - the ones that support the axle. You can start with the frame bottom and then fix the uprights to it either side with four rivets. When you've done both ends you will end up with an H shaped assembly.

4) Next you can fit the side and the bottom planks to the end frames and then the middle frame with more rivets.

5) Nearly there! Fix the axle with a rivet right through the middle of it where it goes between uprights of the middle frame - obviously you need to drill through the axle to do this. Another way is to bolt the axle in with a bolt right underneath the axle, but you need a long bolt to do this.

6) If you want to make it so that the ends of the load tray can be removed easily you can do in the way we have shown in

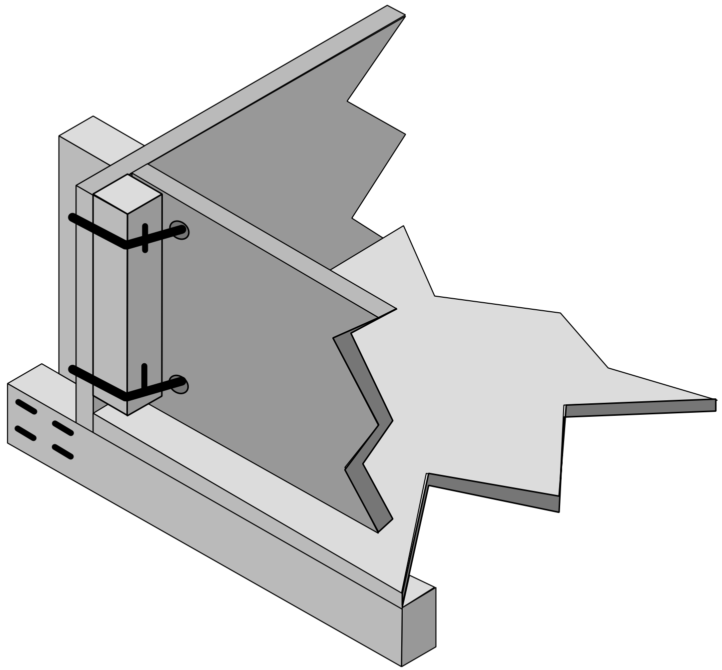

Figure 6: method of fixing tray ends with rubber or rope

7) Paint or creosote the cart. You've finished it!

Modifications

There are many different versions of this cart. You can try longer or shorter carts and you can make them wider or narrower. When you do this, check the length and width of the planks of wood that you will use - you do not want to find that you are two inches short of being able to get two runs of plank out of one piece of timber, or that its just too narrow and you have to fiddle about and fit in a narrow strip.

This cart design does not have ends to the load tray, but if your farmers really want ends you can make them from some more plank. A good way to fix the end planks might be to fix them to the inside of these with bits of truck inner tube as giant bungees or elastic bands. This is an appropriate way because it is cheap and very easily repairable, but the farmers may want some flashy looking thing which will be very expensive to make. You will probably find that things like latches take longer to make than the rest of the cart. Explain to the farmers that they will cost extra too!

Other DTU cart developments

The DTU has been working on a range of cart body types for use with both donkeys and oxen. It has designs for wooden and steel framed types. The wooden types are cheaper in material terms, but the steel framed ones are easier to make because the joints are more straightforward - nevertheless you can make either type of cart in only a few hours, if you are reasonably set up with tools and materials.

The DTU has also been working on new designs of wheels, hubs and bearings to bring down their costs and make things more locally manufacturable. For example it has pioneered a system of hubs using steel pipe such as water pipe which do not need machining to make a roller bearing hub. Obviously friction is low with these hubs and they usually give good milage before being worn out too - we usually get 15 000 km before they are very badly worn, but they may need cleaning and relubrication several times before they get this far. Still they are reasonably cheap - we can make them in Nigeria for about $\$_{US}20$, they only take one man a day, and they do not need any special tools.

Other hub designs using, for example aluminium castings, are in production in Nigeria and we are trying to reduce or eliminate the machining in these. Also wheel designs in steel sheet, cast aluminium and timber are in manufacture or under development.

Making a flatbit

Flatbits for drilling wood are easy to make and quite useful because you can make them very long and drill holes in quite awkward places.

To make the bit, get some round steel bar of the same size as the hole you want to make, or a little bit smaller. Then hammer the end to flatten it a little (a bit like a screwdriver). The drawing shows what we mean. In fact if you can harden the cutting edges you can use the flat bit to drill holes in metal too as long as you do not want to drill deep holes. To get hard cutting edges you will need to use either 'silver steel' or say spring steel or even to case harden the edges - though you will lose the hardness as soon as you re-sharpen the drill if it's just case hardened.

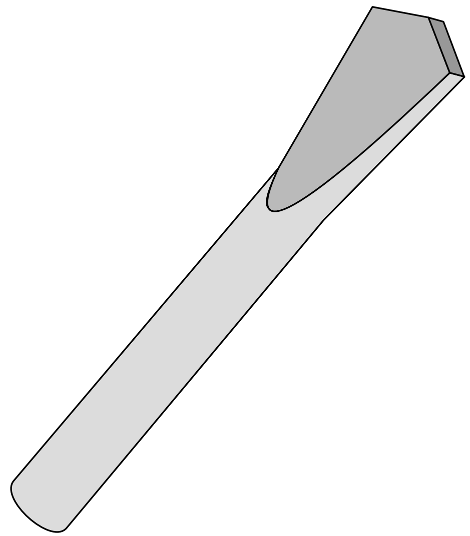

Figure 7: flat bit for drilling holes

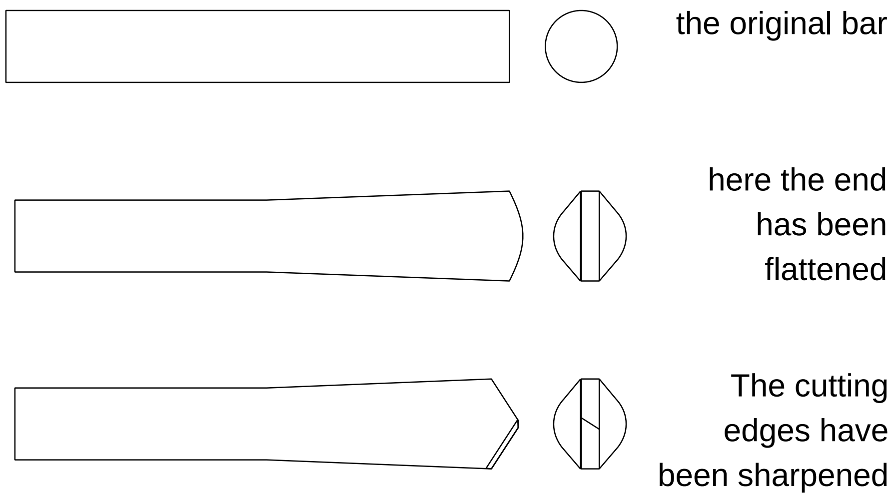

Figure 8: stages in the making of a flat bit for drilling holes.

Cart Drawings

You will find two drawings below, the first one gives a general view of the cart and the second, a view of the main components. As we have said you can vary the size of the cart quite a bit and even make it much longer if you add extra frames. You could even make a four wheeled cart like this!

Lightweight Donkey Cart Body Made From Square Box Tubing and Timber Planks

Introduction

Not enough farmers in developing countries have animal carts. Those who have carts can take their produce to places where they can get good prices. They can also get into town and buy fertilizer and better seeds and move things around their farm easier. The trouble is that carts are too expensive for many farmers. What can be done?

Carts are made in many different places. Some carts are made in factories in industrial countries and some are made in African factories, but most are made by local blacksmiths or carpenters using scrap car and Land-Rover axles. These people cannot get enough axles to meet the demand, so the price is high. Even if they did have the axle, they still end up building heavy bodies that take ages to make. In another booklet in this series we have told you how you can make simple low-cost axles; in this booklet we tell you about a simple steel and timber body. You should be able to make the body for about $\$_{US}$ 30 depending on the cost of the materials and labour. Once you get organised, two men can probably make two bodies per day.

What you need is a cart body which carpenters and fabricators can make with their simple tools. These people will probably be in the small market towns used by the farmers and they will have an electric welder and some basic handtools like a hacksaw. Experts think that having the cart maker close to the farmer is a good thing because they can talk to each other easily and sort out any problems. Also if the cart is made locally, it can be repaired locally, so there should not be any problems with spare parts.

Idea Behind Design

The idea behind the design of donkey cart described in this technical release is to allow construction without lots of special tools and jigs, and without any hard-to-get materials. The only tools which you must have are a welder and a hacksaw. You might also find that a couple of 4" or a 5" G clamps (or something like it) are useful too. (The symbol " means inches here, so that 4" is about 100mm since there are about 25mm in an inch.) A wheelbrace or carpenters brace is also useful - you can make the drill bit yourself.

You will see that there are no mitres and unusual angles to cut in the square tubing so you save time when making the cart. Also the exact lengths of the components are not very fussy. But you will find that the carts look better if you take trouble to get things square and straight.

These carts have been tested in Nigeria, but we would like to test them more. The only problems which we have found so far have been breaking of the animal shafts and we have fixed this by welding some strengtheners (bits of 8mm, 10mm or 12mm round bar or re-bar) to the top and bottom of the chassis. (Re-bar means concrete reinforcing bar). The construction tends to be a bit light in Nigeria, because they sell square tubing with very thin walls (much less than 1mm thickness). If you used tubing with a wall thickness of 2.5mm or more you probably would not need to put these strengtheners on. But really to get a cart at a reasonable cost you need to experiment a bit to see how the farmers treat their carts and what they expect them to stand. It's no good saying it must be strong enough so that they cannot ever break it - somebody will always break anything - and it will be very expensive to make it nearly unbreakable. At least with this design you can repair it easily and cheaply.

Cutting list and costs

Table 1 shows a cutting list for a complete cart. Recent prices of materials in Nigeria are shown converted to $\$_{US}$. The square box tube (sometimes called rolled hollow section or RHS) is about 2" or 50mm on one side. You can often buy it in a variety of wall thicknesses. It's best with a wall thickness of 2.5mm (12 gauge) or more, but we have used wall thicknesses down to 1.6mm (16 gauge) as we mentioned earlier.

Construction step by step

1) The first job, is to get all the material together and clear a space to work. Ideally you will be able to work on a flat area of concrete. Start by cutting the square box tube into the right lengths, as in the cutting list shown in Table 1. Then cut the various bits of re-bar or whatever you are going to use. You could cut the timber also at this stage, but it might be easiest to leave it till last.

TABLE 1: cutting list for light steel framed donkey cart.

component	material	# lengths & length reqd	total material in cart	materials cost in Nigeria
[#*mm]				
animal shafts	50×50 RHS	2×3150	6300	8.94
body cross pieces	50×50 RHS	3×700	2100	2.98
axle struts	50×50 RHS	2×600	2400	3.40
shaft strengtheners	8mm to 12mm round bar[1]	8×600	4800	1.02
axle strut braces	8mm to 12mm round bar	3×850	2550	0.54
axle fixing studs	M12 threaded rod or bolts	2×125	250	0.85
axle fixing loops	6mm dia re-bar or similar	2×330	660	0.07
plank fixing studs	6mm dia re-bar or similar	14×75	1050	0.11
tray planks	1"×12" or similar timber	6×1100	6600	3.90
TOTAL =				21.82

[1] The round bar can be anything actually - it doesn't even have to be round, so deformed or high-yield re-bar is fine. You could even use flat strip as long as its more than say 8mm thick.

2) Next weld the axle supports to the animal shafts. The method shown in Figure 2 is probably the easiest way to support the components during welding the first shaft and support. It's quick and if you do not tighten the clamps too

tight to start with, you can tap the parts with a hammer until everything is square and straight. Then tighten the clamps before you weld.

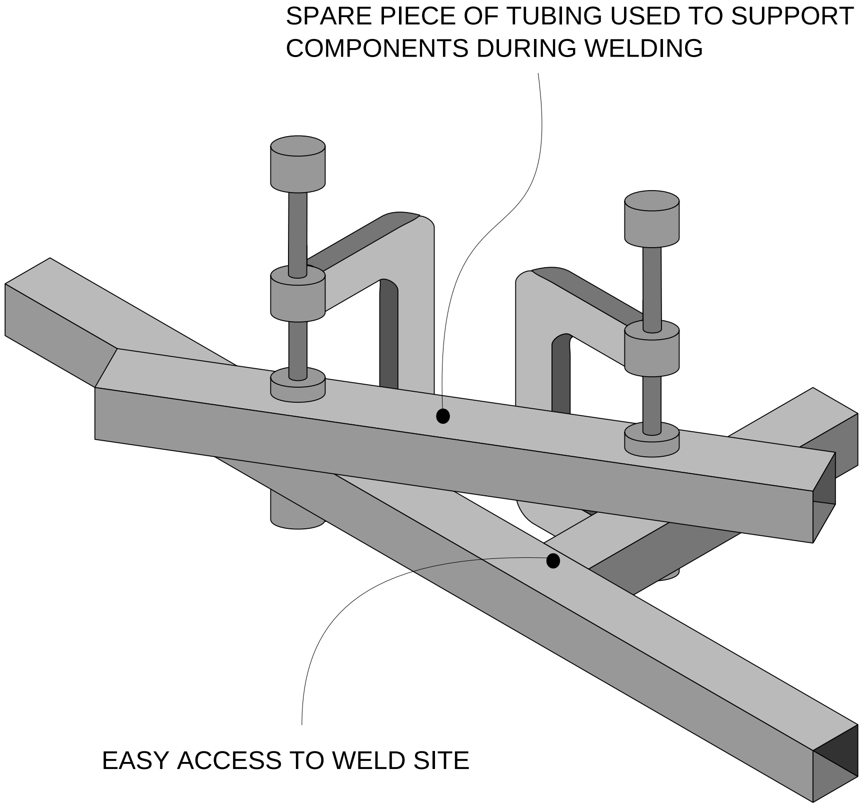

Figure 2: supporting components during welding.

Repeat the process using the first shaft and support as a pattern for the second as shown in Figure 3. Make sure you do not weld the two assemblies together!

3) It may be easiest to fix the axle retaining bolts and loops on at this stage so that you can use them in the next stage. Figure 4 shows a good way to fix a square axle on.

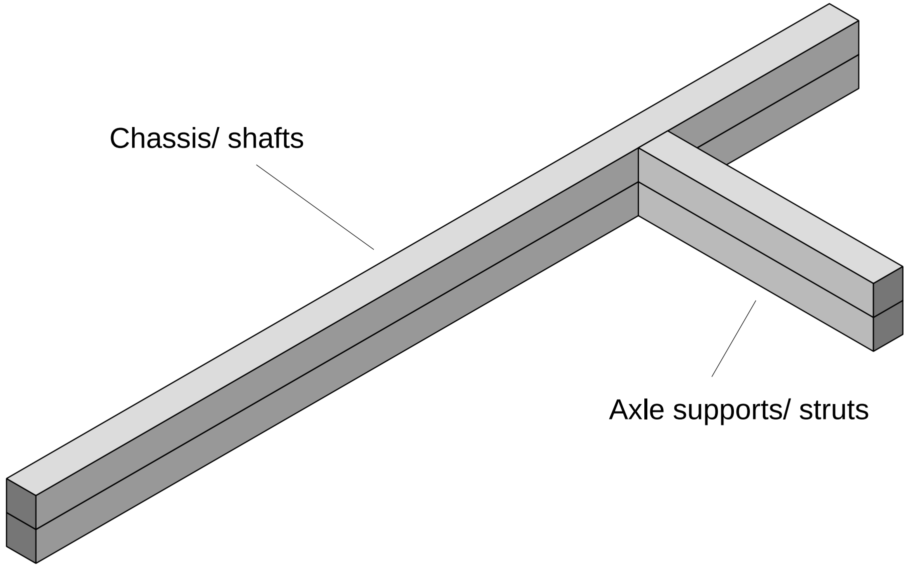

Figure 3: welding animal shaft and axle support strut assemblies.

4) Now you can weld the three cross pieces under the animal shafts after you have checked for squareness etc.

5) Next you need to weld on the various reinforcements to the square tube. These are the axle braces and the pieces where the shafts might get broken - over the axle supports and at the front of the load tray/ wooden planking. Figure 5

shows the frame nearly ready for fixing the planking.

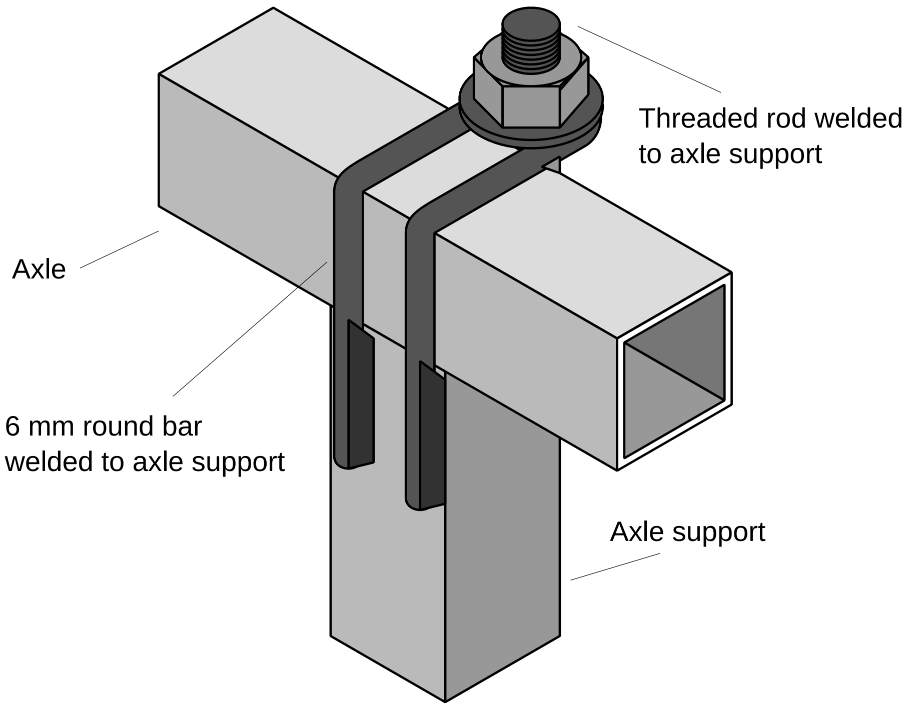

Figure 4: method of fixing axle to axle supports.

6) Nearly there! Now you need to fix the wood onto the square tube. You can do this with staples or studs. Staples use more steel but studs need more welding. Figure 6 shows the choices - staples are like big U s, and studs are just pieces of 6 mm wire sticking up which you bend over the wood.

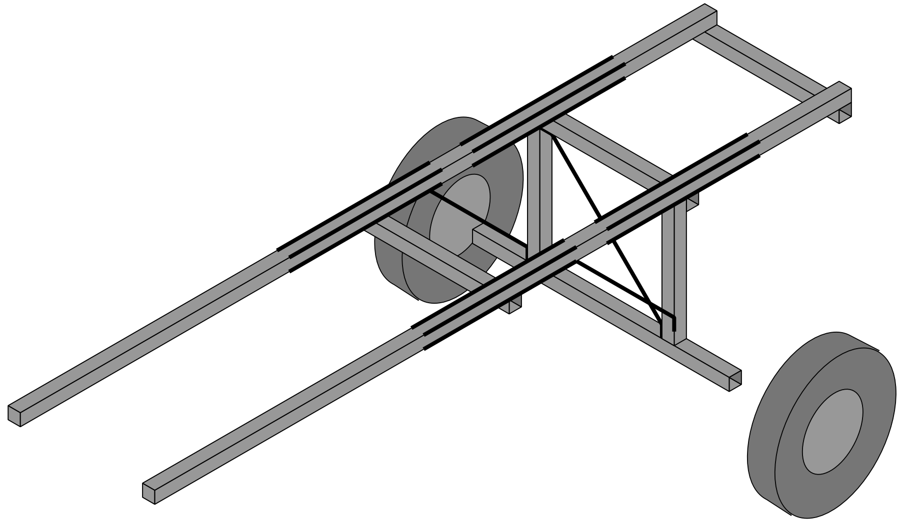

Figure 5: cart frame before planking.

To make staples you can make a jig from some bolts in a piece of wood or you can just bend the staples in a vice. They do not have to be very accurate, but as usual the more accurate the better.

To fit the staples, drill a hole in the plank both sides of the tubing and push both legs of the U through the wood using a hammer if necessary. When it's through, hold another hammer or something heavy against the bottom of the U whilst you knock the protruding legs over with another hammer. You might find this easier with someone to help you. Then clench the legs by knocking them into the surface of the wood to leave the surface flush. Once you are happy that all is in the right place, weld the staple to the square tubing as shown in Figure 6. Then put the rest of the staples in in the same way.

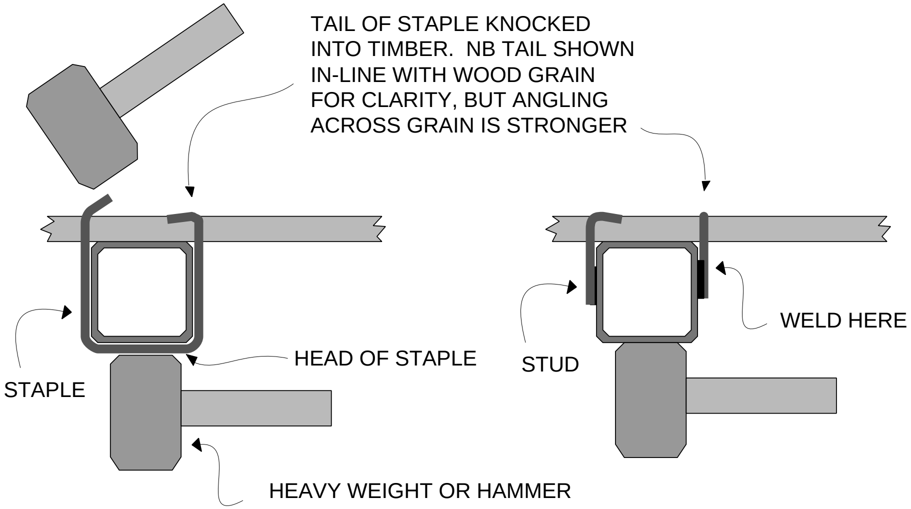

Figure 6: fixing wood with staples or studs.

If you want to use studs, weld them on to the side of the square tube as shown in Figure 6. You can either drill holes for them as described earlier for staples, or you can bring them up past the edge of the planks, which saves drilling holes.

7) Paint the cart. You've finished it!

Modifications

There are many different versions of this cart. The one shown in this document has no sides, because it is for one donkey and is as light as possible. It is good for everything except loose materials such as sand, but you can always put this into sacks. To fix ropes for tying firewood or sorghum stoba etc, you can cut slots or notches in the ends of the planks as shown in Figure 7, which shows two ways of doing it.

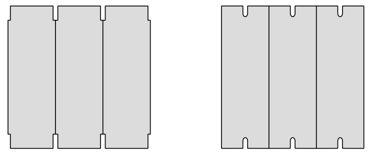

Figure 7: notched ends in planks to tie rope to.

You could put side planks on a cart like this using the same 6mm wire/ round bar/ re-bar to tie them on. This would be cheap and very easily repairable.

A danger with building carts is that the farmers will want something flashy looking which will be very expensive to make. You would probably find that things like hinges and latches take as much time to make as the basic parts of the cart.

If you want a cart with permanent sides you could build our medium weight donkey cart.

You can try longer and shorter carts and you can make them wider or narrower. When you do this, check the length and width of the planks of wood that you will use - you do not want to find that you are two inches short of being able to get two runs of plank out of one piece of timber, or that its just too narrow and you have to fiddle about and waste time filling the gap with an extra little strip.

Another thing is the height of the cart. No-one seems to know why some carts are made high and others low. Its better for the animals if the load tray is low particularly if the carts will be operated over rough ground. But you may find that farmers want a high load tray to keep loads dry if they are fording rivers a lot, or it may be a status thing (if you are wealthy enough to own a cart, your eye level must be above a pedestrian's). Or it may be that it's too tiring to load a low cart - if, for example, you have to bend your back twice for each bundle - once to pick it up off the ground and again to put it down onto a low load tray. We have also found that farmers usually want the body to come out over the wheels so they can load on lots of straw or light materials.

Other DTU cart developments

The DTU has been working on a range of cart body types for use with both donkeys and oxen. It has designs for both wooden and steel framed types. The wooden types are cheaper in material terms, but the steel framed ones are easier to make because the joints are more straightforward - but you can make either type of cart in only a few hours, if you have all the tools and materials you need before you start.

The DTU has also been working on new designs of wheels, hubs and bearings to bring down their costs and make things more locally manufacturable. For example it has worked on a system of hubs using water pipe which do not need machining to make a roller bearing hub. Friction is low with these hubs and they usually give good milage before being worn out too - we usually get 15 000 km before they are very badly worn, but they may need cleaning and relubrication several times before they get this far. But they are reasonably cheap - we can make them in Nigeria for about $\$_{US}$20. They only take one man a day to make and they do not need any special tools.

Other hub designs using, for example aluminium castings, are in production in Nigeria and we are trying to reduce or eliminate the machining in these. Also wheel designs in steel sheet, cast aluminium and timber are in manufacture or under development.

Cart Drawings

The drawing for the cart is shown on the following page and the list of materials has been shown on a previous page.

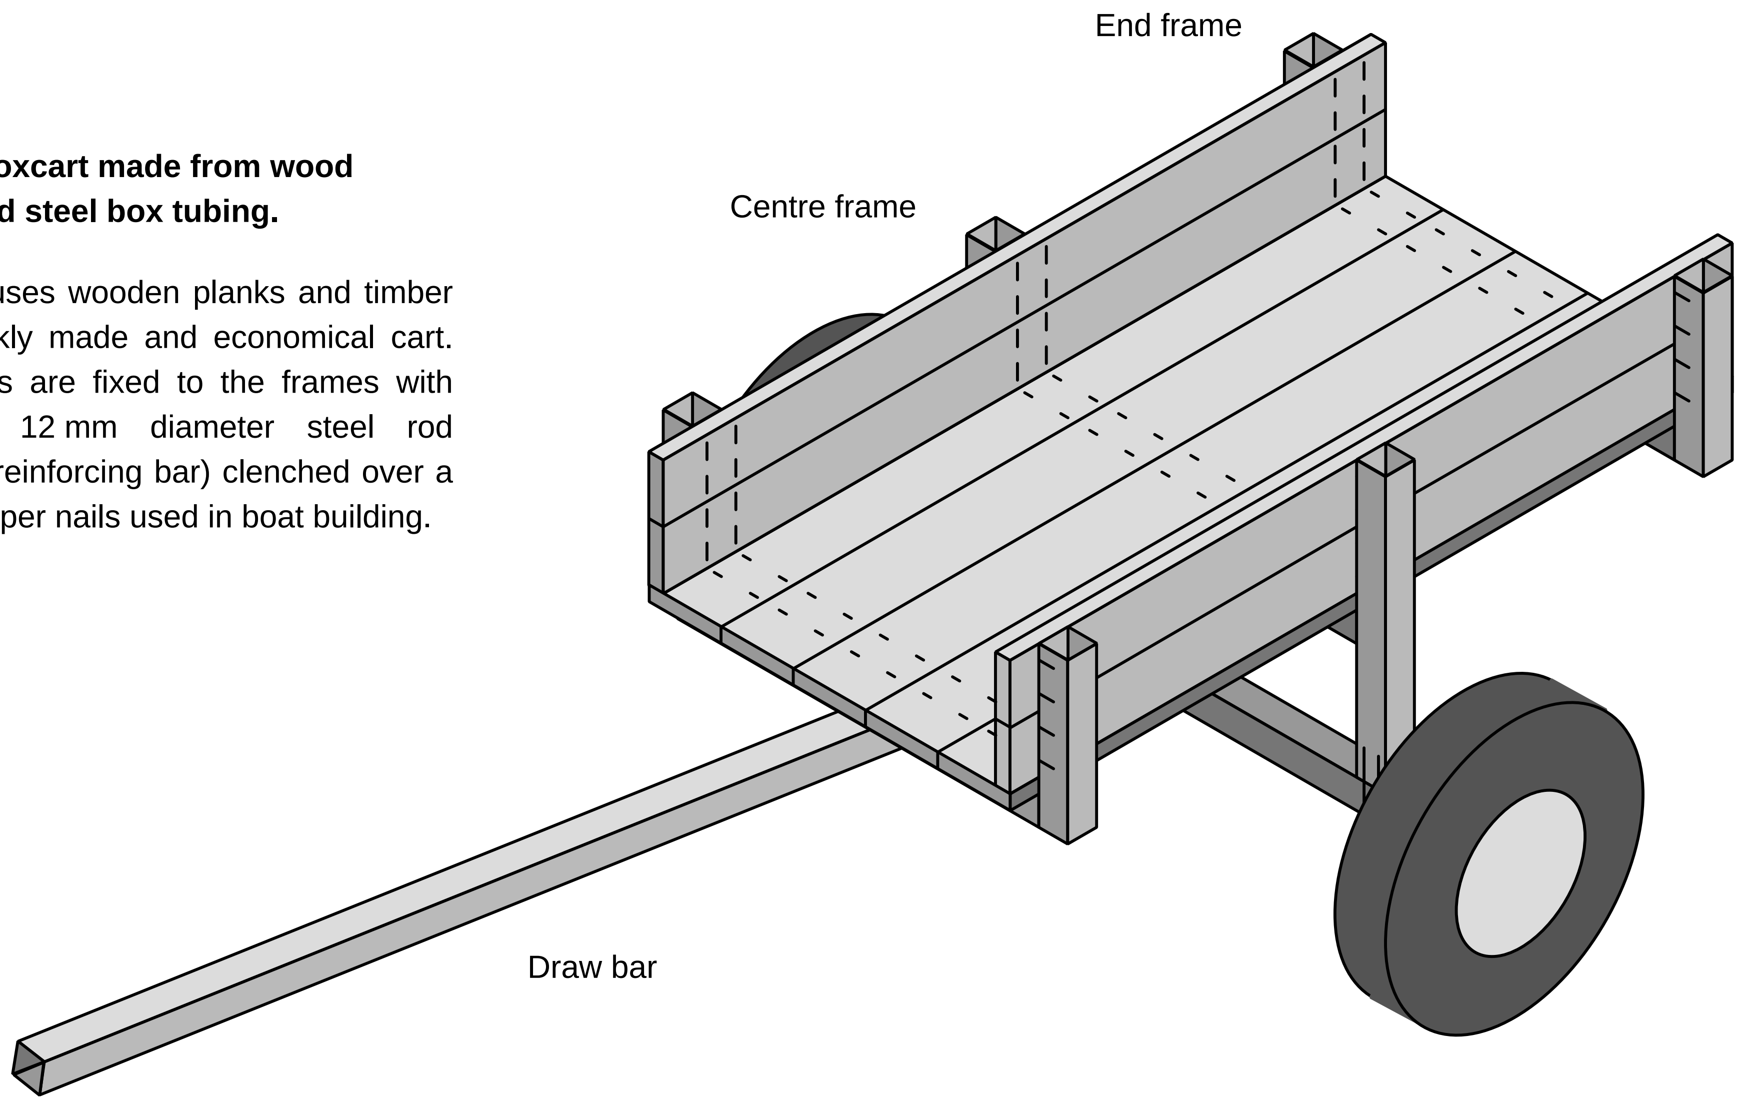
RELEASE

LOW-COST STEEL & WOOD OX CART

Development Technology Unit, Department of Engineering, University of Warwick, Coventry, CV4 7AL UK, tel: +44 (0)1203 523523 extn 2339, fax: +44 (0)1203 418922, email: dtu@eng.eng.warwick.ac.uk

Figure 1: oxcart made from wood planks and steel box tubing.

This cart uses wooden planks and timber for a quickly made and economical cart. The planks are fixed to the frames with 6 mm to 12 mm diameter steel rod (concrete reinforcing bar) clenched over a bit like copper nails used in boat building.



Ox Cart Body Made From Steel Box Tubing and Timber

Introduction

Not enough farmers in Africa have animal carts. Those who have carts can take their produce to places where they can get the best prices. They can also get into town and buy fertilizer and better seeds and move things around their farm easier. The trouble is that carts are too expensive for many farmers. The question is what can be done about it?

What you need is a body which fabricators and carpenters can make quickly with simple tools. These cart makers will probably be in the small market towns used by the farmers. Experts think that having the cart maker close to the farmer is a good thing because they can talk to each other easily and sort out any problems. And of course if the cart is made locally, it can be repaired locally, so there should not be any problems with spare parts.

Carts are made in many different places. Some carts are made in factories in industrial countries and some are made in factories in Africa, but most are made by local blacksmiths or carpenters using scrap car and Land-Rover axles. These people cannot get enough axles to meet the demand so the carts are expensive. Even if they do have the axles, they still end up building heavy bodies that take ages to make. In another booklet in this series we have told you how you can make simple low-cost axles; in this booklet we tell you about a simple steel and timber body. You should find that you can make the body for about $\$_{US}60$, depending on the cost of the materials and labour. Once you get organised, two men can probably make one body in a day. This is quite a lot faster than most carts can be made and it follows from the simplifications which we have made to the design. We've designed these carts to be easy to make.

Idea Behind Design

The idea behind the design of oxcart described in this technical release is to allow construction without lots of special tools and jigs, and without any hard-to-get materials. The only tools which you must have are a simple welder, a woodsaw, a hacksaw, a hammer and a drill able to make a 10 mm or 12 mm hole in wood. (In fact you can make the drillbit yourself if you have to - read our booklet **Making a flatbit** - it's not too difficult.) You might find that a couple of 4" or a 5" G clamps (or something like it) are useful too. (The symbol " means inches so 4" means about 100mm because there are about 25mm in an inch.)

The cart frames are fixed together by welding and the wooden planks are fixed to the frames with clenched steel bar. This is a bit like the way small boats used to be fixed together. It's called clenching. What you do is make a holes through the wood to be fixed, put a giant staple made from 6 mm, 8 mm or 10 mm diameter re-bar (concrete reinforcing bar) over the steel box tubing and through the wood so it sticks out about 50 mm, and then knock the ends over with a hammer so they lie on the surface of the wood. You can tighten the joint more by putting a big hammer or something hard and heavy under the staple as shown in Figure 5 and then hitting the ends harder. If you put some washers (or something like them made from sheet steel) on the re-bar before you bend it over it will make the joint a bit stronger still. It does not make a very rigid joint, but you will find that the flexibility gives the cart some resilience so that it takes knocks better.

You will see that there are no mitres or complicated angles or joints to cut so you save time when making the cart. Also the exact lengths of the components are not very critical - again it saves a little time, but you will find that the carts look better if you take a little trouble to get things square and even etc and welding is easier with good square ends.

These carts have been tested a bit in Nigeria, but we have not tested them enough. We think that they are strong enough, but we cannot be sure. Really to get a reasonable price you need to experiment a bit to see how the farmers treat their carts and what they expect their carts to stand. It's no good saying it must be strong enough so that they cannot ever break it - somebody will always break anything. It is very expensive to make something unbreakable. At least you can repair these carts easily and cheaply.

Cutting list and costs

Table 1 shows a cutting list for a complete cart - Recent prices of materials in Nigeria are shown converted into $\$_{US}$.

TABLE 1: cutting list for steel and wood oxcart.

component	material	number of lengths & length required [No.×mm]	total material in cart [mm]	materials cost in Nigeria [$us]
animal draw bar	80×80 box tubing	1 × 3 600	3 600	12.77
frame bottoms	80×80 box tubing	3 × 1 000	3 000	10.64
end frame sides	80×80 box tubing	4 × 415	1 660	5.89
centre frame sides	80×80 box tubing	2 × 750	1 500	5.32
tray bottom planks	30 × 150 or similar timber	6 × 2 000	12 000	3.87
tray side planks	30 × 150 or similar timber	4 × 2 000	8 000	2.58
tray ends	30 × 150 or similar timber	2 × 1 000	4 000	1.29
plank fixing staples	8 mm dia re-bar or similar	60 × 400	24 000	2.55
axle fixing studs	M12 threaded rod or bolts	4 × 150	600	2.55
axle fixing loops	8 mm dia re-bar or similar	4 × 550	2 200	0.23
TOTAL->				47.69

Construction step by step

1) The first job, is to get all the material together and clear a space to work. Ideally you will be able to work on a flat area of concrete. Start by cutting the 80 × 80 box section steel into the right lengths, as in the cutting list, then cut the bottom and side planks. Lastly cut the 6 mm or 10 mm dia or whatever re-bar for the fixings (the staples etc).

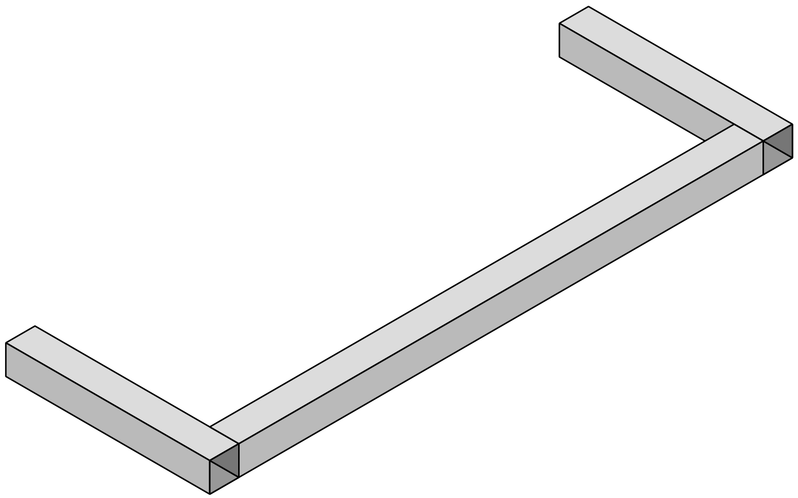


Figure 2: finished end frame.

2) Next make up the two U-shaped front and back frames (endframes). If you have a couple of G clamps you can use them to hold two pieces of the frame together during welding as shown in Figure 3. It's quick and you can tap the parts with a hammer until everything is square and straight and then weld.

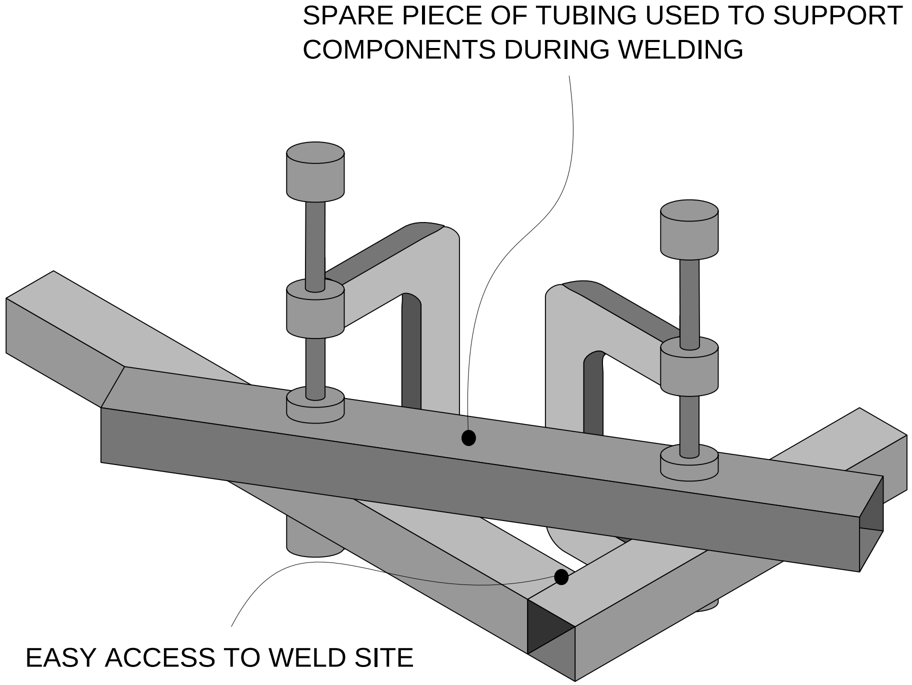

Figure 3: holding frame components during welding.

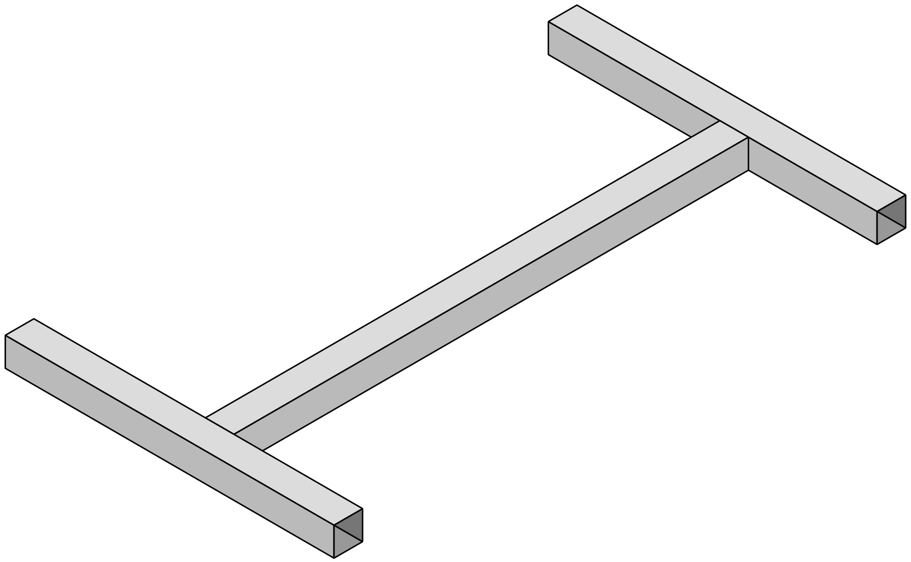

Figure 4: a finished centre frame.

3) Then make up the frame that goes in the middle (as shown in Figure 4) - the one which supports the axle.

4) Next you can fit the side and the bottom planks to the end frames and then the middle frame with staples or studs. Figure 5 shows how these staples and studs can be tightened with a hammer and a weight or another hammer. You need to fix the staples in the right place with a small weld. Studs are another way of fixing the planks. Studs are just short lengths of round bar welded to the sides of the box section as shown in the right of Figure 5. This saves round bar but means more welding.

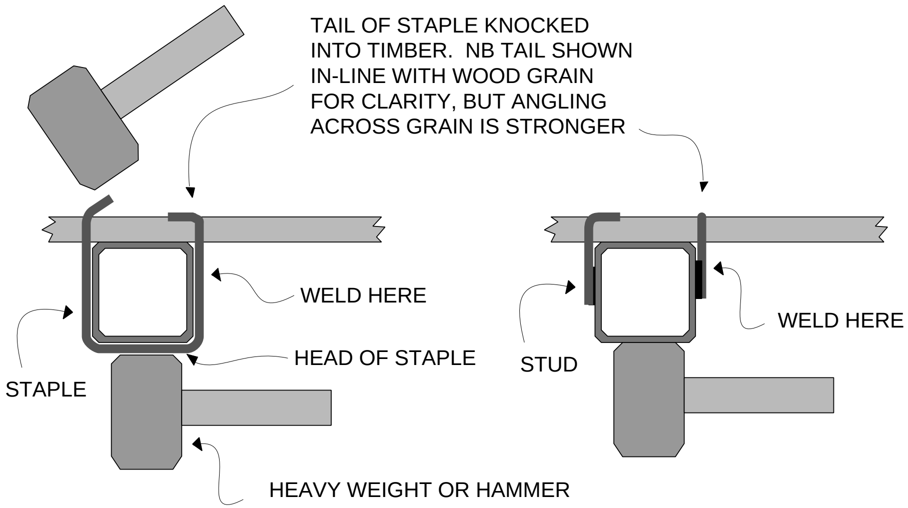

Figure 5: tightening staple or welded stud.

When you bend the end of the stud or staple over you can either bend it in line with the grain of the wood or across the grain, as shown in Figure 6. Bending it in line as shown on the left lets it go into the wood nicely and looks neat, but bending it over across the grain gives a stronger joint.

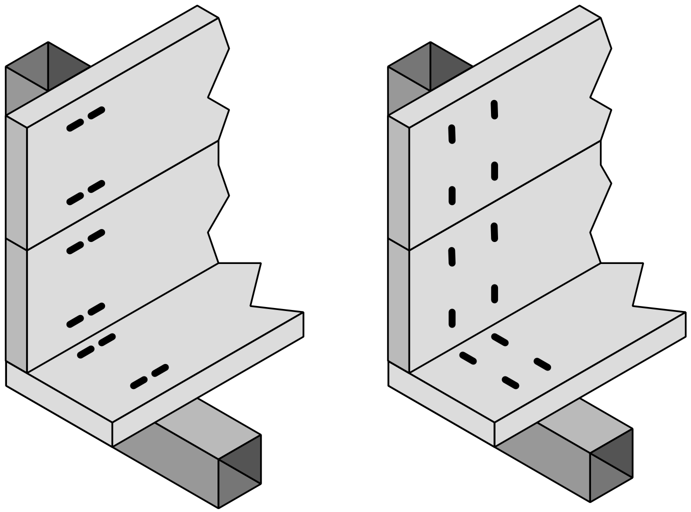

Figure 6: studs or staples bent in line with grain (left) or across it (right).

One thing we have not tried is bending the staple or fixing over the edge of a plank instead of putting it through a hole.

5) Next fix the axle with a one or two loops of round bar and some threaded rod and nuts and washers as shown in Figure 7. If you can get big threaded rod (say 16 mm and some 10 mm plain rod, you can fix the axle with one loop and threaded rod, but if you have only 12 mm then you must use two loops as shown.

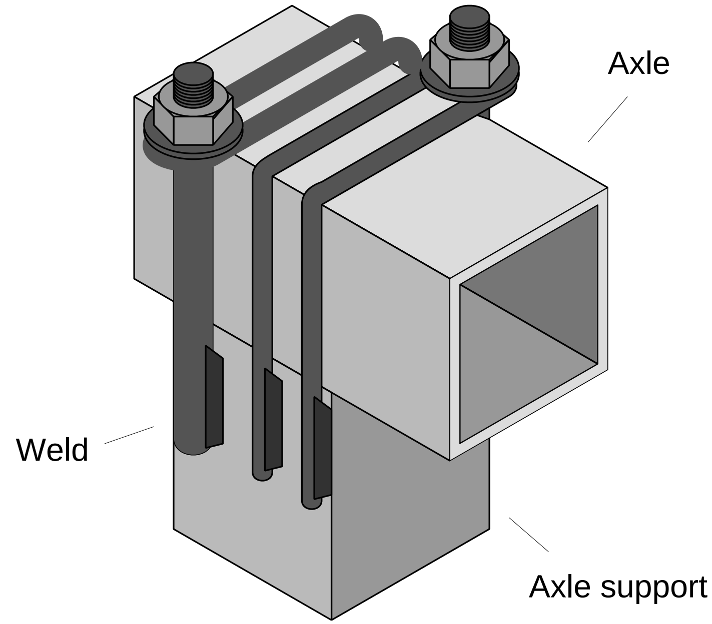

Figure 7: method of fixing axle to axle supports.

6) Nearly there! Now you need to fix the draw bar (or pole or dissel boom - there are so many names for this!). It is best to fix the draw bar to the body so it can be taken off and replaced if it gets damaged. A good way to do this is with stops made of short lengths of box tubing, and round bar welded on as shown in Figure 8. The stops carry the main loads and it is easy to cut through the re-bar hoops if you need to change the draw bar. You will need to put new hoops on of course when you put the new draw bar on.

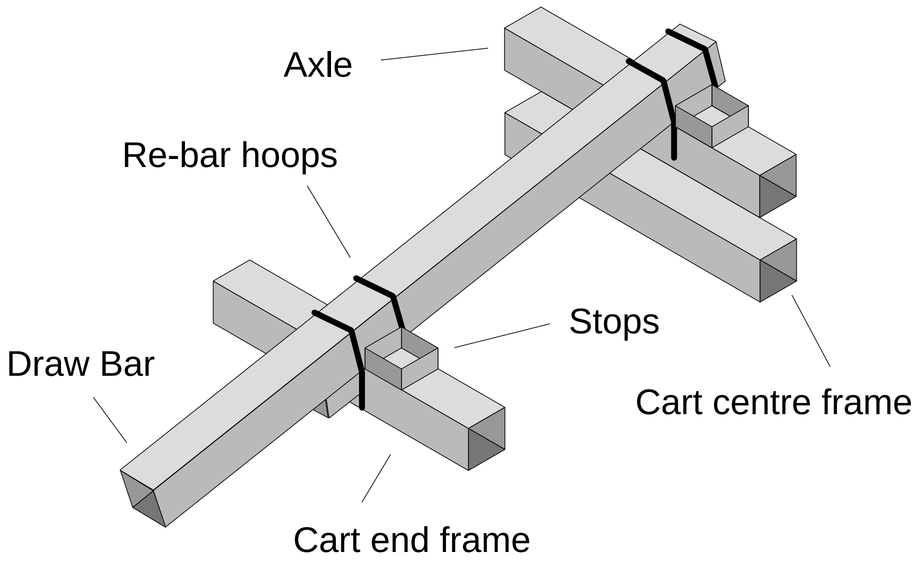

Figure 8: method of fixing draw bar to body. (View of cart upside down.)

7) If you want to make it so that the ends of the load tray can be removed easily you can do so in the way we have shown in Figure 9. Here a piece of the box section steel is fixed to the side planks by clench bars or bolts and stops the end being able to fall out. It is better if box does not touch the bottom planks because then it is easier to clean the corners. The end can be tied to these end stops with rope or inner tube rubber. This is a good way because it is cheap and very easily repairable, but the farmers may want some flashy looking thing which will be very expensive to make. You will probably find that things like latches take longer to make than the rest of the cart. Explain to the farmers that they will cost extra too!

8) Paint or creosote the cart. You've finished it!

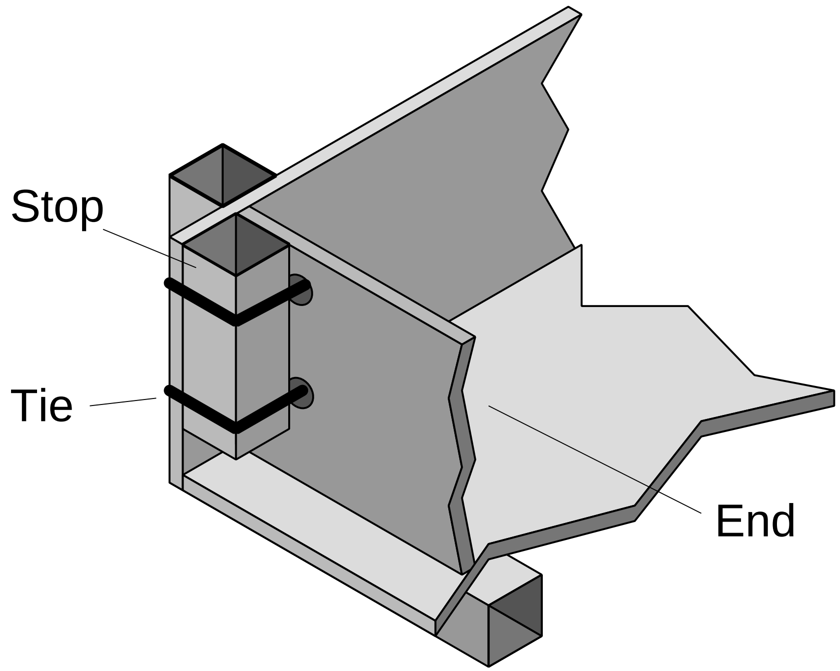

Figure 9: method of fixing ends with rubber or rope

Modifications

There are many different versions of this cart. You can try longer or shorter carts and you can make them wider or narrower. When you do this, check the length and width of the planks of wood that you will use - you do not want to find that you are two inches short of being able to get two runs of plank out of one piece of timber, or that its just too narrow and you have to fiddle about and fit in a narrow strip.

Other DTU cart developments

The DTU has been working on a range of cart body types for use with both donkeys and oxen. It has designs for wooden and steel framed types. The wooden types are cheaper in material terms, but the steel framed ones are easier to make because the joints are more straightforward - nevertheless you can make either type of cart in only a few hours, if you are reasonably set up with tools and materials.

The DTU has also been working on new designs of wheels, hubs and bearings to bring down their costs and make things more locally manufacturable. For example it has pioneered a system of hubs using steel pipe such as water pipe which do not need machining to make a roller bearing hub. Obviously friction is low with these hubs and they usually give good milage before being worn out too - we usually get 15 000 km before they are very badly worn, but they may need cleaning and relubrication several times before they get this far. Still they are reasonably cheap - we can make them in Nigeria for about $\$_{US}40$, they only take one man a day, and they do not need any special tools.

Other hub designs using, for example aluminium castings, are in production in Nigeria and we are trying to reduce or eliminate the machining in these. Also wheel designs in steel sheet, cast aluminium and timber are in manufacture or under development.

Cart Drawings

You will find two drawings on the next pages, the first one gives a general view of the cart, and the second gives a view of the main components. As we have said you can vary the size of the cart quite a bit and even make it much longer if you add extra frames. You could even make a four wheeled cart like this!

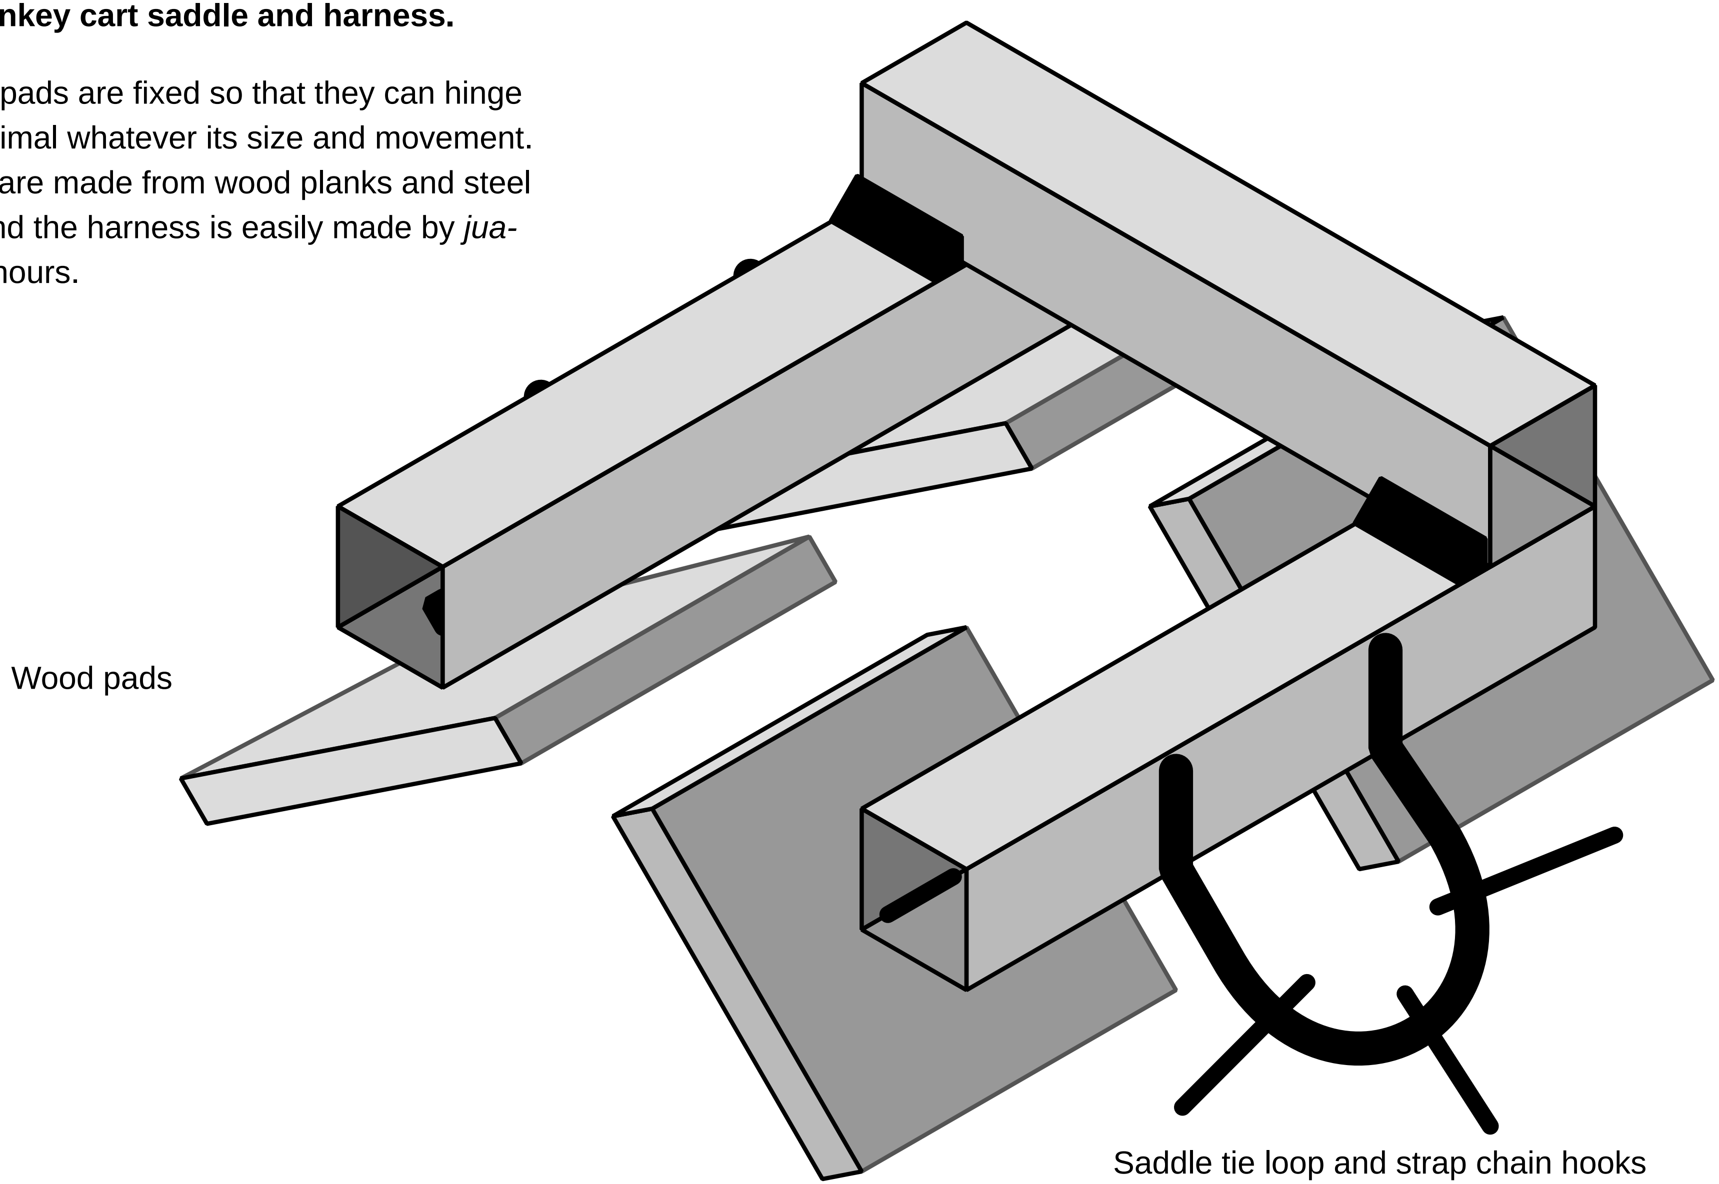
Figure 1: donkey cart saddle and harness.

The wooden pads are fixed so that they can hinge and fit the animal whatever its size and movement. The saddles are made from wood planks and steel box tubing and the harness is easily made by *jua-kali* in a few hours.



Donkey Harness for Carts Made From Steel Box Tubing, Timber and Canvas/ Sacking

Introduction

This Technical release tells you how to make a saddle and harness system for one donkey to pull a cart with two shafts. Another Technical Release tells you how to make a saddle and yoke harness for two donkeys and a cart with a single draw pole.

You should find that you can make the whole harness for less than £$_{UK}$5, depending on the cost of the materials and labour. Once you get organised, two men can probably make a complete harness in two hours - we have designed this harness to be easy to make.

Other booklets in this series tell you how to make simple low-cost axles and carts: we have designs for steel framed and wooden framed carts and for many different kinds of axle. All carts and axles can be made without special tools - even drilling metal is not required.

Idea Behind Design

Saddles are used in many countries to hitch animals to carts. Our saddles use a system of hinged pads which swivel to fit any animal in any reasonable condition. As the animal moves and changes condition the saddle still fits. Using this harnessing method carts can be pulled, steered and braked, and stabilised if the load is too far back on the cart body.

These harness has been tested in Kenya and work well - we have even had donkeys jump over a hedge pulling a cart with this harness! But we would like to test them for a year or two more to see how the animals react.

Special tools and jigs and hard-to-get materials are not required to make the harness. The only tools which you must have are a simple welder, a woodsaw, a hacksaw and a hammer.

The saddle frame is welded and the wooden pads are fixed to the frames with nails which are put through holes in the steel

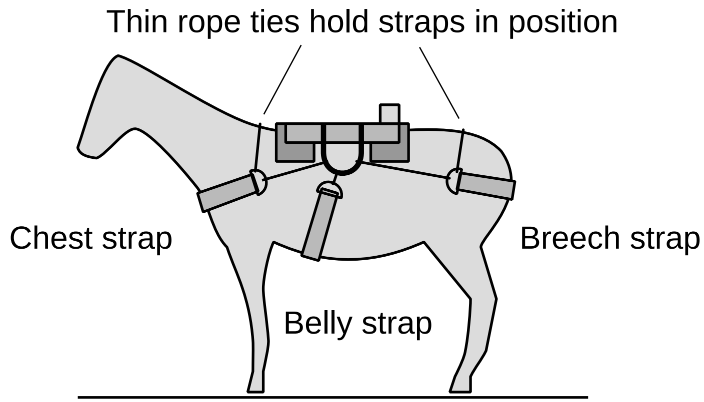


Figure 2: saddle secured to donkey with straps.

frame and welded so that they are loose and allow the pads to follow the shape of the animal.

Cutting list and costs

Table 1 shows a cutting list for a complete harness - recent prices of materials in Kenya are shown converted into £$_{UK}$.

Construction step by step

1) The first job, is to get all the material together and clear a space to work. Ideally you will be able to work on a flat area of concrete.

2) Make up the U-shaped frame as shown in Figure 4. If you have a G clamp you can use it to hold two pieces of the frame together during welding.

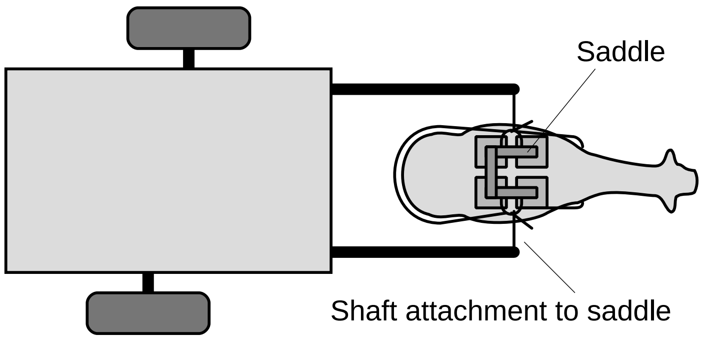

Figure 3: donkey harnessed to cart.

3) Then weld the tie loops and the yoke attachment stub and loop onto the U frames so that the frame looks as shown in Figure 5.

4) Next cut the wooden load pads and round off all the edges so that there are no sharp corners to stick into the donkey.

   Hammer two nails through each of the pads in the positions shown in the drawings. With some timbers you may need to drill holes for the nails to avoid splitting or burn the holes with a hot nail. Then cut the nails so that about 30 mm projects from the timber as shown in Figure 9.

5) Now mark the position of the holes required to accommodate the pad nails in the steel tubing. These holes

TABLE 1: harness materials cutting list.

component	material	# components	total mat [mm]	mat cost [£$_{UK}$]
main frames	50×50 box tubing	3×325	1800.00	1.06
strap loops	12 mm re-bar	2×300	1200.00	0.19
load pad pivots	12 mm re-bar	4×20	160.00	0.03
load pads	25×150 timber	4×150	1200.00	0.14
pad fix nails	nail or 6mm re bar	8×50	800.00	0.04
strap rings	6mm re bar	6×180	2160.00	0.11
strap clenchers	6mm re bar	6×120	1440.00	0.07
strap hooks	6mm re bar	6×150	1800.00	0.09
straps	CC5 canvas	3×4×65	1560.00	1.97
strap chains	dog chain	3×300	900.00	0.70
			TOTAL =	**4.40**

should be 15 mm and 65 mm from the ends of the square tube as shown in Figure 7. Blow the holes through with the welder at maximum current setting or use an angle grinder or file or hacksaw.

6) Next you can weld on the pad pivots blocks as shown in Figure 7.

7) Now put the nails through the blown holes and weld a piece of nail across the ends of the nails as shown in Figure 10. Welding down inside the tube looks difficult but skilled workers can weld the pads in about one minute.

An alternative way of doing it is to cut slots 70 mm long along the corners where the holes would be as shown in Figure 8. The slots should be 8 mm wide so that the nails are very loose in them. Make up the pads as shown in Figure 9, put the nail loop into the slot in the right place and weld the pad pivot blocks into place across the slot so that they are in the same place as in Figure 7.

8) Next you need to make up the six straps to hold the saddles onto the donkeys. The D rings at the end of the straps can be made from 6 mm diameter concrete reinforcing bar as shown in Figure 11. A separate piece of the re-bar is clenched over the strapping using hammer blows to fix the D rings to the ends of the straps as shown.

The straps themselves can be made from heavy canvas or hessian sacking. You should use three or four thicknesses

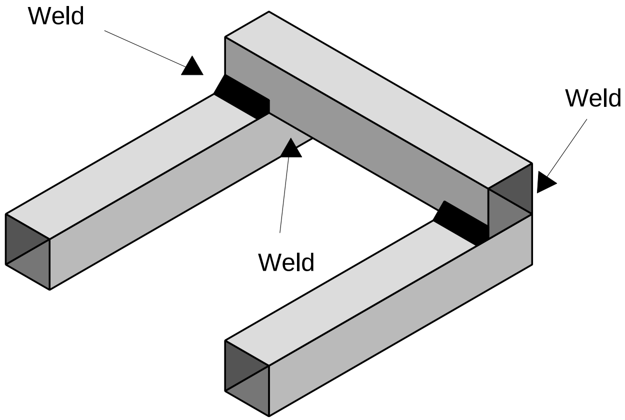

Figure 4: welding of frame cross piece.

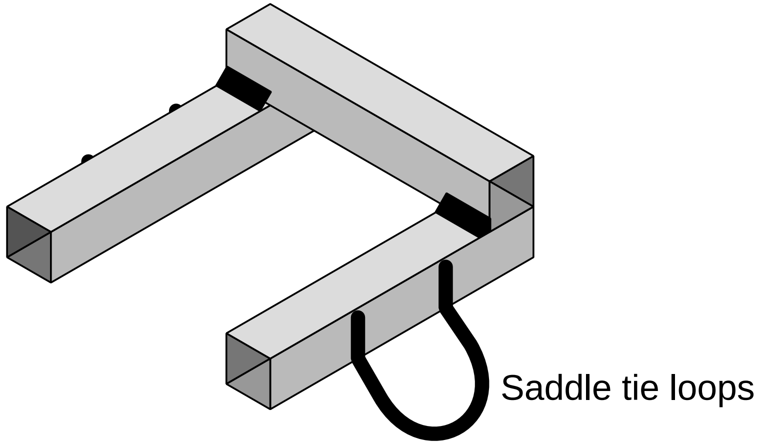

Figure 5: tie loop welded to U-frame.

of material for them to make them strong enough and soft enough not to hurt the donkey.

9) Make the strap chain hooks from more 6 mm re-bar as shown in Figure 12 and fit the fixed ends to the saddle tie loops.

10) Paint and creosote the saddle. You've finished it!

Method of harness use

1) First put a blanket or two folded hessian or jute sacks (not plastic) onto the donkey's back to protect it.

Remember that protecting the donkey will save money because it can work harder if it is comfortable and will not get sick from skin wounds.

2) Put the saddle on so that the cross beam is towards the animal's rear. Position the fronts of the wood pads about 100 mm behind the animal's shoulder blades. This means that the saddle should never come near parts of the animal's back which move.

3) Next hook the breaching strap to the loops hanging from the side of the saddle. It should be tight enough to tend to pull the saddle a little rearwards. Make sure that the breaching strap is pulled up high so that it does not rub the backs of the legs. But it should not be so high that the animal cannot defecate. Tie a piece of thin rope across the animal's back between the rings of the strap to hold the

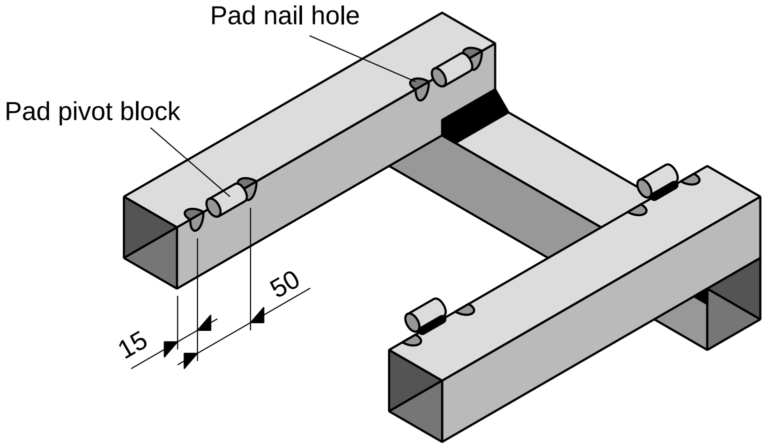

Figure 6: pad nail hole positions and pad pivots.

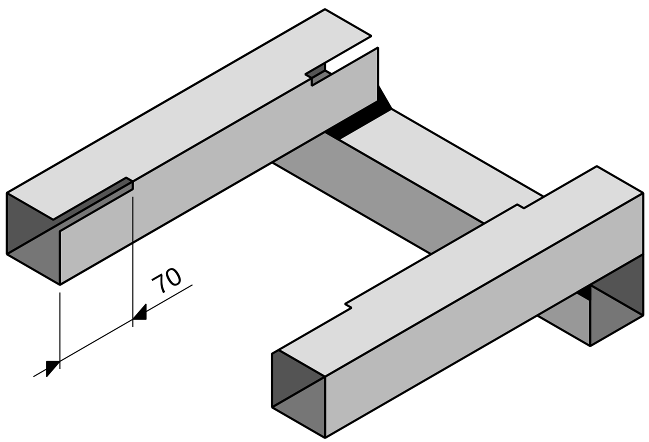

Figure 7: pad nail slots.

strap up.

4) Now hook the chains for the belly strap onto the hooks fixed to the saddle tie loops. The strap should be 50 mm or 100 mm behind the front legs - check that the legs do not rub on the strap when the animal walks. Tighten the strap so that you can just get a couple of fingers under it between the strap and the animal. This will be much tighter than the other straps.

5) Hook the chest strap to the loop and adjust the tension so that it is a little loose. Use another short piece of rope to hold the chest strap up so that it is just below the windpipe. The strap goes tight when the animal pulls really hard. We have noticed that the belly strap and breaching strap are nearly enough without the chest strap and so we leave the chest strap a bit loose.

6) You are ready to go! You should be able to saddle an animal in only a few seconds when you get practised.

Saddle Drawing

You will find drawings of the saddle and yoke on the last pages of this Technical Release.

Other DTU cart developments

The DTU has been working on a range of cart designs for use with both donkeys and oxen. It has designs for wooden and

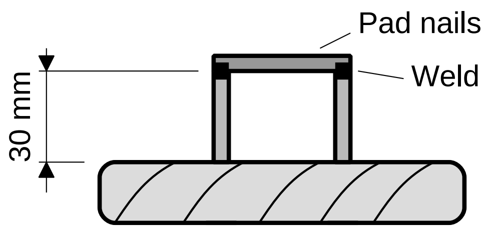

Figure 8: welded pad nails.

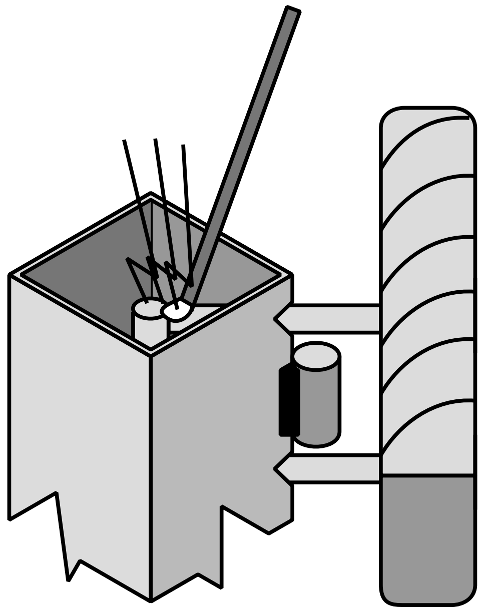

Figure 9: welding re-bar to frames for wooden load pads.

steel framed types. You can make either type of cart in only a few hours, if you are reasonably set up with tools and materials.

The DTU has also been working on new designs of wheels, hubs and bearings to bring down their costs and make things more locally manufacturable. It has a system of axles with bearings made from PVC pipe, another with wooden bearings and a third using scrap ball bearings. None of these axles need machining and they only take two men a day to make.

Acknowledgements

The DTU is grateful to the DFID (British Government) for the financial support necessary to carry out the research and development project under which this product was developed.

The DTU would also like to thank Dr Pascal Kaumbutho of KENDAT in Kenya and Mr Joseph Mugaga of TOCIDA in Tororo, Uganda for their very considerable help with this project. A large number of other people and organisations have contributed to the success of the project, most notably Mr Anthony Ndungu in Kajiado Kenya, Mr JD Kimani in Kikuyu Kenya and Mr Joseph Gitari in Wanguru Kenya in whose workshops most of the development work of this project was performed. Thanks are due also to Mr Stanley Lameria in Kajaido, Mr Patrick Gitari in Wanguru and Mr Mathew Masai in Machakos for their assistance.

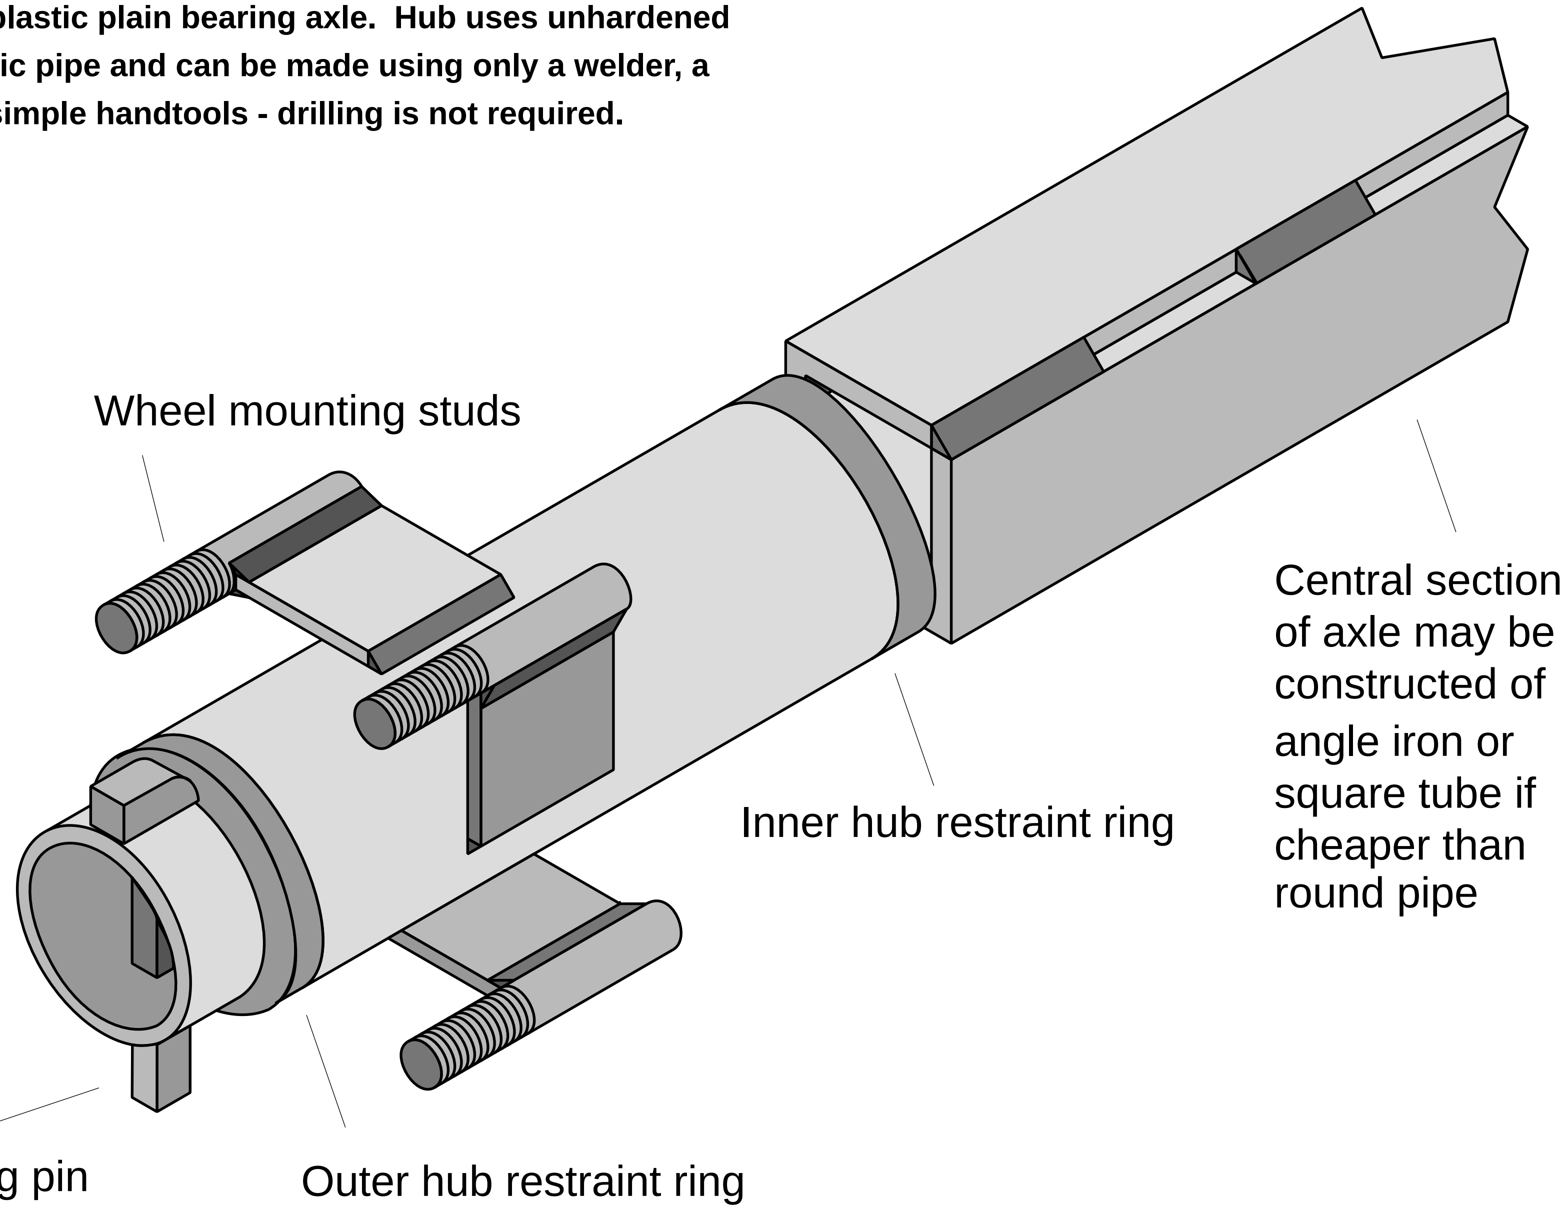
RELEASE

PIPE PLAIN BEARING DONKEY CART AXLE

Development Technology Unit, Department of Engineering, University of Warwick, Coventry, CV4 7AL UK, tel: +44 (0)203 523523 extn 2339, fax: +44 (0)203 418922, email: esceo@eng.warwick.ac.uk

Figure 1: pipe and plastic plain bearing axle. Hub uses unhardened mild steel and plastic pipe and can be made using only a welder, a hacksaw and very simple handtools - drilling is not required.



Pipe Plain Bearing Donkey-Cart Axle

Introduction

Not enough farmers in Africa have animal carts. Those who have carts can take their produce to places where they can get the best prices. They can also get into town and buy fertilizer and better seeds and move things around their farm easier. The trouble is that carts are too expensive for many farmers. The question is what can be done about it?

Carts are made in many different places. Some carts are made in factories in industrial countries and some are made in factories in Africa, but most are made by local blacksmiths or carpenters using scrap car and 4WD axles. In many countries these people cannot get enough axles to meet the demand so the price is high. Another problem is that the axles are often so worn that they do not last long. Lots of farmers take the (differential) unit out of the axle too, which makes the axle break sooner and lets the dirt in.

What you need is an axle which blacksmiths and fabricators can make with fairly simple tools - without having to get parts machined. There are usually blacksmiths and fabricators in the small market towns used by the farmers. Experts think that having the cart maker close to the farmer is a good thing because they can talk to each other easily and sort out any problems. And of course if the cart is made locally, it can be repaired locally, so there will not be problems with spare parts.

Idea behind design

The idea behind the design of axle described in this technical release is to allow construction without the use of machine tools (drills, lathes and milling machines), and to use materials which should be readily available. The materials can be used 'as bought' - no hardening of any of the components is needed. The only tools which you must have are a welder and a hacksaw, but a file and a vice are also very handy. Of course if you do have power tools - especially a power hacksaw or anglegrinder with cutoff wheel - things can be made much faster. This axle is suitable for a wide range of production methods so that if you have to make many of them you can make special tools to make it quicker.

The hubs in this design use 2"BSP pipe on $1^1/_2$" BSP axles so that they have a small diameter and will fit most scrap car wheels. Most wheels have a hole in the middle for the axle.

This hole is usually about 60mm diameter, or a bit bigger. Sometimes they are smaller and the wheel will not fit, but you can sometimes saw or file the hole bigger if you have to. Another way of avoiding the hole in the wheel problem is to use live axles as described in Technical Release 29.

The best way to make these axles is to use a piece of plastic pipe between the axle and the hub tube to make a bearing. The best plasic is probably polythene, but this is hard to get in short lengths so we have used PVC in Kenya. Search around the stores in your area to see what is available. If the only steel pipes you can find for the axle and hub tube do not have enough gap between them for a plastic bearing then you can still get good performance without it, but the axle will wear a bit faster and the cart will be a little harder to pull. Alternatively you can enlarge the hub tube a little see the **modifications** section.

You will see from Figure 1 that the wheels are fixed to the axles by struts rather than by thick metal discs as on most axles. Putting the fixing studs on struts like this is much easier and cheaper. It also means that you might be able to fit a slightly different wheel by bending the struts a bit to fit. Or if that does not work you can even cut nearly through the welds and then weld them in the right place. You could even cut the struts right off and weld on a different number if your wheels have a different number of holes.

Performance

We have not yet properly tested axles like these, but many farmers and water carriers in Kenya have used them on their carts for three years or more without even a plastic bearing. Of course you need to clean the axle and hubs out and regrease them every year at least and if you use them heavily you should grease them every day. Actually this is easy because all you need to do is remove the hub restraint pin through the end of the axle, take the wheel and hub off, put some grease on the axle and replace everything. It should only take a few seconds.

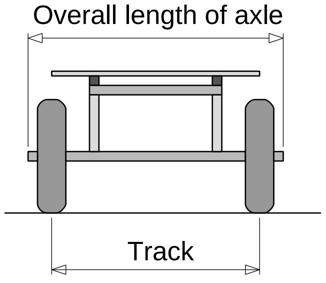


Figure 2: track width of cart.

Length of axle

You need to decide how long to make your axle. Of course you can make the axle any length you like to suit your cart, but most carts will need an overall axle length of between 1400 to 1600 mm. In the **cutting list and cost** section you will see that you can make the axle with a central section of some other material than the $1^1/_2$" BSP if this is very expensive. We have assumed that you will use square box tubing but you could use angle iron. To calculate how long to make the axle decide how big you want the **track** to be (see Figure 2) and add 280 mm. This distance will now be the **overall length of the axle** (see Figure 2 for this also). If you are going to use square box tubing or angle iron for the central section of the axle then you should subtract 240 mm from the **track** and make the central section this long.

Cutting list and costs

The table shows a cutting list for a complete axle - two wheel hubs with stub axles joined by a square tube section in the middle. We have shown this way because round pipe is very expensive in some countries. But if pipe is reasonably cheap where you are then make the whole axle out of one piece of pipe. Recent prices of materials in Kenya for the axle are shown in $\$_{US}$. The 2" BSP (British Standard Pipe) is about 61mm outside diameter, or a bit less, with a wall thickness of about 3.6mm. The 1½" BSP is about 49mm outside diameter, with a wall thickness of about 3.2mm.

component	material	number & length reqd [no.× mm]	total material in axle [mm]	materials cost in Kenya [$US]
central axle	2" square box tubing	1×1200	1200	3.20
hub stub axles	1½" BSP malleable iron pipe	2×350	700	2.60
hub outer tube	2" BSP malleable iron pipe	2×200	400	1.80
optional plastic brg	1½" or 2" plasic pipe	2×200	400	0.47
hub retaining rings	6mm or 8mm square bar	4×154	616	0.12
hub restraint pegs	6mm or 8mm square bar	90×2	180	0.04
wheel studs	50 × 12mm bolts	8×50	na	2.40
wheel stud struts	6×40 black or bright steel strip	8×37	296	0.60
TOTAL COST =				11.23

Construction step by step

1. The first and probably most difficult job, is to get some suitable pipes. Obviously the axle has to be strong enough to carry the cart, so it should be made from pipe bigger than about 40mm outside diameter. You must also make sure that the pipe has a wall thickness of more than about 2.5 mm.

The hub pipe also must have a wall thickness of 2.5mm or more. And it must have a bore (or inside diameter), which goes easily over the axle with enough room for the plastic bearing and some grease. There can be quite a lot of clearance (slackness or looseness) between the hub and the axle (say up to 3mm) - it does not have to be tight. If you cannot get steel pipes with enough clearance for a plastic pipe bearing then the axle will work quite well without it, but you should grease it more often.

These instructions deal with making an axle to the design shown in the drawings. If you find that you cannot get the right sizes of material you might still be able to make an axle with other sizes. See the **Modifications** section later in this booklet.

2. You will probably find that no plastic pipe fits properly between the axle pipe and the hub tube but all you need to do is slit a piece along its length and open it up a bit or close it down until it fits. A better way is to make a helical saw cut in the plastic pipe so it is like a spring. Then it will open up or close down to the size easily and it will not tend to wear the area around the slit.

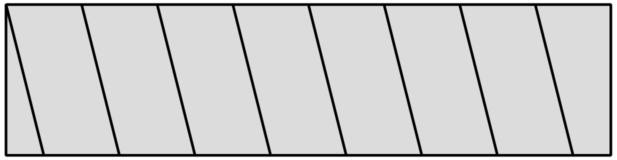

Figure 3: helical sawn cut in platic pipe bearing sleeve.

3. When you have got the right pipe sizes, you can cut the two hub pipes each 200 mm long and the axle pipe about 1500 mm or 1600 mm long or if you are going to do it with a central section in square pipe or angle iron you need to cut the central section about 1200 mm long plus the two stub axles each about 350mm long. If you need to support a simple one piece pipe axle an easy way is to weld short pieces of round bar onto it as shown in Figure 4. If you make these about 300 mm long they will strengthen the axle quite a lot as well.

   Figure 5 shows how you can weld the stub axle tube into the square box tubing. You will need to cut slots in the sides of the square tube so that it can bend in or out to accept the stub-axles. When you are welding the stub axles in, make sure you tack weld them in first and check that they are straight before you do the final weld.

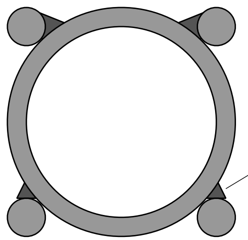

Figure 4: method of adding round bar to support pipe axle and strengthen it if needed.

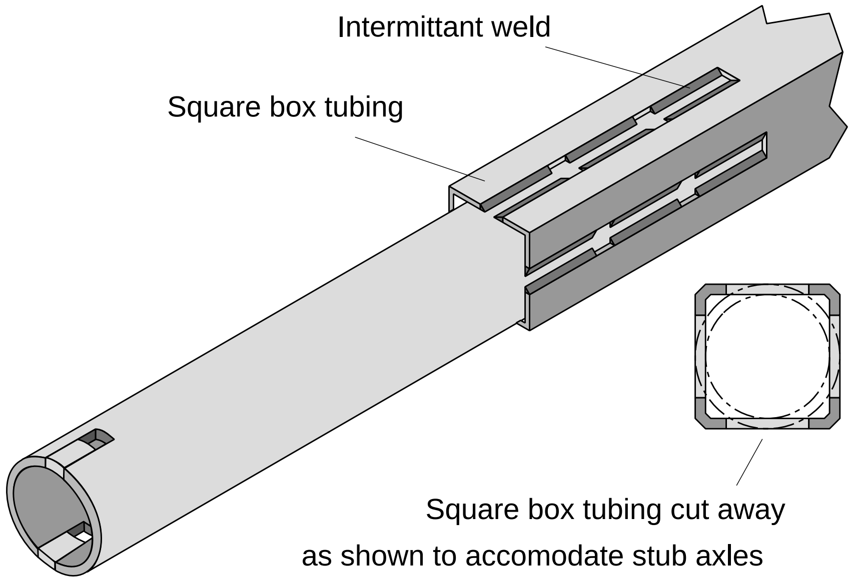

Figure 5: method of welding stub axles into square tube.

4. Next you need to make a hole near each end of the axle pipe for the hub restraint pin. To do this without using a drill cut a slot in each side of each end of the axle. Make the slots about 30 mm long to start with and about 10 mm wide. You want the slots just the right length so that with the hub restraint pins in place the hub tubes are not pinched tight. It does not matter of they are a bit loose.

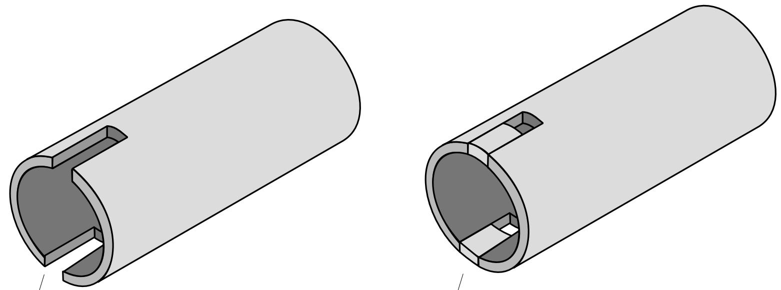

Figure 6: method of making hole for hub restraint pin without drilling.

5. The next step is to weld the stud bolts or bits of threaded rod onto the struts. If you have a vice it makes welding the bits together easier because you can clamp the pieces together while you tack weld them. You need to make one strut for each wheel stud unless you are using five or six

stud wheels on a single donkey cart. If so you could use only three studs per wheel if the cart user wants only light use from the cart.

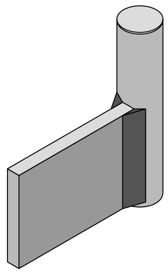

Figure 7: stud welded to the wheel struts.

We have used this method of fixing wheels successfully with the old VW wheels which have very large holes in the middle.

When you've made up the struts you can put a nut on each stud and then put the studs through the wheels, and put a second nut on each stud. Then get everything even and straight with the hub pipe in place as well in preporation for welding the struts to the hub tube. You want to get the middle of hub pipe level with the middle of the tyre, as is shown in Figure 7. Most car wheels need the studs to be about 40mm offset and this is what is on the drawings.

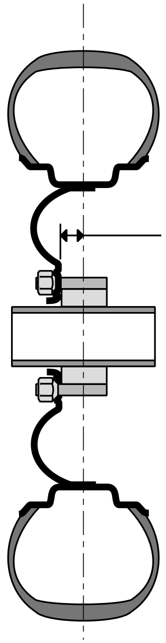

Figure 8: cross section of tyre wheel and hub tube showing centering of hub tube in wheel

Getting the hub in the middle of the wheel and tyre means that the bearings in the hub are evenly loaded. You might find that holding the hub tube in the wheel with some wedges as shown in Figure 8 is a good way to do it.

When you are happy, tack weld the struts to the hub pipe. Then remove the wheel and wedges so you've got room and finish the welding of the struts to the hub tube. Repeat this for the other hub. If you are going to make several axles you can make up a simple jig, rather than the wedges, to hold everything for welding. We have used a piece of plywood with a central hole to fit snugly over the hub tube and four holes for the studs. In other words its a bit like a dummy wheel.

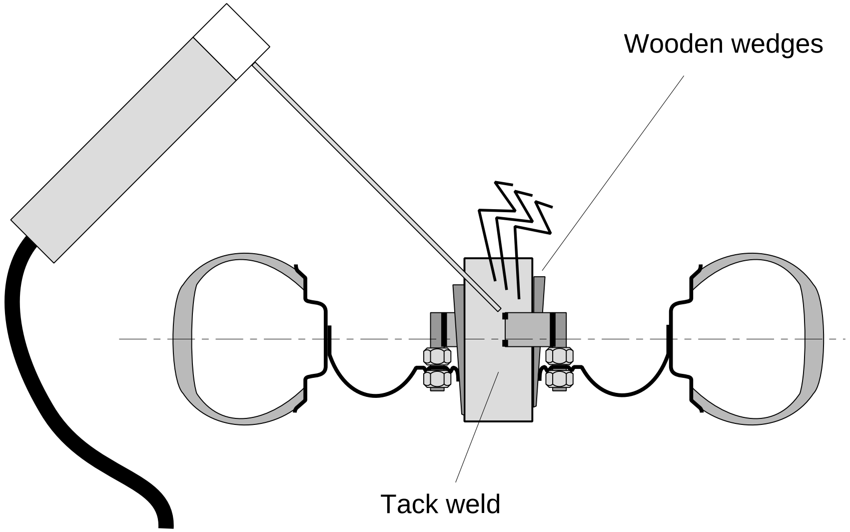

Figure 9: cross section of tyre wheel and hub tube during tack welding of stud support struts

It is best to check that the hubs, and stub-axles still go together when you've finished welding because sometimes weld contraction can pull it all out of shape and make it all too tight. You might need to file off some high spots inside the hub. If you can get it together without a hammer you'll be ok because it will wear to the right shape.

6. Nearly there! Now take the wheels off the hubs and make up four rings (called hub restraint rings on the drawing) from 6 mm or 8 mm square steel bar (or round bar if you cannot find square). One ring must be welded about 230 mm from each end of the axle pipe or from the ends of the stub axles to stop the hubs going too near the centre of the axle.

7. Now put it together! Smear some grease onto the plastic bearing pipe (if you are using one) and onto the axle and put the hub tube and plastic bearing onto the axle. Then put the outer hub restraint ring on and secure it with the hub restraint pin. Do the same for the other hub.

8. Paint everything!

9. You've done it!

Modifications

Pipes can be made slightly bigger (up to 1mm bigger) by forcing a short piece of round bar of the right diameter through them with a press. Another way to do it is to saw the pipe along its length and open it up to the right size and then weld it. You can also make it a bit smaller like this by cutting a wider slot and squashing the pipe down. Try to clean the weld back flush with the tube using a file if you can as this will give longer life. It does not matter if

If you find that you cannot get anything like the materials talked about in the cutting list then maybe you can adapt the design a bit. If the hole in the middle of the wheels is big then you stand a better chance of finding a combination of pipes and rollers that will fit. You can often cut a bit out of the middle of the wheel to make the hole bigger. The hole in Land Rover wheels is big and you can get 4" pipe into them. Of course the shaft does not have to be a pipe - it could be solid and then it could be a bit smaller, say 30mm diameter if the steel is high quality.

Another idea that we have tried is to use a hardwood as the hub and even the wheel. If you think about it, the wear on something which is rolling must be less than when something is sliding over it, so a wooden bearing should be better than a sliding one. Some bearings we have tried have had a steel ring fitted inside so that the rollers roll on this steel. We have also tried making these rings from round bar like wire so that it's like the rollers roll on the inside of a spring. This seemed to work quite well.

Other DTU cart developments

Other methods of hub design using aluminium castings, for example, which might need no machining, are under development at Warwick and wheel designs in steel sheet, cast aluminium and timber are also in manufacture or under development. A range of designs for donkey and ox carts made of steel and wood, is also available, some of which are in production in Kenya and Nigeria.

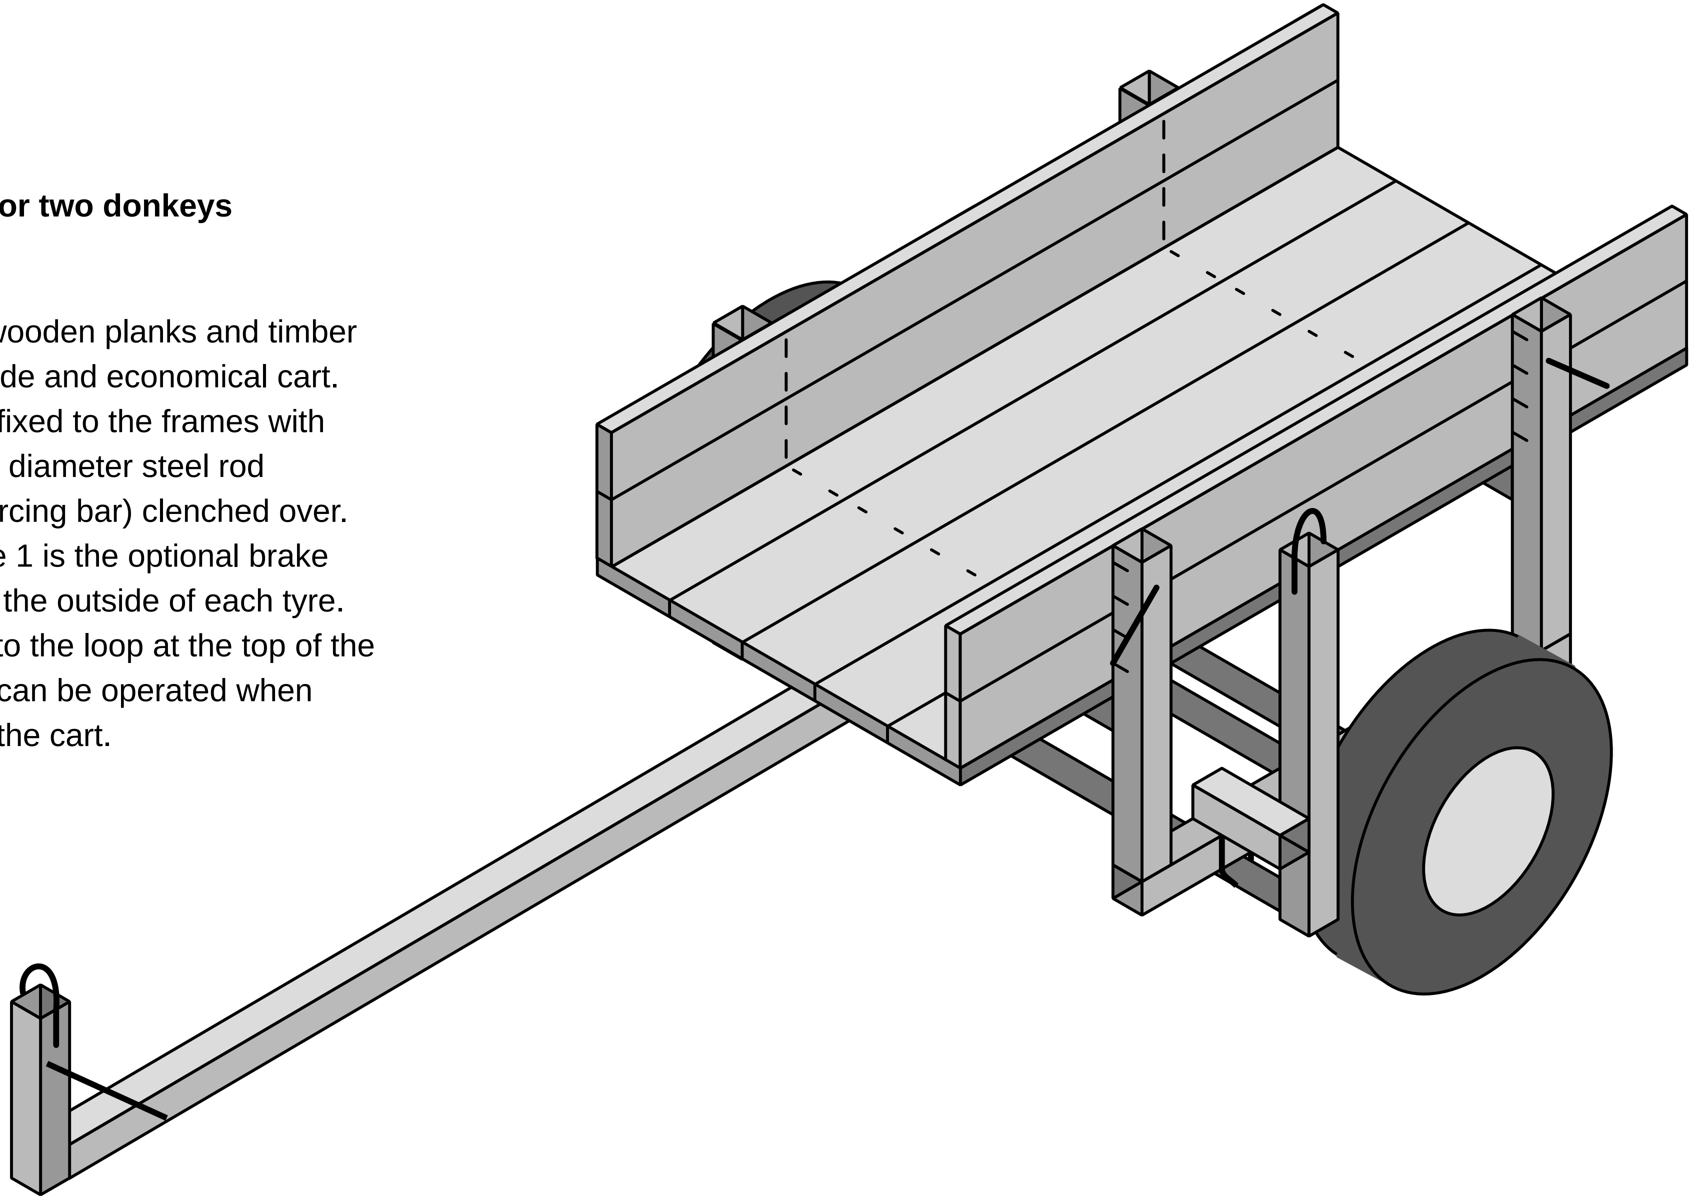
Low Cost Steel Framed Cart for Two Donkeys

Development Technology Unit, Department of Engineering, University of Warwick, Coventry, CV4 7AL UK, tel: +44 (0)203 523523 extn 2339, fax: +44 (0)203 418922, email: esceo@eng.warwick.ac.uk

KENDAT, PO Box 61441, Nairobi, Kenya, tel/fax: +254 2 766939, email: kendat@africaonline.co.ke

Figure 1: cart for two donkeys with brake.

This cart uses wooden planks and timber for a quickly made and economical cart. The planks are fixed to the frames with 8 mm or 10 mm diameter steel rod (concrete reinforcing bar) clenched over. Shown in Figure 1 is the optional brake which works on the outside of each tyre. If a rope is tied to the loop at the top of the lever the brake can be operated when walking behind the cart.



Two Donkey Cart made from Steel Box Tubing and Timber.

Introduction

In this booklet we tell you how to make a simple cart from square steel tube and timber. This Technical Release does not tell you here how to make the axle - you will have to read another Technical Release to for this. We have designs for stub axles with PVC bearings and with needle roller bearings that you can make yourself and we have designs for twin offset axles using PVC, wood and scrap ball bearings. All axles can be made without machine tools - in fact you do not even need a drill!

You should find that you can make the cart itself for about £ 40 depending on the cost of the materials and labour. An axle plus wheels, tyres and tubes will cost another £ 50 - £ 60. Once you get organised, two men can probably make one cart in a day. We've designed these carts to be easy and quick to make.

Idea Behind Design

These carts are designed to be constructed without lots of special tools and jigs, and without any hard-to-get materials. The only tools which you must have are a welder, a wood saw, a hacksaw, and a hammer. You might find that a couple of 4" or a 5" G clamps (or something like it) are useful too.

The cart frames are fixed together by welding and the wooden planks are fixed to the frames with clenched steel bar. You weld 8 mm diameter re-bar (concrete reinforcing bar) to the steel box

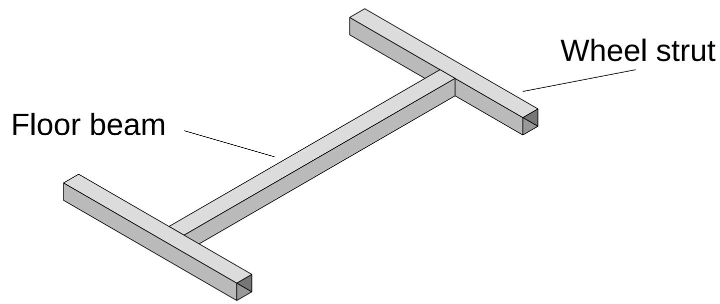


Figure 2: finished H frame.

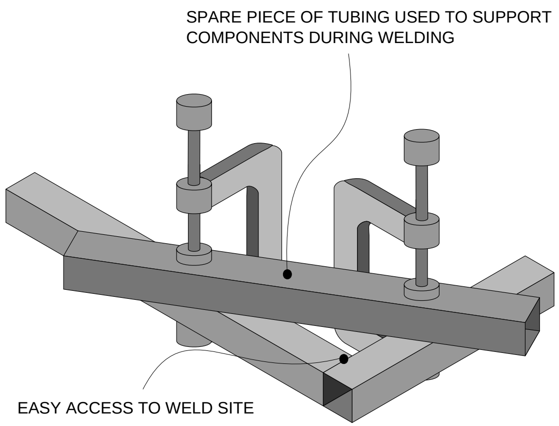

Figure 3: holding frame components during welding.

tubing so it sticks out about 20 mm beyond the surface of the planks, and then knock the ends over with a hammer so they lie on the surface of the wood.

You will see that there are no mitres or complicated angles or joints to cut when making the cart, so you save time. Also the exact lengths of the components are not very critical - again it saves a little time, but you will find that the carts look better if you take a little trouble to get things square and even etc and welding is easier with good square ends. It is much better to

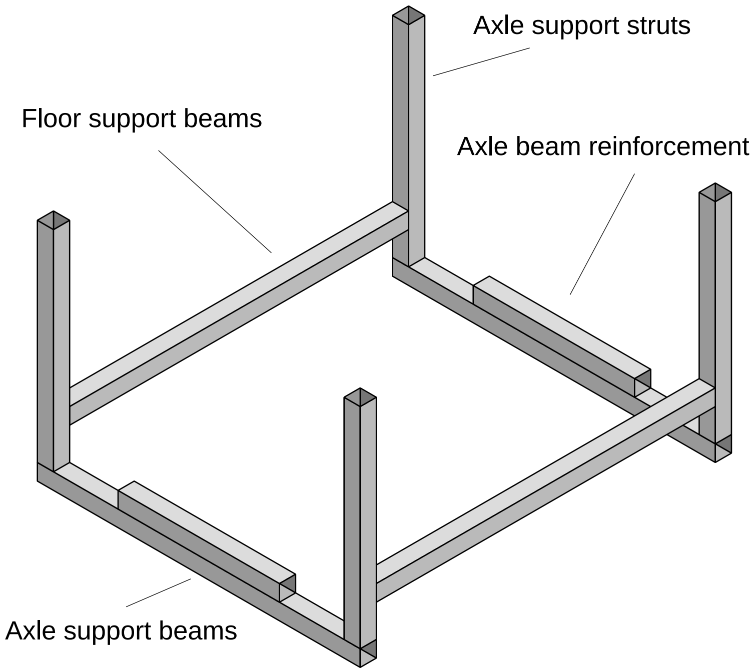

Figure 4: main frame assembly.

use a try square to mark the position of a cut than guess.

These carts have been tested in Nigeria, Kenya and Uganda and we have had only a few serious failures caused by poor welding or incorrect material. We think that they are strong enough, but we cannot be sure - somebody will always break anything.

Cutting list and costs

Table 1 shows a cutting list for a complete cart - Recent prices of materials in Kenya are shown converted into £$_{UK}$.

TABLE 1: 50×50 RHS vestigial frame donkey cart.

description	length m	#	total m	cost £$_{UK}$
50×50 RHS:			**11560.00**	27.71
floor beams 7 × 160 mm (planks 160 mm)	1120.00	2	2240.00	
wheel struts 3 × 160 + 25 + 60 + 240	805.00	4	3220.00

6"×1" timber			23.40	4.99
tray planks 13 off	1.80	13	23.40	
TOTAL COST =				39.04

Construction step by step

1) First get all the material together and clear a space to work. Ideally you will be able to work on a flat area of concrete. Start by cutting the 50 × 50 box section steel into the right lengths, as in the cutting list, then cut the bottom and side planks. Lastly cut the 8 mm dia or whatever re-bar for the fixings ie the studs.

2) Next make up the two H-shaped frames shown in Figure 2. If you have a couple of G clamps you can use them to hold two pieces of the frame together during welding as shown in Figure 3. It's quick and you can tap the parts with a hammer until everything is square and straight and then weld.

3) Then stand the two H frames on the axle support beams as shown in Figure 4 and weld up the main frame. If you are using our PVC bearing system then weld on some axle beam reinforcement as shown in the figures but with the ball bearing and wooden bearing types you do not need this.

4) Next you can fit the side and the bottom planks to the

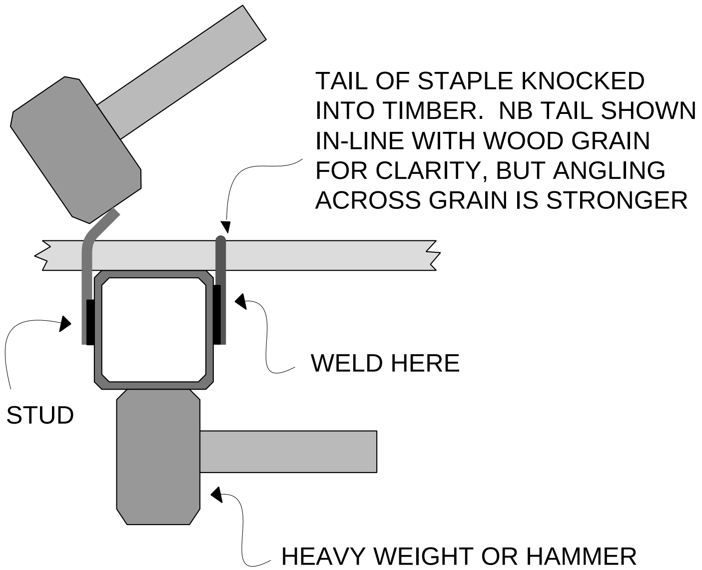

Figure 5: tightening welded stud.

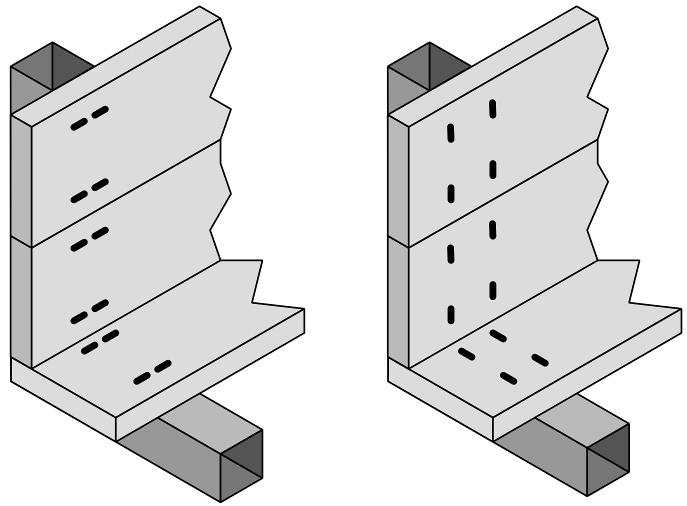

Figure 6: studs or staples bent in line with grain (left) or across it (right).

frames with studs. Studs are just short lengths of round bar welded to the sides of the box section as shown in Figure 5 (which also shows how these studs can be tightened with a hammer and a weight or another hammer).

Studs can either be put through holes in the planks or they can just be welded at the edge of each plank and then simply bent over the edge.

When you bend the end of the stud over you can either bend it in line with the grain of the wood or across the grain, as shown in Figure 6. Bending it in line as shown on the left lets it go into the wood nicely and looks neat, but bending it over across the grain gives a stronger joint.

5) Nearly there! Now you need to fix the draw pole. It is best to fix the draw pole to the body so it can be taken off and replaced if it gets damaged. A good way to do this is with short lengths of round bar welded on as shown in Figure 7. It is easy to cut through the re-bar hoops if you need to change the draw bar. You will need to use new re-bar of course when you put the new draw bar on. Also shown in Figure 7 is an easy way to reinforce the boom with an extra piece of steel tube welded to the main tube.

6) If you want to make it so that the ends of the load tray can be removed easily you can do so in the way we have shown in Figure 8. This is a good way because it is cheap and very easily repairable.

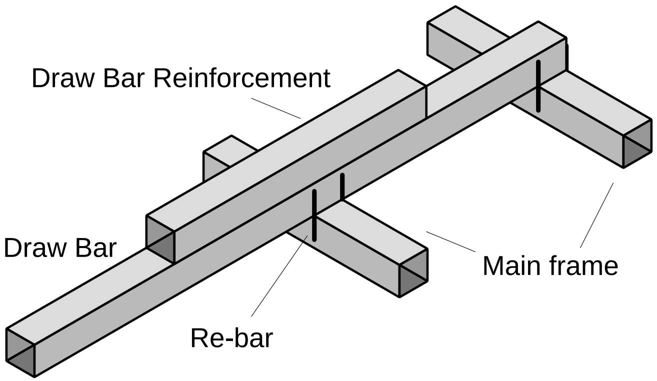

Figure 7: method of fixing draw bar to body. (View of cart upside down.)

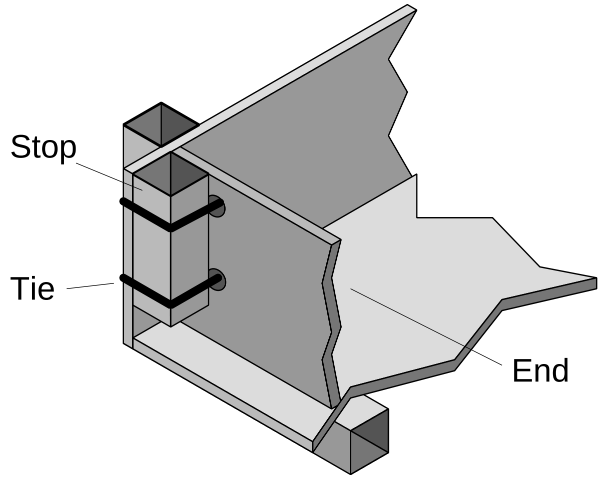

Figure 8: method of fixing tray ends with rubber or rope

7) Paint or creosote the cart. You've finished it!

Modifications

There are many different versions of this cart. You can try longer or shorter carts and you can make them wider or narrower. When you do this, check the length and width of the planks of wood that you will use - you do not want to find that you are two inches short of being able to get two runs of plank out of one piece of timber, or that its just too narrow and you have to fiddle about and fit in a narrow strip.

Other DTU cart developments

The DTU has been working on a range of carts for use with both donkeys and oxen. It has designs for wooden and steel framed bodies and for a range of wheels and axles. All steel framed carts can be fitted with a simple brake. The DTU also has designs for single and double donkey harness.

Cart Drawings

You will find two drawings on the next pages, the first one gives a general view of the cart, and the second gives a view of the main components. As we have said you can vary the size of the cart quite a bit and even make it much longer if you add extra frames. You could even make a four wheeled cart like this!

Acknowledgements

The DTU is grateful to the DFID (British Government) for the financial support necessary to carry out the research and development project under which this product was developed.

The DTU would also like to thank Dr Pascal Kaumbutho of KENDAT in Kenya and Mr Joseph Mugaga of TOCIDA in Tororo, Uganda for their very considerable help with this project. RELEASE

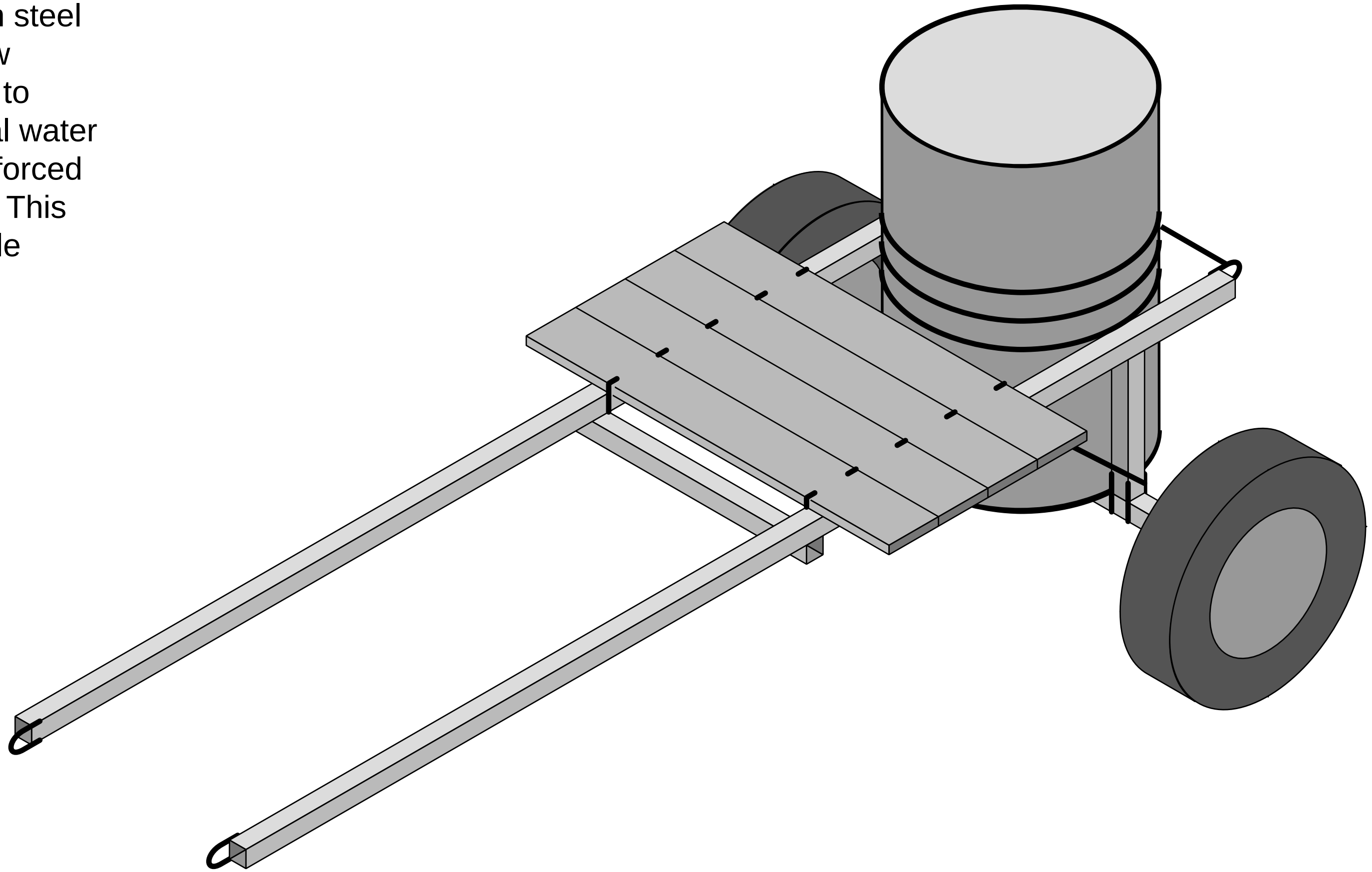
LIGHT SINGLE DRUM WATER CARRIER

Development Technology Unit, Department of Engineering, University of Warwick, Coventry, CV4 7AL UK, tel: +44 (0)203 523523 extn 2339, fax: +44 (0)203 418922, email: esceo@eng.warwick.ac.uk
KENDAT, PO Box 61441, Nairobi, Kenya, tel/fax: +254 2 766939, email: kendat@africaonline.co.ke

Figure 1: donkey cart made from square box tubing.

This cart uses square section steel box tubing (RHS rolled hollow section) and a 200 litre drum to make a quick and economical water carrying cart. The cart is reinforced with concrete reinforcing bar. This cart has two shafts for a single donkey.



Lightweight water carrier cart for one donkey.

Introduction

In many towns and villages in Africa water is delivered commercially. You buy water from people selling it from carts. This cart design was developed in Kenya where water is widely sold like this and the cart is as simple and cheap as we can design it from new materials there.

This booklet tells you how to construct a water carrier cart - you will need to use another booklet Technical Release 28 to tell you how to make the axle. You should be able to make the cart make one cart including the axle per day.

In other booklets in this series we tell you how you can make other simple low-cost carts and axles

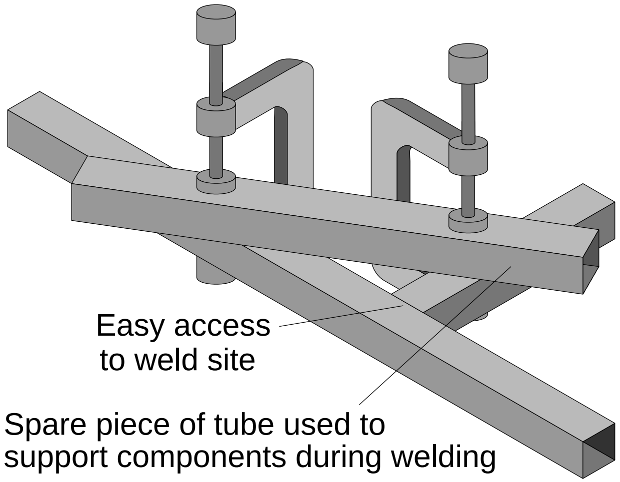


Figure 2: supporting components during welding.

Idea Behind Design

The idea behind the designs in these booklets is to allow construction without lots of special tools and jigs, and without any hard-to-get materials. The only tools which you must have are a welder and a hacksaw. You might also find that a couple of 4" or a 5" G clamps (or something like it) are useful too. A wheelbrace or carpenters brace is also useful - you can make the drill bit yourself.

You will see that there are no mitres and unusual angles to cut in the square tubing so you save time when making the cart. Also the exact lengths of the components are not very fussy. But you will find that the carts look better if you take trouble to

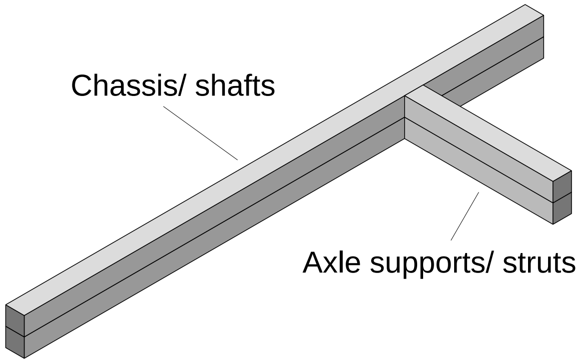

Figure 3: welding animal shaft and axle support strut assemblies.

get things square and straight.

Carts like these have been tested in Kenya. We have not had problems with them but if you find that the square tube breaks too easily you can reinforce it by welding on some round bar or concrete reinforcing bar 8mm, 10mm or 12mm. If you used tubing with a wall thickness of 2.0 mm or more you probably would not need to put these strengtheners on.

Cutting list and costs

Table 1 shows a cutting list for a complete cart. Recent prices of materials in Kenya are shown converted to £ UK. The

Table 1: materials and costs.

TABLE 1: cutting list.				
component	material	# lengths	total	materials
		& length	material	cost in
		reqd	in cart	Kenya
		[#*mm]		[£UK]
animal shafts	50×50 RHS	2×3000	6000	14.37
body cross pieces	50×50 RHS	2×700	1400	3.35
axle struts	50×50 RHS	2×375	750	1.80
shaft strengtheners	8mm to 12mm round bar[1]	4×600	2400	0.66
axle strut braces	8mm to 12mm round bar[1]	2×600	1200	0.33
axle fixing bars	8mm to 12mm round bar[1]	8×70	560	0.15
hitch/ drum tie loops	8mm to 12mm round bar[1]	2×250	500	0.14
TOTAL =				20.67

[1] The round bar can be anything actually - it doesn't even have to be round, so deformed or high-yield re-bar is fine. You could even use flat strip as long as its more than say 8mm thick.

method shown in Figure 2 is probably the easiest way to support the components during welding the first shaft and support. It's quick and if you do not tighten the clamps too tight to start with, you can tap the parts with a hammer until everything is square and straight. Then tighten the clamps before you weld.

Repeat the process using the first shaft and support as a pattern for the second as shown in Figure 3. Make sure you do not weld the two assemblies together!

3) Now you can weld the cross pieces under the animal shafts after you have checked for squareness etc.

4) Next weld the axle on using the method shown in Figure 4. Here small pieces of round bar eg 12 mm are welded across the join. If you do it like this you can easily remove the axle just by cutting the rod. This is much easier than grinding welds away. Alternatively you can bolt the axle on

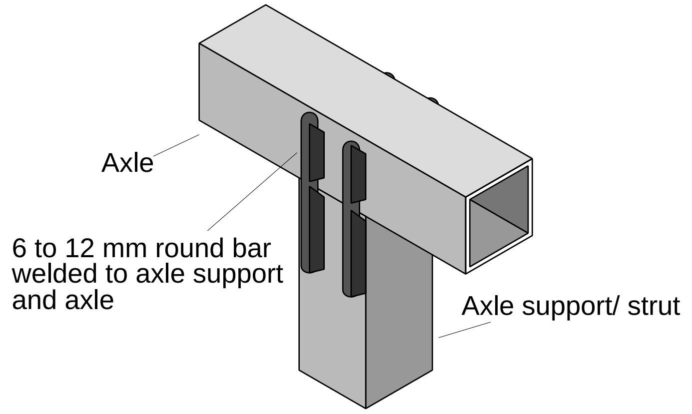

Figure 4: method of fixing axle to axle supports.

as shown in Figure 5.

5) Next you need to weld on the axle support strut braces to the square tube. Figure 5 shows the frame nearly ready.

6) Now fix the planks on using clenched over 8 mm re-bar as shown in Figure 6

7) Paint the cart. You've finished it!

Getting water out

Users usually cut a hole in the top of the drum or cut the whole top off to make it easy to pour water in quickly. To get water out some users in Kenya fix some 3 inch layflat hose onto a piece of pipe fixed to the larger threaded hole in one end of the drum. Tying the end up stops water coming out and letting it down squirts water out very quickly.

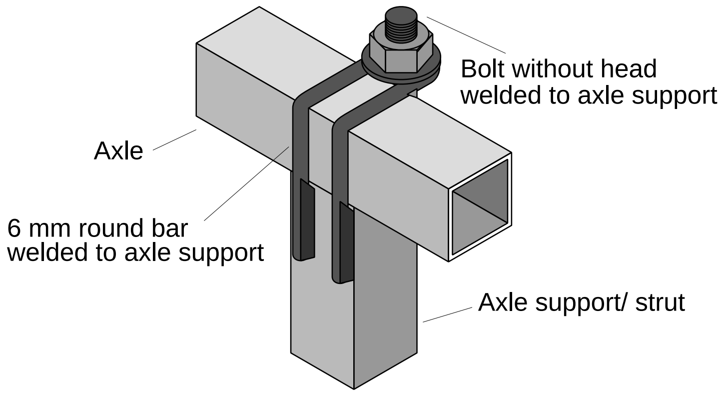

Figure 5: fixing planks to frame with clenched studs.

Modifications

This cart could be used as a flatbed cart by removing the drum and putting more planks on top of the shafts.

Other DTU cart developments

The DTU has been working on a range of cart body types for use with both donkeys and oxen. It has designs for both wooden and steel framed types. The wooden types are cheaper in material terms, but the steel framed ones are easier to make because the joints are more straightforward - but you can make either type of cart in only a day or two.

The DTU has also been working on new designs of wheels, hubs and bearings to bring down their costs and make things

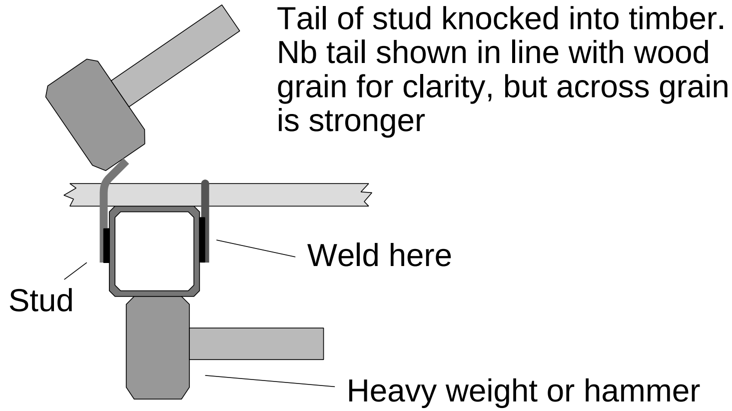

Figure 6: fixing planks to frame with clenched studs.

more locally manufacturable. We have developed easily made wooden bearings, bearings from PVC pipe, axles using old ball races and axles where you make your own roller bearings. Technical releases for all these are available.

Cart Drawings

The drawing for the cart is shown on the following page and the list of materials has been shown on a previous page.

Acknowledgements

The DTU is grateful to the DFID (British Government) for the financial support necessary to carry out the research and development project under which this product was developed.

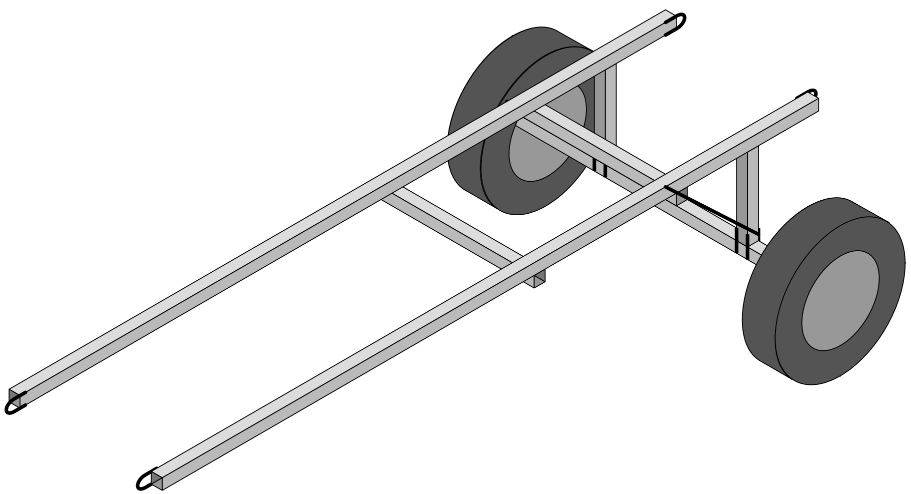

Figure 7: cart frame without drum and planks.

The DTU would also like to thank Dr Pascal Kaumbutho of KENDAT in Kenya and Mr Joseph Mugaga of TOCIDA in Tororo, Uganda for their very considerable help with this project. A large number of other people and organisations have contributed to the success of the project, most notably Mr Anthony Ndungu in Kajiado Kenya, Mr JD Kimani in Kikuyu Kenya and Mr Joseph Gitari in Wanguru Kenya in whose workshops most of the development work of this project was performed. Thanks are due also to Mr Stanley Lameria in Kajaido, Mr Patrick Gitari in Wanguru and Mr Mathew Masai in Machakos for their assistance.

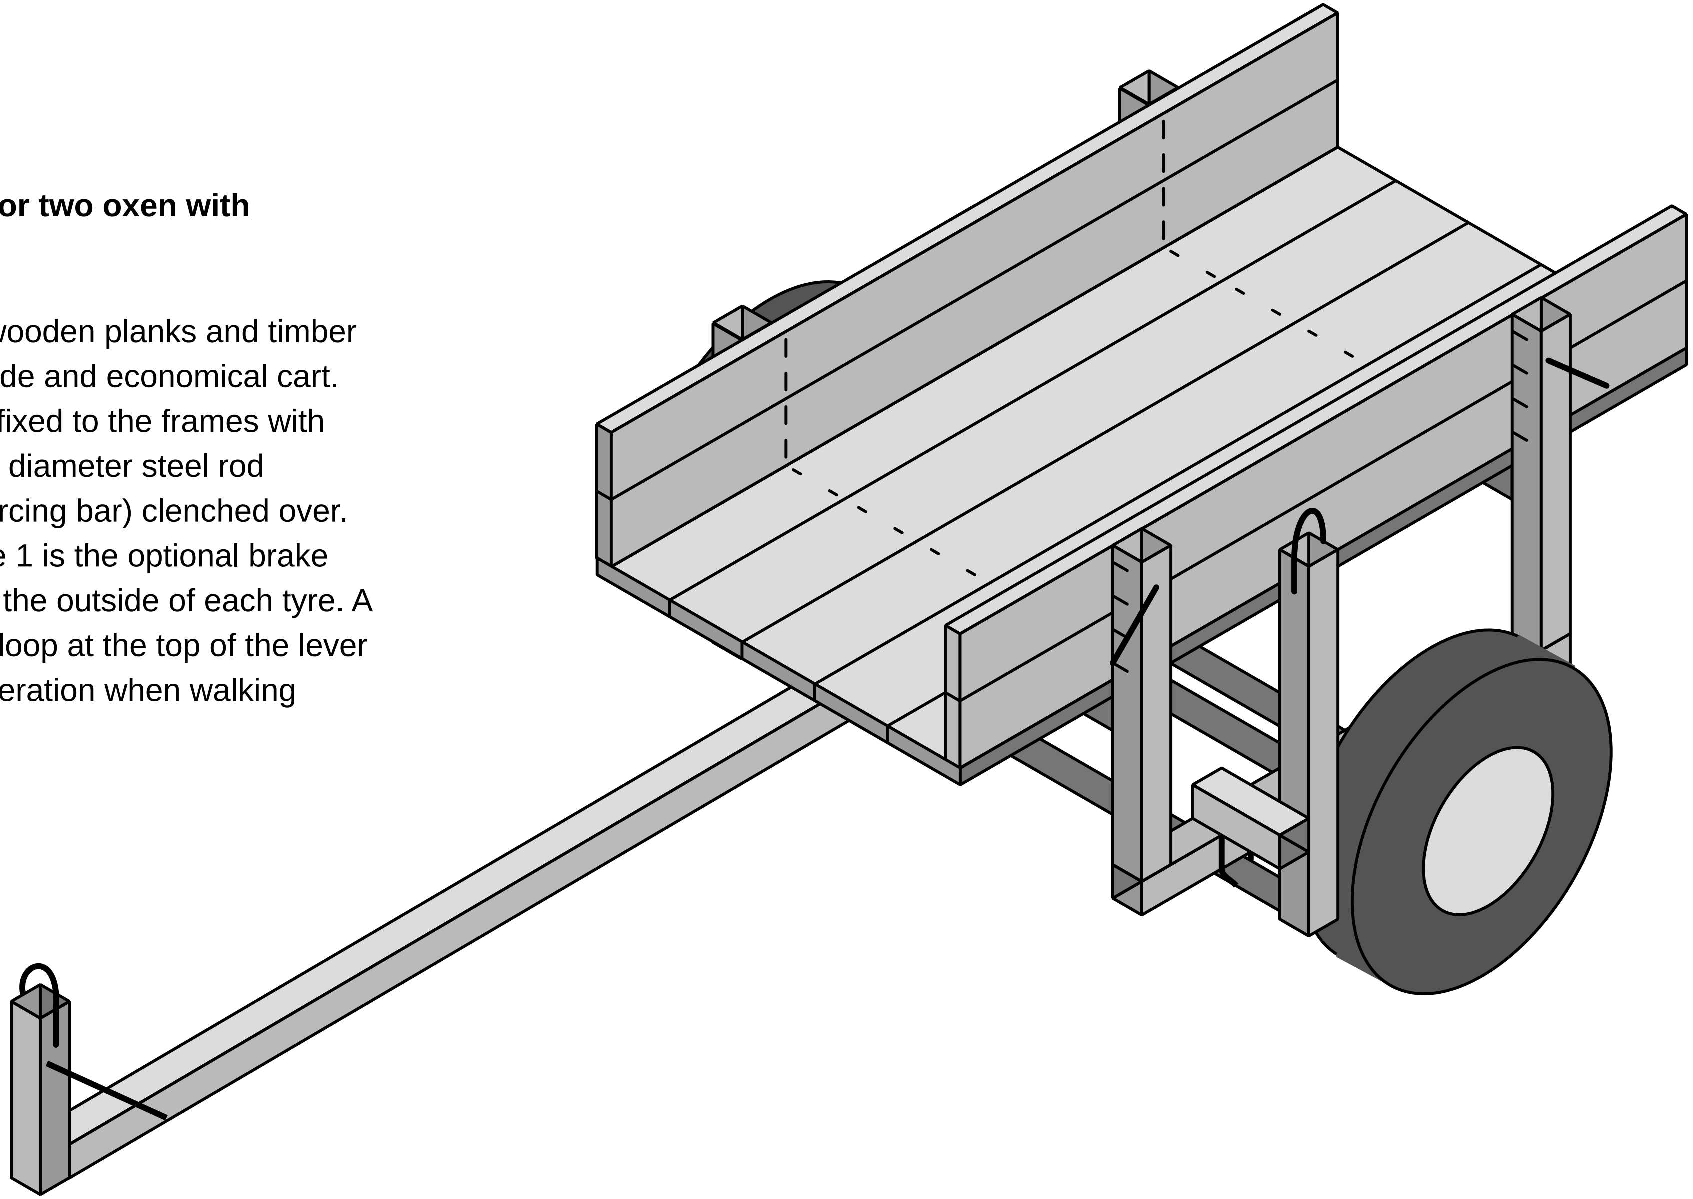
Figure 1: cart for two oxen with brake.

This cart uses wooden planks and timber for a quickly made and economical cart. The planks are fixed to the frames with 8 mm or 10 mm diameter steel rod (concrete reinforcing bar) clenched over. Shown in Figure 1 is the optional brake which works on the outside of each tyre. A rope tied to the loop at the top of the lever allows brake operation when walking behind the cart.



Steel Box Tubing and Timber Cart for two Oxen.

Introduction

In this booklet we tell you how to make a simple cart from square steel tube and timber. This Technical Release does not tell you here how to make the axle - you will have to read another Technical Release to for this. We have designs for stub axles with PVC bearings and with needle roller bearings that you can make yourself and we have designs for twin offset axles using PVC, wood and scrap ball bearings. All axles can be made without machine tools - in fact you do not even need a drill!

This Technical Release describes an ox cart made from 60×60×3 square steel tubing and is suitable for oxen weighing 350 kg to 500 kg. If you have really strong animals then use 75×75×3 tube - its only a little bit more expensive.

You should find that you can make the 60×60×3 cart body for about £ 50 depending on the cost of the materials and labour. An axle plus wheels, tyres and tubes will cost another £ 60 - £ 70. Once you get organised, two men can probably make one cart in a day. We've designed these carts to be easy and quick to make.

Idea Behind Design

These carts are designed to be constructed without lots of special tools and jigs, and without any hard-to-get materials. The only tools which you must have are a welder, a wood saw,

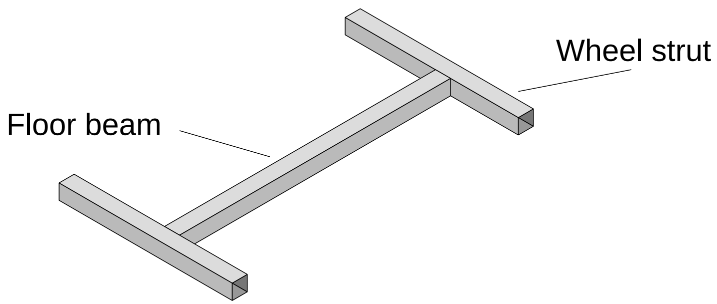


Figure 2: finished H frame.

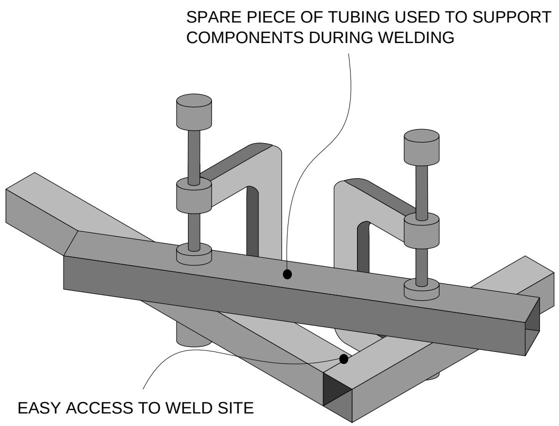

Figure 3: holding frame components during welding.

a hacksaw, and a hammer. You might find that a couple of 5" or a 6" G clamps (or something like it) are useful too.

The cart frames are fixed together by welding and the wooden planks are fixed to the frames with clenched steel bar. You weld 8 mm diameter re-bar (concrete reinforcing bar) to the steel box tubing so it sticks out about 20 mm beyond the surface of the planks, and then knock the ends over with a hammer so they lie on the surface of the wood.

You will see that there are no mitres or complicated angles or

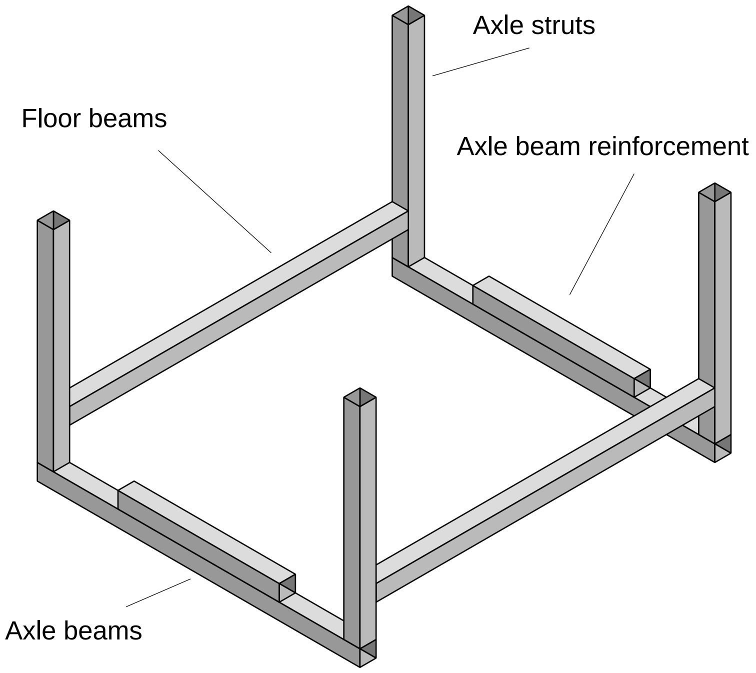

Figure 4: main frame assembly.

joints to cut when making the cart, so you save time. Also the exact lengths of the components are not very critical - again it saves a little time, but you will find that the carts look better if you take a little trouble to get things square and even etc and welding is easier with good square ends. It is much better to use a try square to mark the position of a cut than guess.

These carts have been tested in Kenya and Uganda and we have had only a few serious failures caused by poor welding or incorrect material. We think that they are strong enough, but we cannot be sure - somebody will always break anything.

Cutting list and costs

Table 1 shows a cutting list for a complete cart - Recent prices of materials in Kenya are shown converted into £$_{UK}$.

Construction step by step

1) First get all the material together and clear a space to work. Ideally you will be able to work on a flat area of concrete. Start by cutting the 60 × 60 box section steel into the right lengths, as in the cutting list, then cut the bottom and side planks. Lastly cut the 8 mm dia or whatever re-bar for the fixings ie the studs.

2) Next make up the two H-shaped frames shown in Figure 2. If you have a couple of G clamps you can use them to hold two pieces of the frame together during welding as shown in Figure 3. It's quick and you can tap the parts with a hammer until everything is square and straight and then weld.

3) Then stand the two H frames on the axle beams as shown in Figure 4 and weld up the main frame.

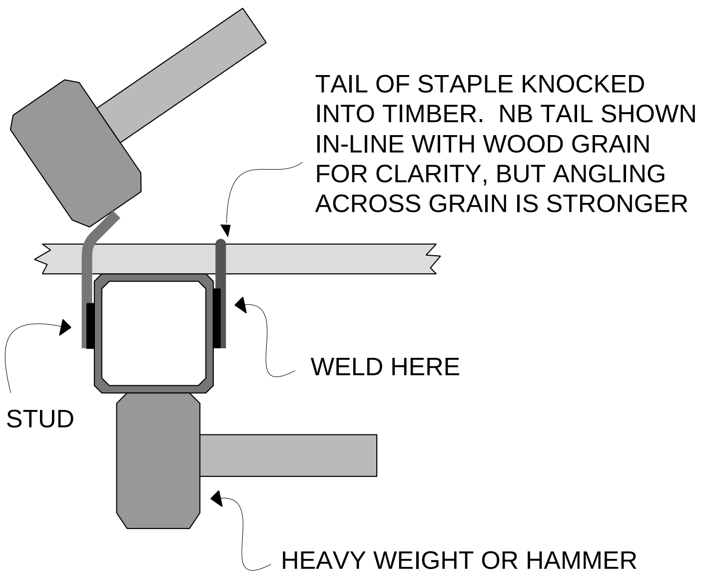

Figure 5: tightening welded stud.

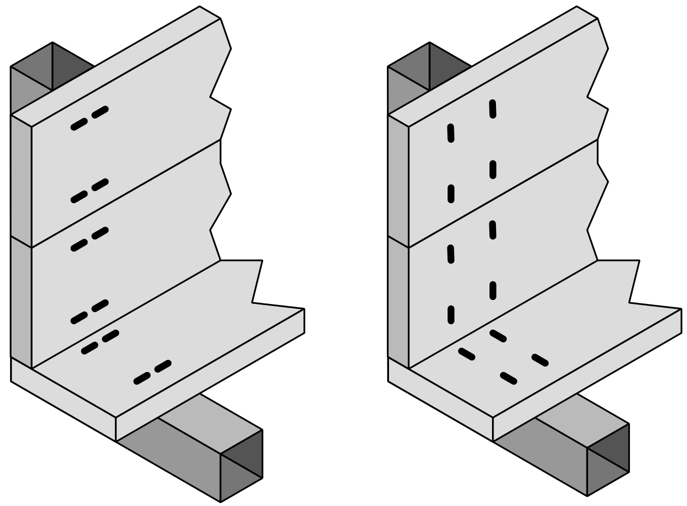

Figure 6: studs or staples bent in line with grain (left) or across it (right).

4) Next you can fit the side and the bottom planks to the frames with studs. Studs are just short lengths of round bar welded to the sides of the box section as shown in Figure 5 (which also shows how these studs can be tightened with a hammer and a weight or another hammer).

Studs can either be put through holes in the planks or they can just be welded at the edge of each plank and then simply bent over the edge.

When you bend the end of the stud over you can either bend it in line with the grain of the wood or across the grain, as shown in Figure 6. Bending it in line as shown on the left lets it go into the wood nicely and looks neat, but bending it over across the grain gives a stronger joint.

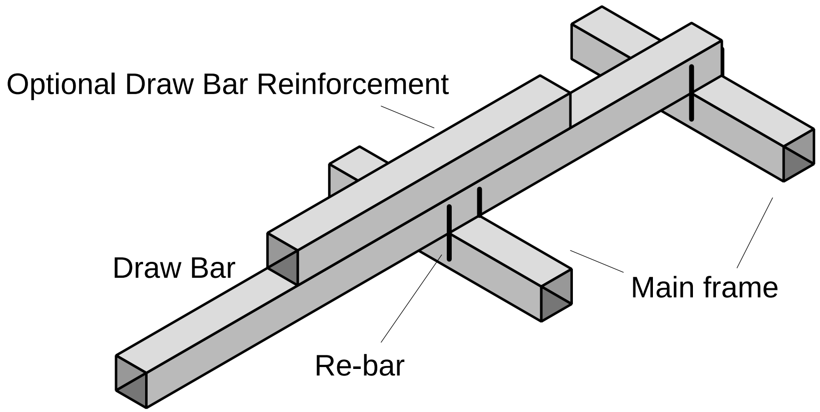

Figure 7: method of fixing draw bar to body. (View of cart upside down.)

5) Nearly there! Now you need to fix the draw pole. It is best to fix the draw pole to the body so it can be taken off and replaced if it gets damaged. A good way to do this is with short lengths of round bar welded on as shown in Figure 7. It is easy to cut through the re-bar hoops if you need to change the draw bar. You will need to use new re-bar of course when you put the new draw bar on. Also shown in Figure 7 is an easy way to reinforce the boom with an extra piece of steel tube welded to the main tube.

6) If you want to make it so that the ends of the load tray can be removed easily you can do so in the way we have shown in Figure 8. This is a good way because it is cheap

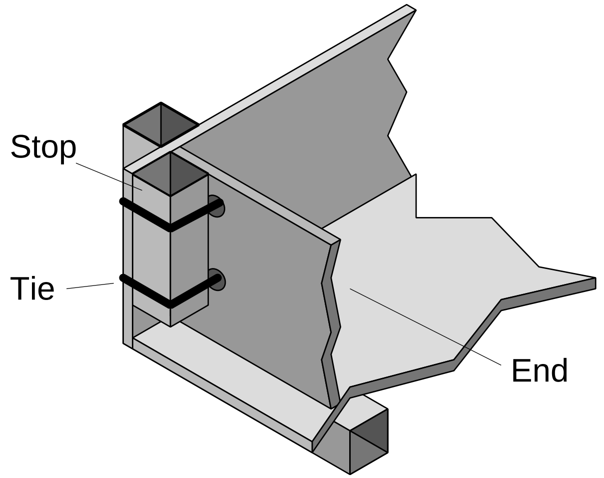

Figure 8: method of fixing tray ends with rubber or rope

and very easily repairable.

7) Paint or creosote the cart. You've finished it!

Modifications

There are many different versions of this cart. You can try longer or shorter carts and you can make them wider or narrower. When you do this, check the length and width of the planks of wood that you will use - you do not want to find that you are two inches short of being able to get two runs of plank out of one piece of timber, or that its just too narrow and you have to fiddle about and fit in a narrow strip.

Other DTU cart developments

The DTU has been working on a range of carts for use with both donkeys and oxen. It has designs for wooden and steel framed bodies and for a range of wheels and axles. All steel framed carts can be fitted with a simple brake. The DTU also has designs for single and double donkey harness.

Cart Drawings

You will find two drawings on the next pages, the first one gives a general view of the cart, and the second gives a view of the main components. As we have said you can vary the size of the cart quite a bit and even make it much longer if you add extra frames. You could even make a four wheeled cart like this!

Acknowledgements

The DTU is grateful to the DFID (British Government) for the financial support necessary to carry out the research and development project under which this product was developed.

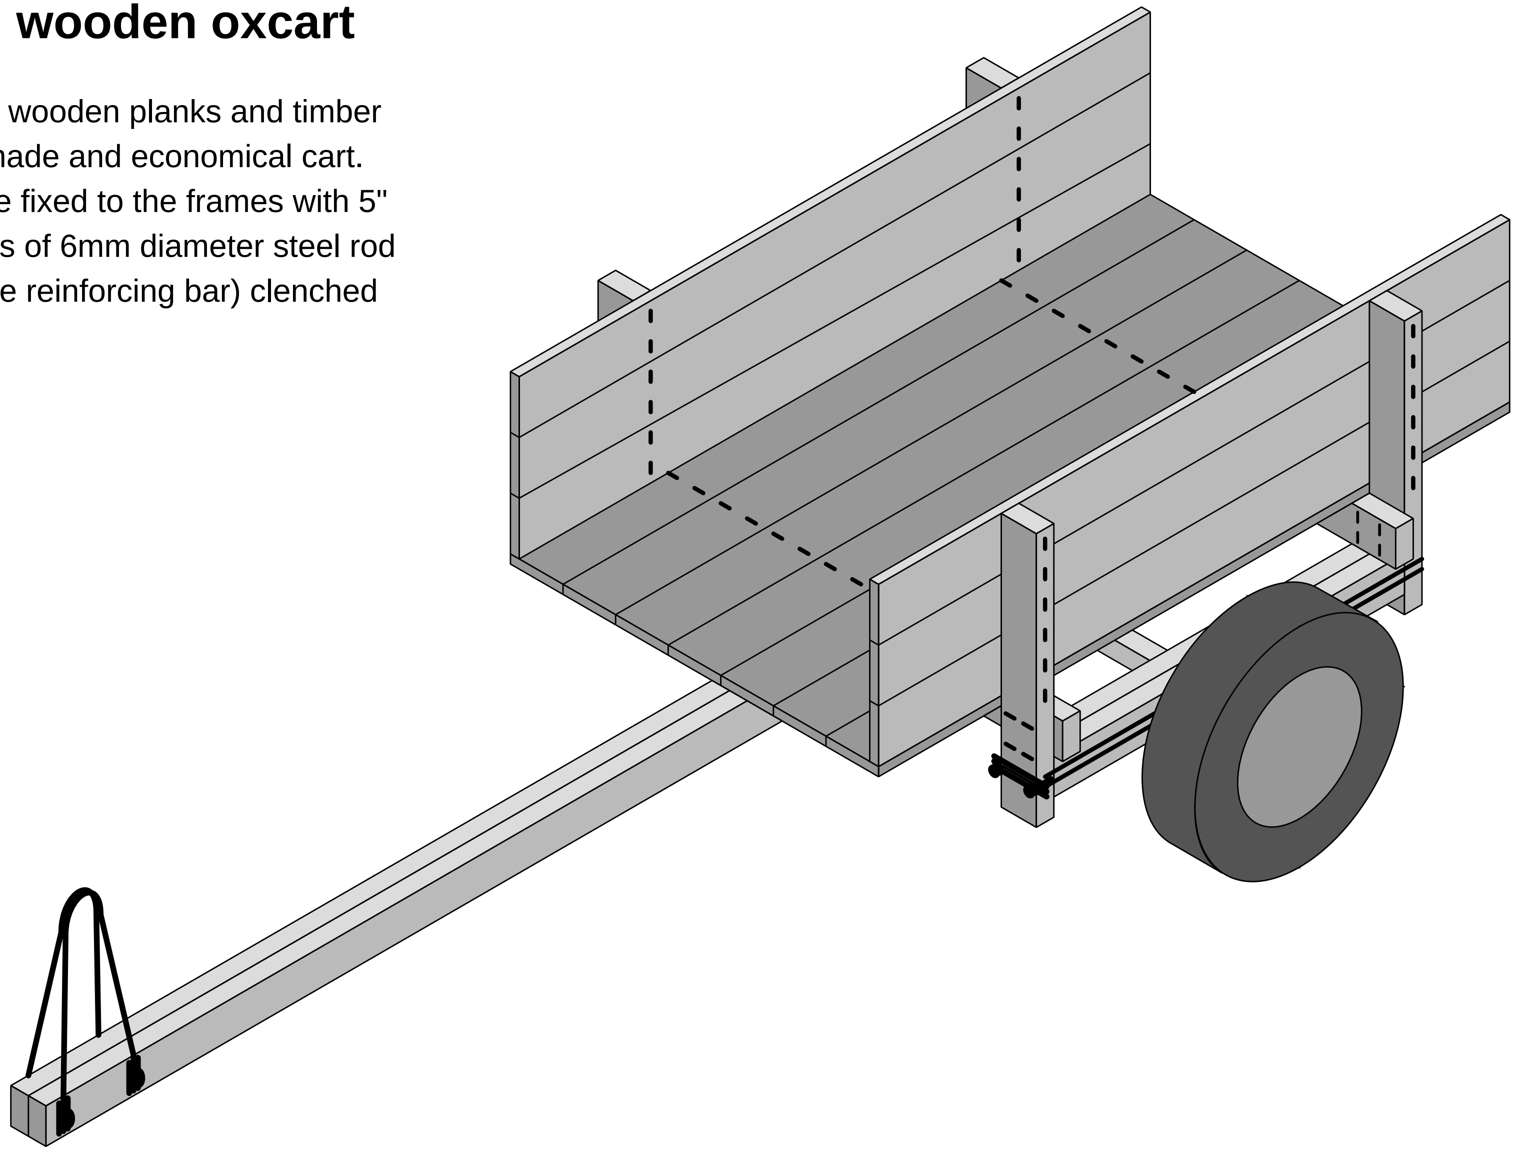
Figure 1: wooden oxcart

This cart uses wooden planks and timber for a quickly made and economical cart. The planks are fixed to the frames with 5" nails or lengths of 6mm diameter steel rod (small concrete reinforcing bar) clenched over.



Ox Cart Body Made From Timber

Introduction

This Technical Release tells you how to make a low-cost wooden cart to be pulled by two oxen. It does not cover the construction of the axle. You can use either a scrap axle from a pick-up truck or car or you can make one. We can supply a number of Technical Releases which cover different axle designs.

We have designs for fixed axles with PVC plastic bearings or roller bearings you can make yourself if you are a good welder/ fabricator. And we have double axle systems using wooden bearings, PVC bearings and ball bearings. These ball bearings can be new or scrap and no machining is needed.

You should find that you can make the cart body for about £ 30 depending on the cost of the materials and labour. Once you get organised, two men can make a cart body in one day. This is quite a lot faster than most carts can be made and it follows from the simplifications which we have made to the design. We've designed it to be easy to make.

Idea Behind Design

We have designed this cart to be easy to make without lots of special tools and jigs, and without any hard-to-get materials. The only tools which you must have are a woodsaw, a hacksaw or cold chisel and a hammer and for some of the components

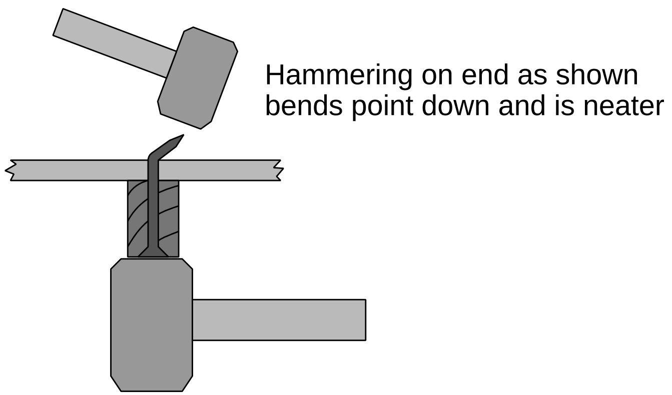


Figure 2: using two hammers to clench nail.

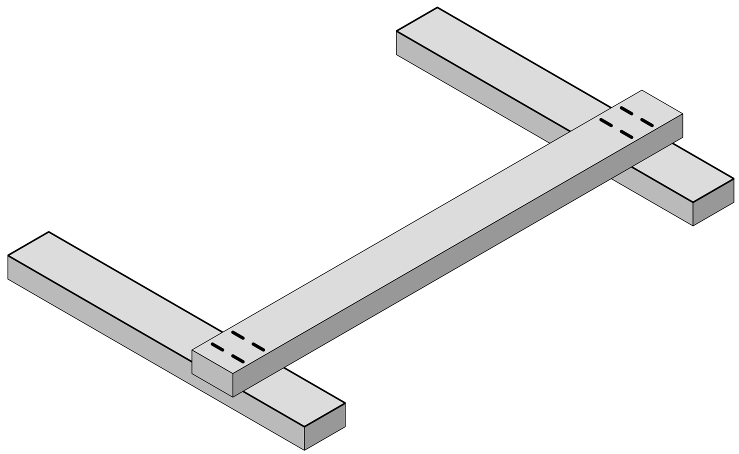

Figure 3: finished U-frame.

shown below you must be able to **weld** - there are alternative ways of making these but they are not as strong. In any case if you make an axle you will have to weld. You might find that a couple of 4" or a 5" G clamps (or something like it) are useful too. For drilling wood we have used flatbits sometimes (Figure 11). We have a Technical Release which describes how to make them.

Most of this cart is joined together using clench nailing which is a bit like riveting. You use nails which are about an inch (25mm) longer than the total thickness of the wood. You probably need to put a piece of scrap timber under the timber

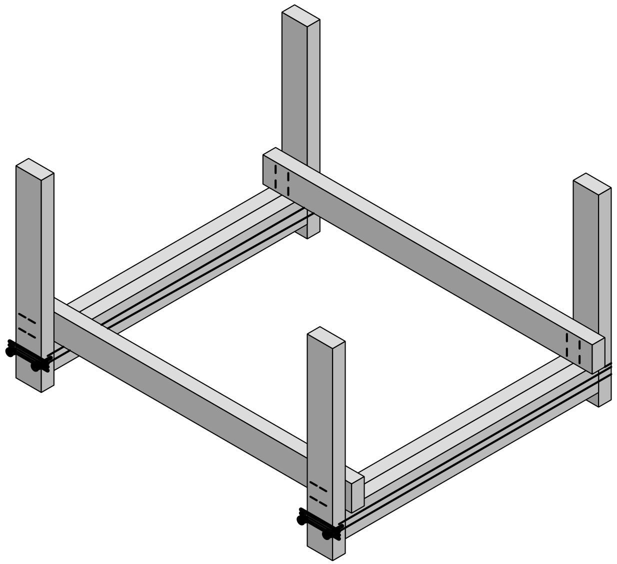

Figure 4: finished framework before planking.

you are working on to stop the nails going into the floor. When you have put all the nails in you put a hammer against the head of each nail in turn and then knock the pointed end over as shown in figure 2. Knock the end of the nail into the timber to make it neat.

If you do not have any nails you can use 6 mm round bar. We tell you how to make joints with 6mm bar at the end of this booklet.

You will see that there are no mitres and complicated angles to

cut in the timber so you save time when making the cart. Also the exact lengths of the components are not very critical - again it saves a little time, but you will find that the carts look better if you take a little trouble to get things square and even etc.

We have tested these carts in Kenya and Uganda and we think that they are strong enough, but we cannot be sure. So treat the cart carefully at first!

Construction step by step

Table 1 shows a cutting list for a complete cart - Recent prices of materials in Kenya are shown converted into £UK.

1) The first job, is to get all the materials together and clear a space to work. Ideally you will be able to work on a flat

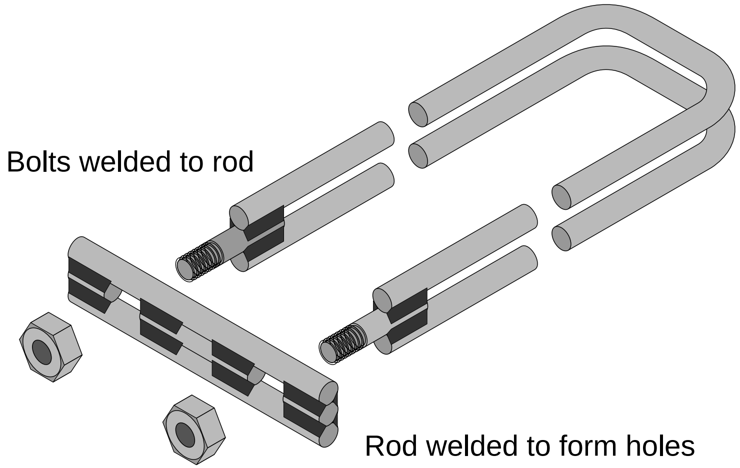

Figure 5: U-bolts for fixing axle beams to U frames.

area of concrete. Start by cutting the 100×50 timber into the right lengths, as in the cutting list, and then you can cut the bottom and side planks. Because timber comes in such variable sizes its best not to cut the steel components until you are sure how big they must be.

2) Next make up the two U-shaped front and back frames like those shown in figure 3. If you have a G clamp you can use it to hold two pieces of the frame together during nailing and clenching. It's quick and you can tap the bits with a hammer until everything is square and straight.

3) Next fit the axle beams in between the two U frames to make the frame shown in figure 4. The best way to join the U frames and the axle beams together strongly is to make up some big U bolts like those shown in Figure 5. These are made from 8 to 12mm round bar and some bolts. You will see from the drawing that they are made by welding rod together, not drilling holes.

If you cannot get these U-bolts made, use some 6 mm or

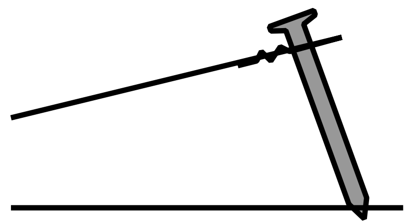

Figure 6: tightening wire by angled nailing.

8 mm round steel bar to tie the frames and beams together. Be very careful if you twist the ends together because some wire breaks quite easily. You can tighten the wire by nailing at an angle as shown in Figure 6 it. You can also tighten the wire slightly after nailing by kinking it.

4) Next you can fit the side and the bottom planks with more clenched nails.

5) Now you need to fix the draught pole. The best way is to use a big U-bolt to fix it to each U-frame. Do not drill holes in the U-frames or the draught pole for these bolts but arrange them as shown in Figure 7. If you cannot get U-bolts made up you will need to fix the draught pole with wood clenched nails and wire.

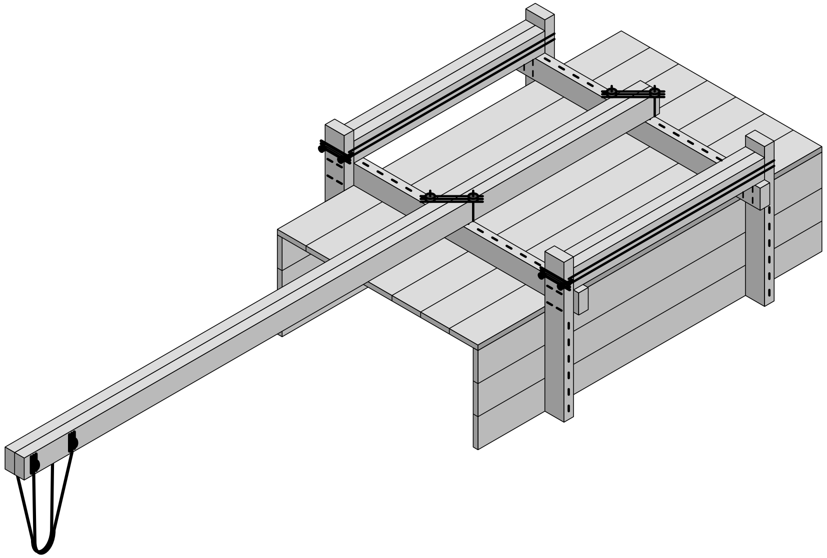

Figure 7: method of fixing draught pole using U-bolts.

6) The draught pole vertical extension is made from 12mm round bar. To fix it you will need to make long bolts as in Figure 8 from round bar and M12 bolts.

7) Nearly there! Fix the axle with more U-bolts around the axle and the axle beams as shown in Figure 9. If you are using a scrap vehicle axle you may need to weld extra pieces of steel to it to make it fit properly to the cart axle beams. Whichever axle you use you will find it stronger to nail pieces of wood to the bottom of the axle beams to stop the axle sliding along it.

8) Removable ends for the load tray can easily be provided in the way we have shown in Figure 10. The end is tied against the stop with rope or rubber. (Notice that there is a gap between the stop and the load tray so that the tray can be cleaned easily.

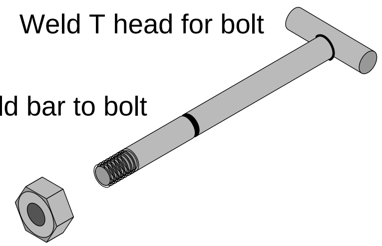

Figure 8: method of fixing draught pole using U-bolts.

9) Paint or creosote the cart. You've finished it!

Modifications

There are many different versions of this cart. You can try longer or shorter carts and you can make them wider or narrower. When you change things check the length and width of the planks of wood that you will use - you do not want to find that you are two inches short of being able to get two runs of plank out of one piece of timber, or that its just too narrow and you have to fiddle about and fit in a narrow strip.

Another modification is to make the cart higher see Figure 11. This lifts the cart body and raises the draught pole reducing the required size of the vertical extension.

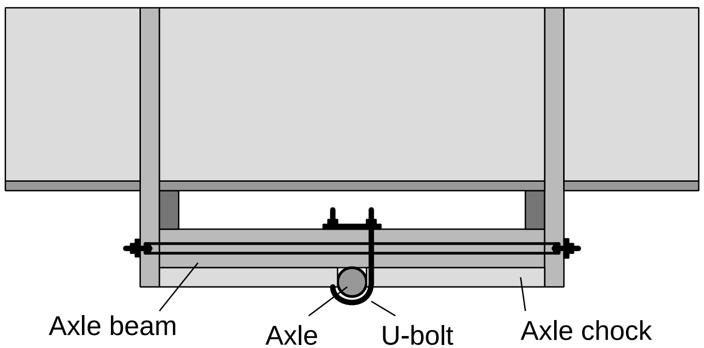

Figure 9: chocking axle to axle beam.

Using 6mm bar instead of nails

You can use 6 mm round bar instead of nails. You will need 16 pieces 150 mm long for the frames and 52 pieces 175 mm long to fix the planks on. You will need to drill a 6mm hole in the wood to use this method. Then put a straight piece of 6mm diameter re-bar (concrete reinforcing bar) right through so it sticks out about 25mm both sides. Then you just knock one end over with a hammer so it lies on the surface of the wood. Next you bend the other end over. Tighten the joint using a second hammer as described above.

You can make the drill yourself if you have to - see our Technical Release on flat bits.

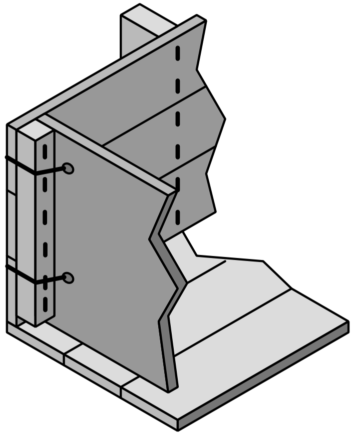

Figure 10: method of fixing tray ends with rubber or rope

Other DTU cart developments

The DTU has been working on a range of cart body types for use with both donkeys and oxen. It has several designs for steel framed types. The wooden types are cheaper in material terms, but the steel framed ones are easier to make because the joints are more straightforward - nevertheless you can make either type of cart in only a day or so if you are reasonably set up with tools and materials.

The DTU has also been working on new designs of wheels, hubs and bearings to bring down their costs and make things more locally manufacturable. It has designs for wooden and PVC plain bearings and for using scrap or new ball bearings - without needing machining, It also has a system of needle roller bearings which you can make without machining.

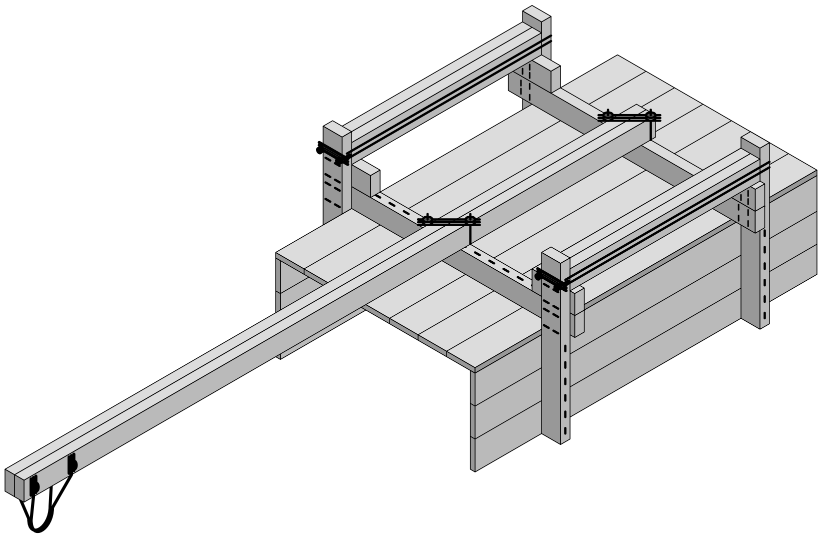

Figure 11: raised cart

Cart Drawings

You will find two drawings below, the first one gives a general view of the cart and the second, a view of the main components. As we have said you can vary the size of the cart quite a bit and even make it much longer if you add extra frames. You could even make a four wheeled cart like this!

RELEASE

Making a flatbit for drilling holes in wood

Development Technology Unit, Department of Engineering, University of Warwick, Coventry, CV4 7AL UK, tel: +44 (0)203 523523 extn 2339, fax: +44 (0)203 418922, email: esceo@uk.ac.warwick.eng

Making a Flatbit.

This type of drill bit can be made in a few minutes and will drill holes well in wood and soft metal such as copper and aluminium. If it is hardened it will work in steel as well.

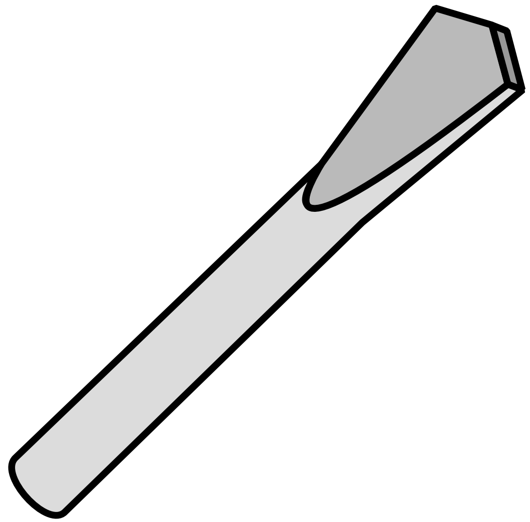

Figure 1: flat bit for drilling holes in wood.

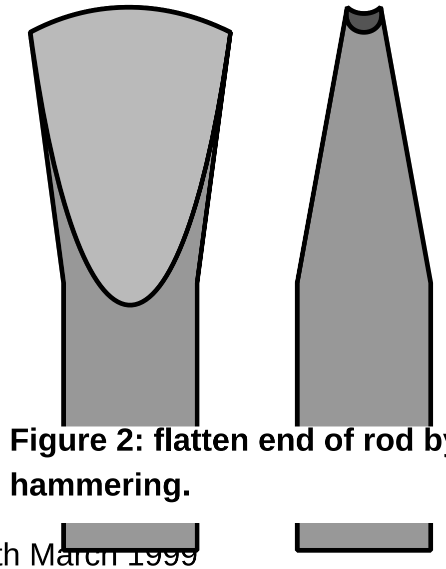

Figure 2: flatten end of rod by hammering.

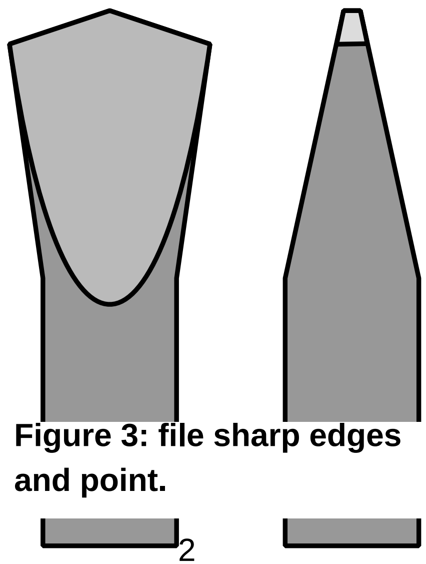

Figure 3: file sharp edges and point.

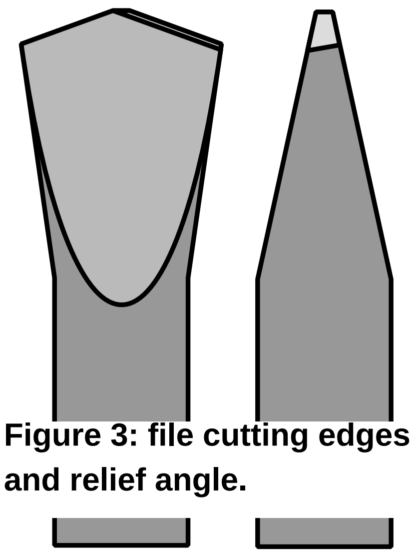

Figure 3: file cutting edges and relief angle.

Making a flatbit

Flatbits for drilling wood are easy to make and quite useful because you can make them very long and drill holes in quite awkward places. Of course you do need something to turn the bit - like a wheelbrace or a 'drill'. You can use a bent piece of steel like that shown in Figure 2 and weld the flatbit to the end of the rod. To make it comfortable to push you could make a handle from a piece of pipe with an end on it or by cutting it and bending a bit of the pipe over. Another way is by winding a spring of say 6mm round bar around the rod and then bending the end of the wire over as we have shown.

If you can harden the cutting edges of a flatbit you can use it to drill holes in metal too as long as you do not want to drill deep holes - it tends to wander if the depth is more than the diameter.

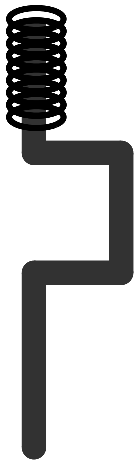

Figure 2: using bent steel rod to rotate drill.

To get hard cutting edges you will need to use 'silver steel' or spring steel, which you will have to harden and temper if you can. To get it very hard, heat until bright red/ orange hot and plunge into water. It will then be very hard and brittle so if you can you need to reheat slowly at a point two inches from the tip. You will see the steel take on a range of colours and just when the cutting edges look yellow or straw coloured, re-plunge into water. This is a fairly skilled operation but it does give a good result if you get it right.

Another way to get a harder cutting edge is to use a hardfacing welding electrode. This will not be as good as the heat treated steel above but it will be better than mild steel.

Lastly some concrete reinforcing bar called 'high yield' may be a bit harder.

1) To make the bit, get some steel bar of the same size as the hole you want to make, or a little bit smaller. Then hammer the end to flatten it a little (a bit like a screwdriver). The drawing shows what we mean.

2) Then file the end pointed and finally sharpen the cutting edges.

3) That's it!

Twin Plastic Plain Bearing Axle for Donkey Carts

Development Technology Unit, Department of Engineering, University of Warwick, Coventry, CV4 7AL UK, tel: +44 (0)203 523523 extn 2339, fax: +44 (0)203 418922, email: esceo@eng.warwick.ac.uk

KENDAT, PO Box 61441, Nairobi, Kenya, tel/fax: +254 2 766939, email: kendat@africaonline.co.ke

These bearings are designed to fit carts like that shown in Figure 2 but any cart could be modified to take the bearings described in this Technical Release.

These bearings are made of PVC water pipe. Polythene pipe would be much better but is not so easily available.

The system shown here is for two offset live axles (ie the axles go round). Using two axles allows any wheels to be used and provides plenty of room for the bearings.

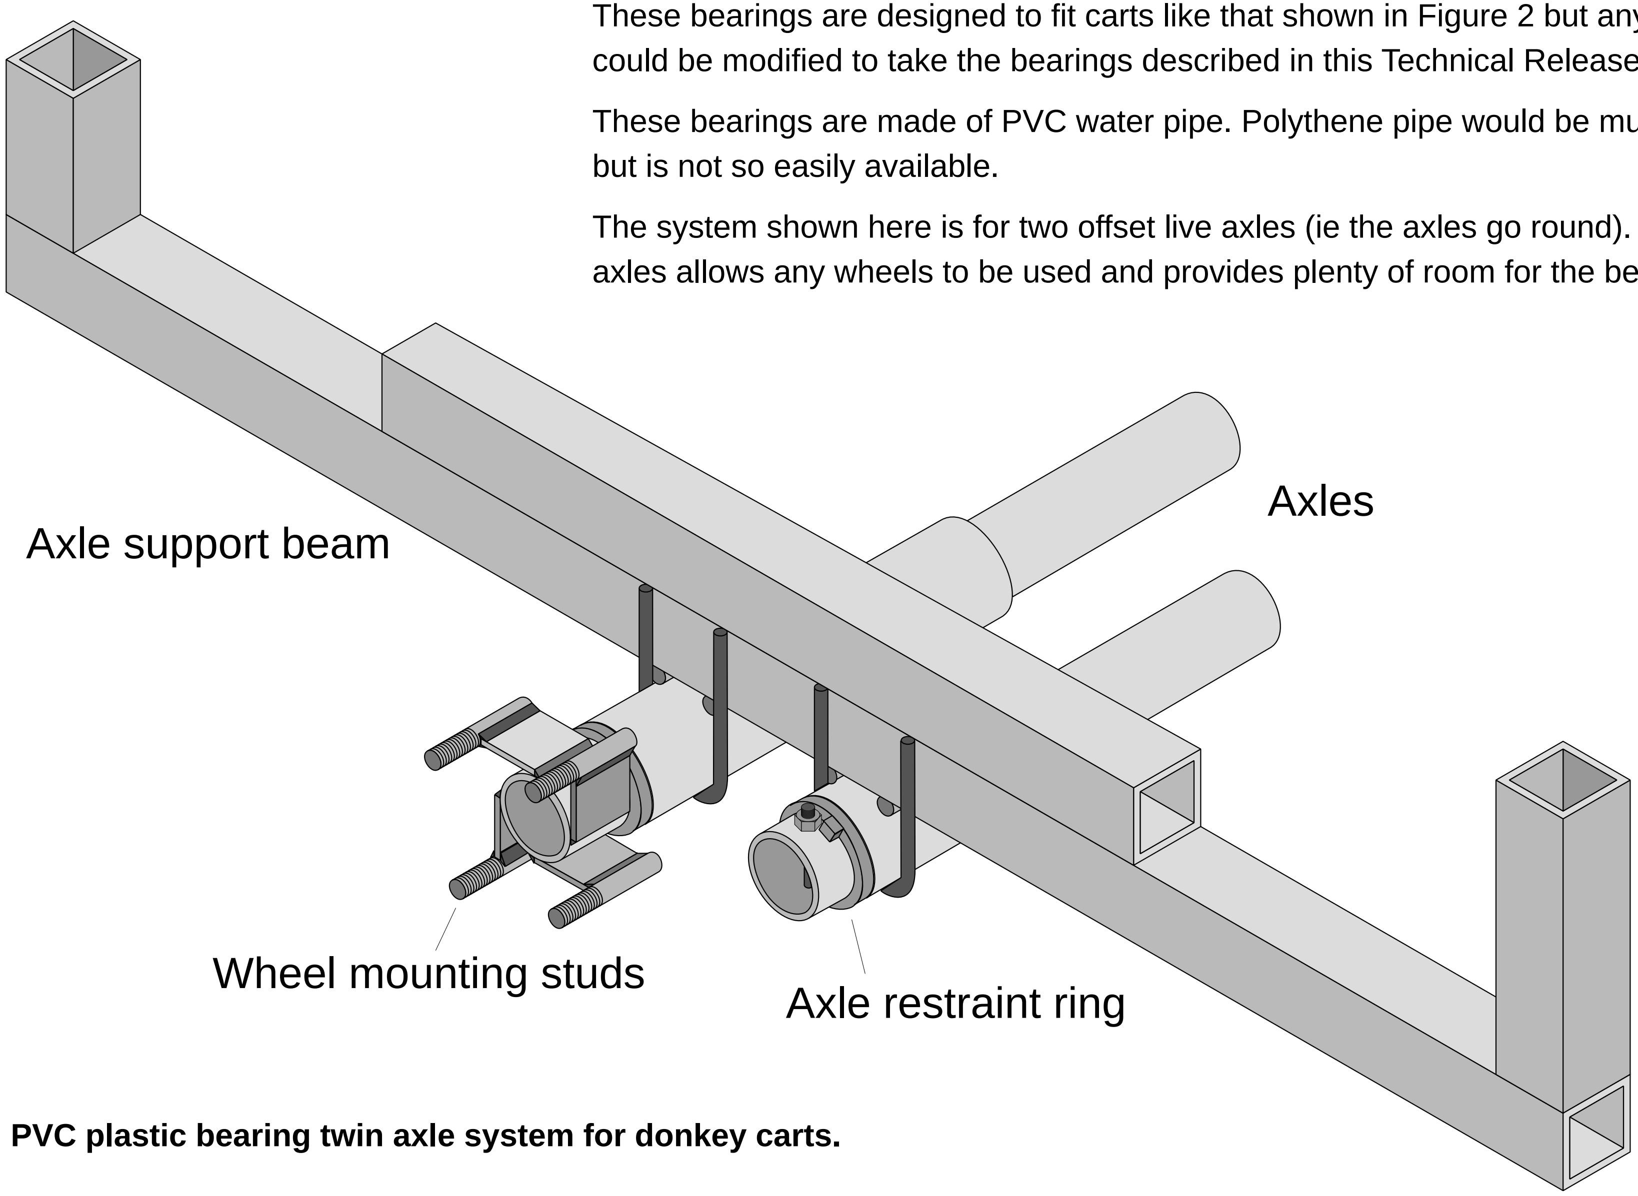

Figure 1: PVC plastic bearing twin axle system for donkey carts.

PVC plastic sleeve plain bearing axle system for a donkey cart.

Introduction

In this booklet we tell you how to make an axle system for a simple donkey cart from round steel tube and PVC plastic pipe. The instructions do not cover how to make the cart itself - you will need to read other Technical Releases from us to find out how to make the carts.

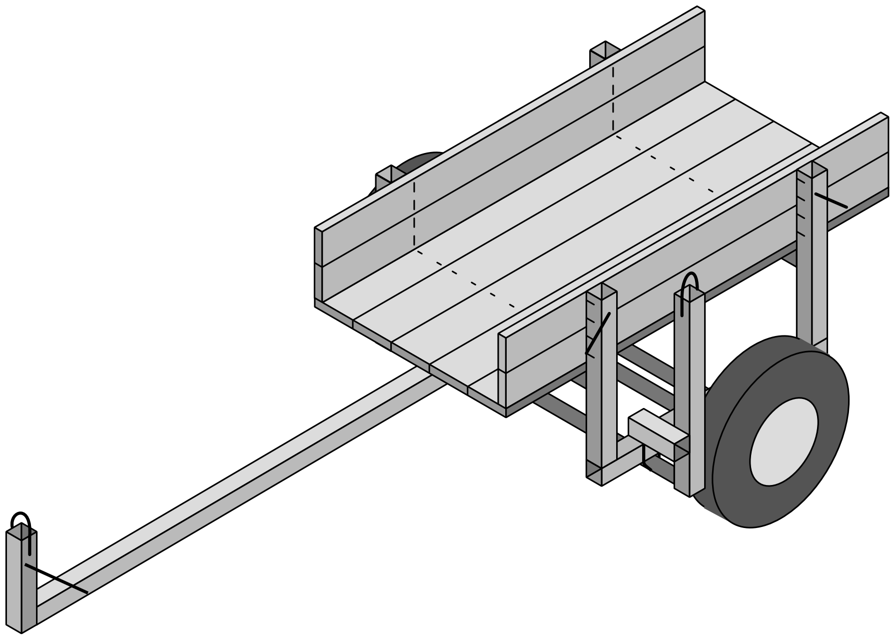

Figure 2: DTU donkey cart fitted with twin axles and PVC bearings.

You should find that you can make the axle system for about £50 including the wheels, tubes and tyres. This cost will depend on the cost of the materials and labour. Once you get organised, two men can probably make and fit one cart with axles in half a day. This is quite a lot faster than it takes to find and a scrap car axle and it will be much cheaper.

In other booklets in this series you can find out how to make other low-cost axle systems and carts.

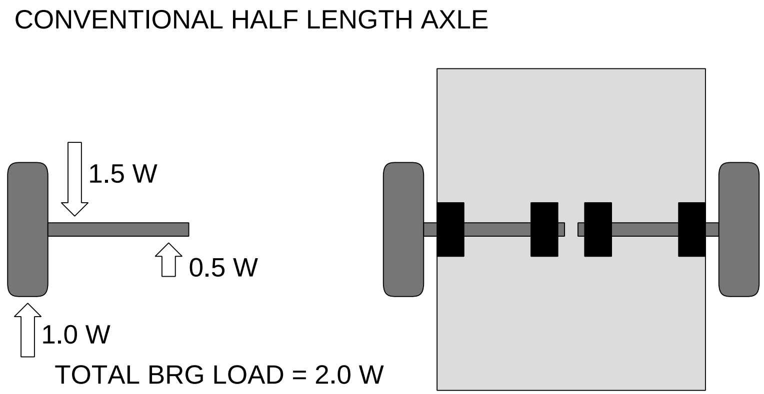

Figure 3: bearing loads in conventional half shaft axle.

Why have twin axles?

There are two types of axle: fixed or stub axle - the wheel hub rotates on the stationary axle; live axle - the axle revolves in stationary bearings.

With the stub axle types the bearings must be inside the wheel. This is easy with expensive ball bearings but more difficult with cheap wooden bearings. You need to make them quite long to stop wheel wobble and so they stick out of the wheel. It is also quite difficult to make without jigs and special tools. If you really want that type we have quite a good system using PVC tube for the bearing. We can send you a Technical Release on how to do it.

Twin axles allow much bigger bearings and do not require great accuracy in manufacture. Figure 3 shows the bearing loads of the usual way of doing it and Figure 4 shows the DTU method. You will see that bearing loads are 30% lower. Surprisingly there is no extra steel required either because there would have to be some steel to support the middle bearings anyway.

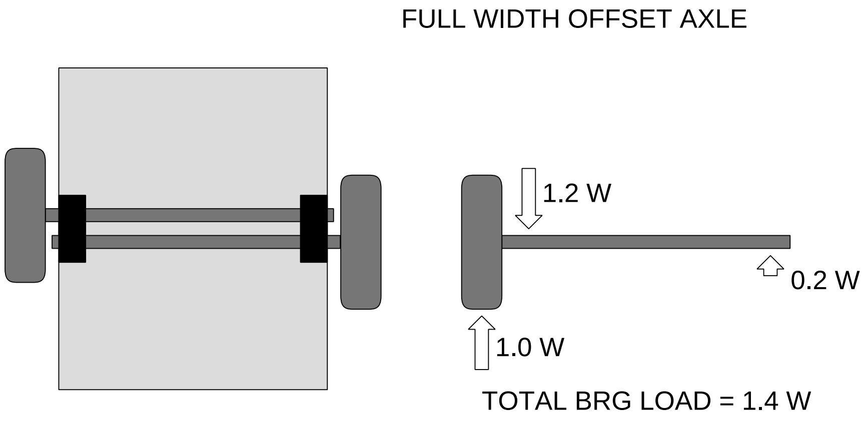

Figure 4: bearing loads in twin offset axles.

Easy to make design

These axles are designed to be constructed without any special tools and jigs, and without any hard-to-get materials. The only tools which you must have are a simple welder, a hacksaw, and a hammer. You might find that a couple of 4" or a 5" G clamps (or something like it) are useful too. We have deliberately designed the cart so that drilling is not required.

You will see that there are no mitres or complicated angles or joints to cut when making the axles either, so you save time. Also the exact lengths of the components are not very critical -

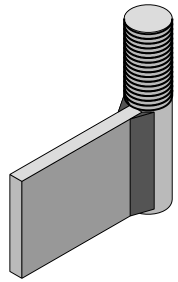

Figure 5: a welded wheel stud and strut fabrication.

again it saves a little time, but you will find that the axles look better if you take a little trouble to get things square and even etc and welding is easier with good square ends. It is much better to use a try square to mark the position of a cut than guess. In the instructions we have described how to mark pipe so you can cut it accurately.

We have tested many of these axles in Kenya and Uganda and we have had only a few failures caused by poor welding or incorrect material ie too thin. We think that they are strong enough, but you can always find someone to break anything. Really to get a reasonable cost you need to experiment a bit to

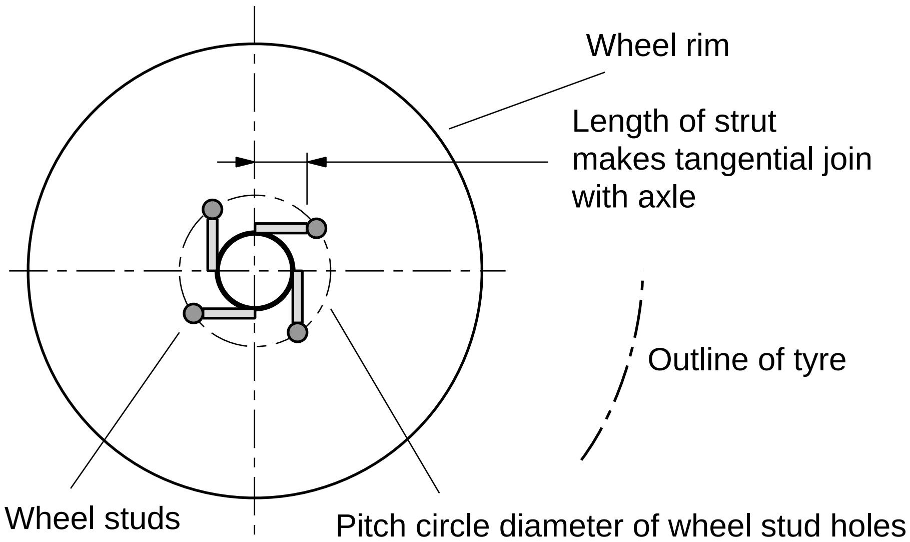

Figure 6: length of wheel strut.

see how the farmers treat their carts and what they expect them to stand.

It is also important to check the plastic sleeve is not worn through and to grease it every few weeks.

Cutting list and costs

Table 1 shows a cutting list for a complete axle - Recent prices of materials in Kenya are shown converted into £UK.

Construction step by step

1) The first job, is to get all the material together and clear a

TABLE 1: 50×50 RHS vestigial donkey cart.

component	material	# lengths reqd [#×mm]	total material for one axle [mm]	cost [UK£]
wheel studs	50×M12 nuts and bolts	10	10	2.60
wheel stud struts	6 × 40 flat bar	10×65	650.00	0.49
axial thrust rings	10 × 10 square bar	4 × 200	800.00	0.25
pipe clips	50 mm pipe clips	4	4	2.40
axle cross bolts	75×M12 nuts and bolts	4	4	1.04
axles	1-½"" BSP malleable iron pipe	2 × 1500	3000.00	6.00
hub outer tube	2 BSP malleable iron pipe	2×200	400.00	0.95
plastic bearing sleeves	1½"" or 2"" PVC plastic pipe	2×300+2×100	800.00	0.53
wheel rims, tyre + tubes				25.00
			TOTAL =	**39.25**

space to work. Ideally you will be able to work on a flat area of concrete.

2) Start by making the wheel stud struts shown in Figure 5. You need to make one of these struts for every stud hole in the wheels you are going to use. Figure 6 shows how to measure the length of the struts. The struts are made from 6×40 flat bar and M12 bolts 50mm long. The flat bar should be long enough so that it meets the axle tube tangentially as shown in Figure 6.

3) Once you have made these struts, screw a nut onto each one until it touches the 40×6 metal. Then put the thread through the hole in the rim and screw another nut onto the thread. Tighten this nut lightly with a spanner. Repeat for all the struts so that they all point the same way round the axle, as in Figure 6, and leave a gap for the axle.

4) Now centre the axle in the rim and get it square using a tape measure, a trysquare and a plank or piece of steel resting on the tyre.

   To do this put the wheel rim on the floor and put the axle in place in the middle. You should put something under the end of the pipe to rest it on to get it in the right position as shown in Figure 7. Get an assistant to hold the top end of the pipe and tell him to keep very still! Use your tape to measure from the outside of the pipe to the inside of the rim as Figure 7 shows. Measure in one place and then measure the gap opposite. Move the axle pipe over until it is central. Repeat this for the other direction at right angles.

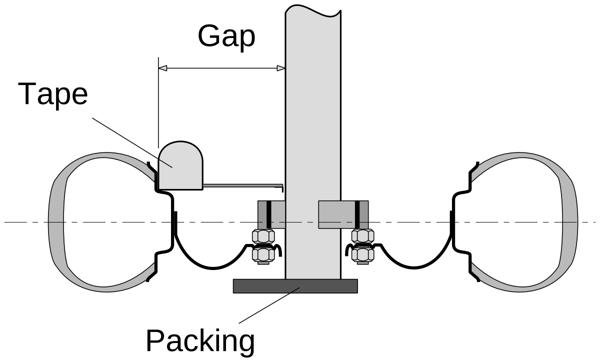

Figure 7: using tape measure to centre axle in wheel.

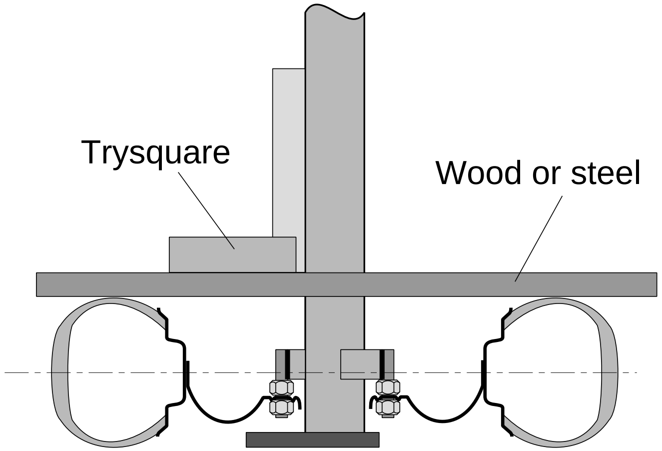

Figure 8: using trysquare to get axle square to wheel.

Now use the trysquare and a piece of wood to get the axle square to the rim as shown in Figure 8. You put the wood on the tyre or rim so that it is flat and you put the trysquare on the wood. You have to move the axle until it is straight with the trysquare and your assistant must hold it without moving. Check it several times - its hard to correct!

5) Once you have it in position, tack weld the ends of the struts to the axle tube as shown in Figure 9, then weld the struts on properly. Do as much welding as you can without taking the axle out of the wheel because the metal changes size as it heats and cools and it may move out of place.

6) Next make the bearing tubes from 2" round pipe to the lengths in the cutting list. To mark a line around the pipe to cut it square, wrap a strong piece of paper or thin card around the pipe, get the edge in line and use the edge to guide the felt tip pen or scriber as you mark the line.

7) Cut eight 50mm pieces of 8 to 12mm round bar for the bearing tube chocks. Mark the centre of the axle support beam of the cart and put marks on the beam 60mm either side of this. You need to weld the chocks on to the beams so that the bearing tubes just sit nicely in the space between the chocks as shown in Figure 10.

8) Fix the axle bearing tubes with loops of 8 to 12mm round bar as shown in Figure 1 and Figure 11. Do not weld the

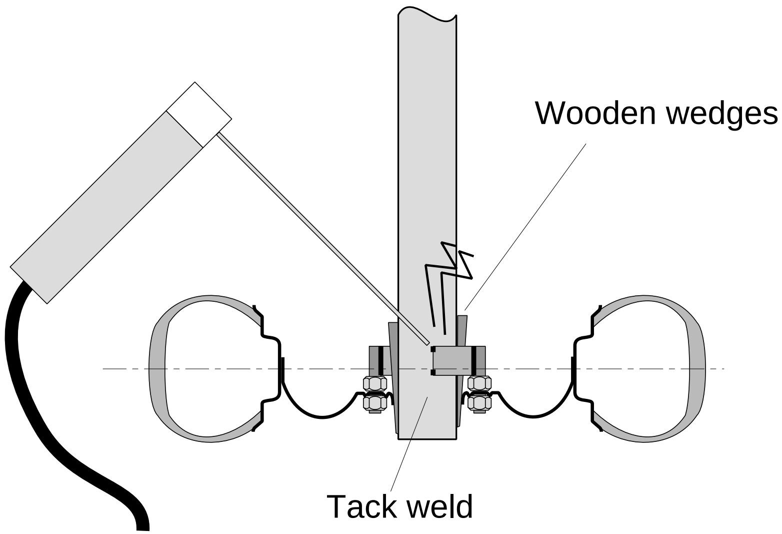

Figure 9: tyre, wheel and axle tube during tack welding stud support struts

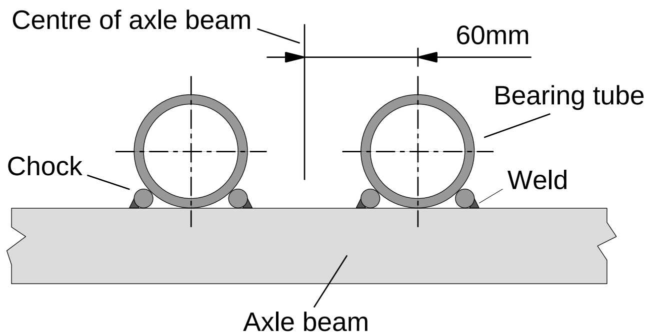

Figure 10: position of bearing tubes and chocks.

bearing tubes directly to the axle support beam. The bearing tubes must be slightly flexible so that they can align themselves with the other bearing on the same axle.

9) Make four axial rings of 10 to 12mm square or round bar which just go over the axles. Square bar is better but round will do. You must remember to weld on a tag made of a 15mm length of bar to each ring as shown in the drawings. This makes the rings go round with the axle and stops wear in the wrong places. Put a ring on each axle so the tag goes between two stud support struts.

10) Insert an axle into its bearing tubes and push right through until the axial ring touches the bearing tube and then put the second axial ring on.

11) Now mark the position of the cross bolt hole. Remember that the nut will have to be turned so do not make the hole too close to the ring - centre about 15mm away is fine. Use the welder to blow a hole through for the bolt. Of course a hole will have to be blown through on the other side of the axle too.

12) Cut pieces of PVC tube to lengths shown in the cutting list and either cut along their length or cut around like a spring or screw as shown in Figure 12. Remove axles from bearing tubes, apply lots of grease, fit the PVC bearing pipes and the pie clips and refit axles. Use the pipe clips to stop the PVC pipe coming out of the bearing tubes. Tighten the cross bolts.

13) You've finished it!

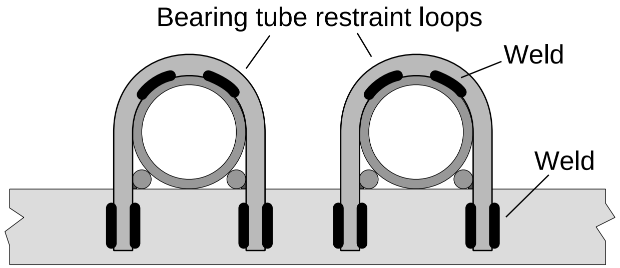

Figure 11: position of bearing tubes and chocks.

Other DTU cart developments

The DTU has been working on new designs of wheels, hubs and bearings to bring down their costs and make things more locally manufacturable. It has designs for twin axles with wooden bearings and twin axles with scrap or new ball bearings which do not need any machining. And it has two systems of fixed axle: one with PVC bearings and another

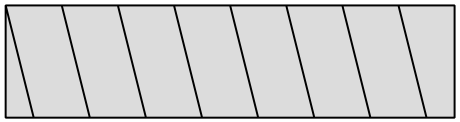

Figure 12: cut PVC bearing tubes like spring to fit axle.

using needle roller bearings which you make yourself. Again for these needle roller bearings no machining is necessary.

Other hub designs using, for example aluminium castings, have been in production in Nigeria and we are trying to reduce or eliminate the machining in these. Also wheel designs in steel sheet, cast aluminium and timber are under development.

The DTU has also been working on a range of cart body types for use with both donkeys and oxen. It has designs for wooden and steel framed types. The wooden types are cheaper in material terms, but the steel framed ones are easier to make because the joints are more straightforward - nevertheless you can make either type of cart in only a few hours, if you are reasonably set up with tools and materials.

Drawings

You will find four drawings on the next pages, the first two give a general section view of the axle. The third gives a view of the components of the axle itself and the fourth a view of the bearing tube and PVC bearing sleeve.

Acknowledgements

The DTU is grateful to the DFID (British Government) for the financial support necessary to carry out the research and development project under which this product was developed.

The DTU would also like to thank Dr Pascal Kaumbutho of KENDAT in Kenya and Mr Joseph Mugaga of TOCIDA in Tororo, Uganda for their very considerable help with this project. A large number of other people and organisations have contributed to the success of the project, most notably Mr Anthony Ndungu in Kajiado Kenya, Mr JD Kimani in Kikuyu Kenya and Mr Joseph Gitari in Wanguru Kenya in whose workshops most of the development work of this project was performed. Thanks are due also to Mr Stanley Lameria in Kajaido, Mr Patrick Gitari in Wanguru and Mr Mathew Masai in Machakos for their assistance.

RELEASE

Twin Wood Plain Bearing Axle for Donkey Carts

Development Technology Unit, Department of Engineering, University of Warwick, Coventry, CV4 7AL UK, tel: +44 (0)203 523523 extn 2339, fax: +44 (0)203 418922, email: esceo@eng.warwick.ac.uk

KENDAT, PO Box 61441, Nairobi, Kenya, tel/fax: +254 2 766939, email: kendat@africaonline.co.ke

These bearings are designed to fit carts like that shown in Figure 2 but any cart could be modified to take the bearings described in this Technical Release.

The system shown here is for two offset live axles (ie the axles go round). Using two axles allows any wheels to be used and provides plenty of room for the bearings.

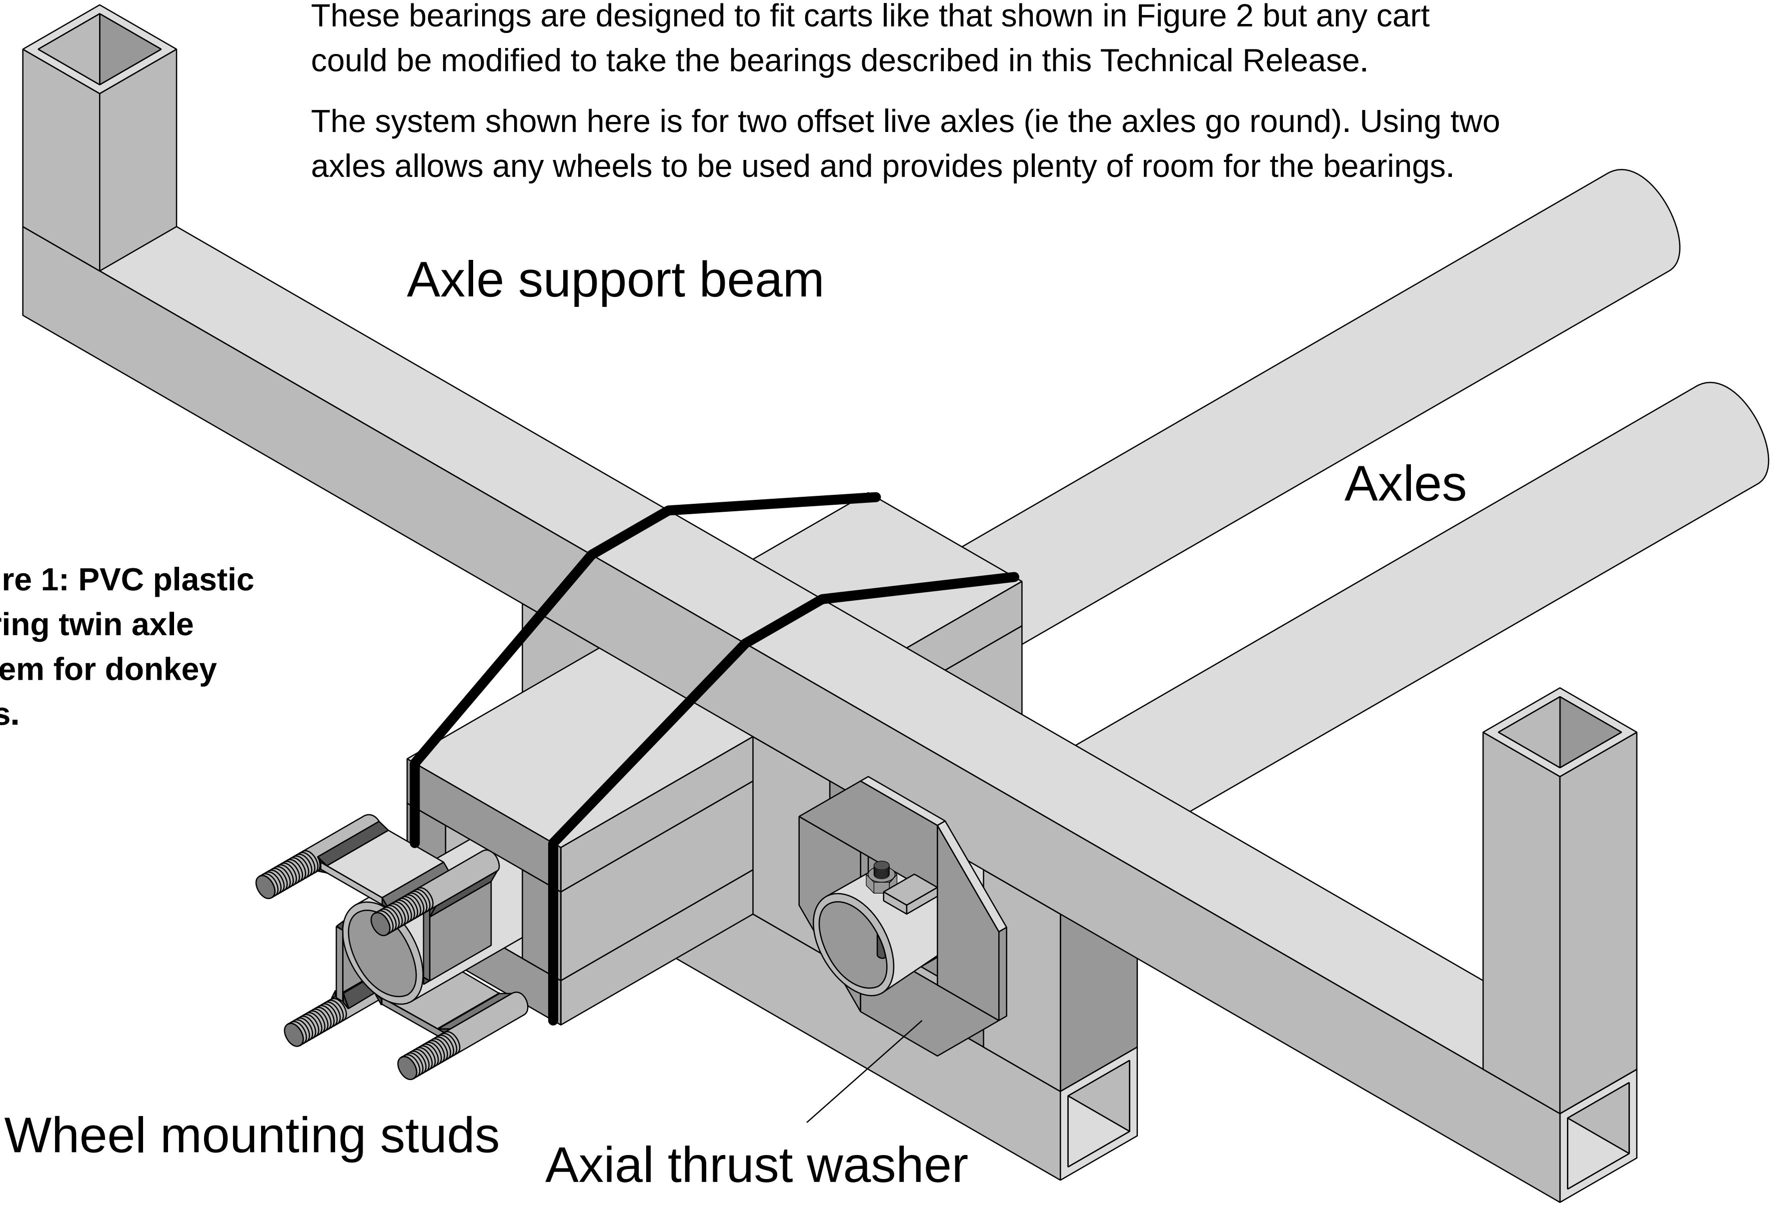

Figure 1: PVC plastic bearing twin axle system for donkey carts.

Wood plain bearing twin axle system for donkey carts.

Introduction

In this booklet we tell you how to make an axle system for a simple donkey cart from round steel tube and wooden planks. The instructions do not cover how to make the cart itself - you will need to read other Technical Releases from us to find out how to make the carts.

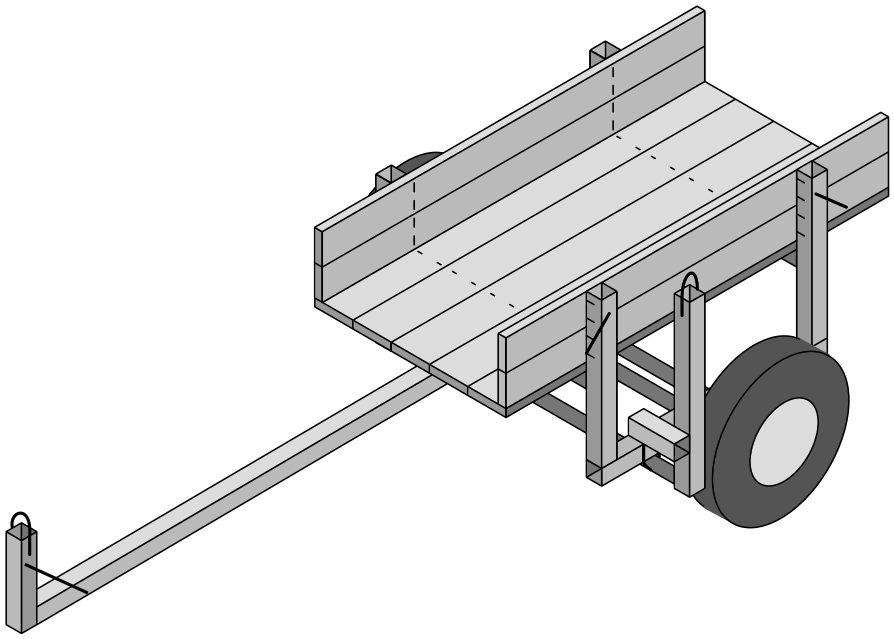

Figure 2: DTU donkey cart fitted with twin axles and PVC bearings.

You should find that you can make the axle system for about £40 including the wheels, tubes and tyres. This cost will depend on the cost of the materials and labour. Once you get organised, two men can probably make and fit one cart with axles in half a day. This is quite a lot faster than it takes to find and a scrap car axle and it will be much cheaper.

In other booklets in this series you can find out how to make other low-cost axle systems and carts.

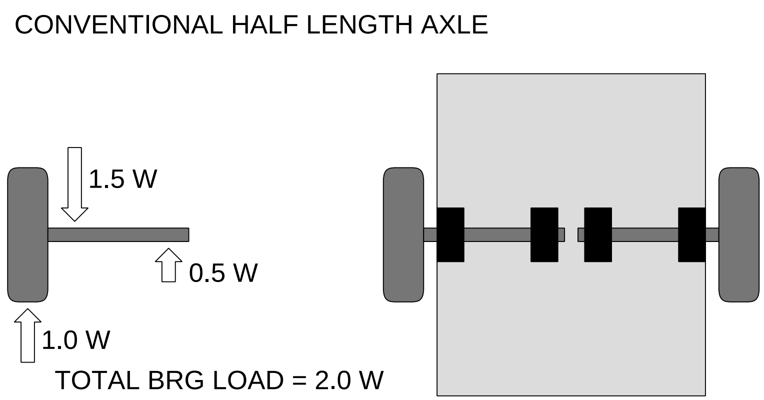

Figure 3: bearing loads in conventional half shaft axle.

Why have twin axles?

There are two types of axle: fixed or stub axle - the wheel hub rotates on the stationary axle; live axle - the axle revolves in stationary bearings.

With the stub axle types the bearings must be inside the wheel. This is easy with expensive ball bearings but more difficult with cheap wooden bearings. You need to make them quite long to stop wheel wobble and so they stick out of the wheel. It is also quite difficult to make without jigs and special tools. If you really want that type we have quite a good system using PVC tube for the bearing. We can send you a Technical Release on how to do it.

Twin axles allow much bigger bearings and do not require such great accuracy in manufacture. Figure 3 shows the bearing loads of the usual way of doing it and Figure 4 shows the DTU method. You will see that bearing loads are 30% lower. Surprisingly there is no extra steel required either because there would have to be some steel to support the middle bearings anyway.

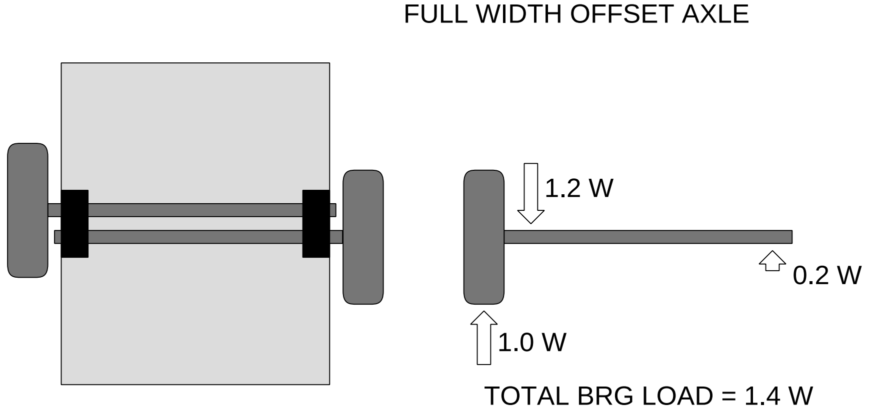

Figure 4: bearing loads in twin offset axles.

Easy to make design.

These axles are designed to be constructed without any special tools and jigs, and without any hard-to-get materials. The only tools which you must have are a simple welder, a hacksaw, and a hammer. You might find that a couple of 4" or a 5" G clamps (or something like it) are useful too. We have deliberately designed the axle so that drilling is not required.

We have tested many of these axles in Kenya and Uganda and we have had only a few failures caused by poor welding or

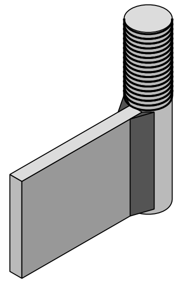

Figure 5: a welded wheel stud and strut fabrication.

incorrect material. We think that they are strong enough, but you can always find someone to break anything. To get a reasonable cost you need to experiment a bit to see how the farmers treat their carts and what they expect them to stand.

It is important to grease the bearings every few weeks.

Cutting list and costs

Table 1 shows a cutting list for a complete axle - Recent prices of materials in Kenya are shown converted into £UK.

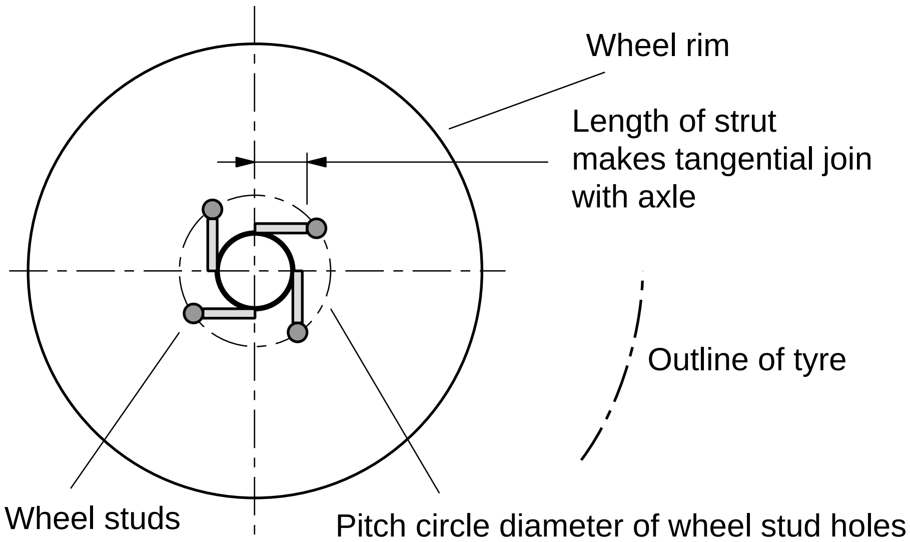

Figure 6: length of wheel strut.

Construction step by step

1) The first job, is to get all the material together and clear a space to work. Ideally you will be able to work on a flat area of concrete.

2) Start by making the wheel stud struts shown in Figure 5. You need to make one of these struts for every stud hole in the wheels you are going to use. Figure 6 shows how to measure the length of the struts. The struts are made from 6×40 flat bar or similar and M12 bolts 50mm or 60mm long. The flat bar should be long enough so that it meets the axle tube tangentially as shown in Figure 6.

TABLE 1: materials for wooden bearing twin axle.

component	material	# lengths reqd [#×mm]	total material for one axle [mm]	cost [UK£]
wheel studs	50×M12 nuts and bolts	10	10	2.60
wheel stud struts	6 × 40 flat bar	10×65	650.00	0.49
axial thrust washers	6 × 40 flat bar	8×90	720.00	0.54
axle cross bolts	75×M12 nuts and bolts	4	4	1.04
axles	1-½" BSP malleable iron pipe	2 × 1500	3000.00	6.00
bearing block restraint loops	R 8 re-bar	8×430	3440.00	0.56
main bearing top + bottom	100×25mm timber	4×300	1200.00	0.20
main bearing sides	50×25mm timber	4×300	1200.00	0.20
small bearing top + bottom	100×25mm timber	4×50	200.00	0.03
small bearing sides	50×25mm timber	4×50	200.00	0.03
wheel rims, tyre + tubes				25.00
			TOTAL	**36.69**

3) Once you have made these struts, screw a nut onto each one until it touches the 40×6 metal. Then put the thread through the hole in the rim and screw another nut onto the thread. Tighten this nut lightly with a spanner. Repeat for all the struts so that they all point the same way round the axle, as in Figure 6, and leave a gap for the axle.

4) Now centre the axle in the rim and get it square using a tape measure, a trysquare and a plank or piece of steel resting on the tyre.

   To do this put the wheel rim on the floor and put the axle in place in the middle. You should put something under the end of the pipe to get it in the right position as shown in Figure 7. Get an assistant to hold the top end of the pipe and tell him to keep very still! Use your tape to measure from the outside of the pipe to the inside of the rim as Figure 7 shows. Measure in one place and then measure the gap opposite. Move the axle pipe over until it is central. Repeat this for the other direction at right angles.

   Now use the trysquare and a piece of wood to get the axle square to the rim as shown in Figure 8. You put the wood on the tyre or rim so that it is flat and you put the trysquare on the wood. You have to move the axle until it is straight with the trysquare and your assistant must hold it without moving. Check it several times - its hard to correct!

5) Once you have it in position, tack weld the ends of the struts to the axle tube as shown in Figure 9. (As Figure 9

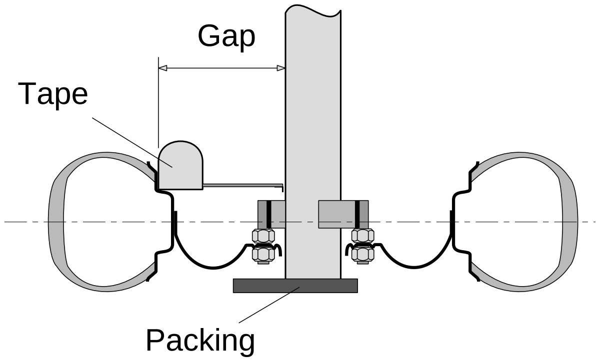

Figure 7: using tape measure to centre axle in wheel.

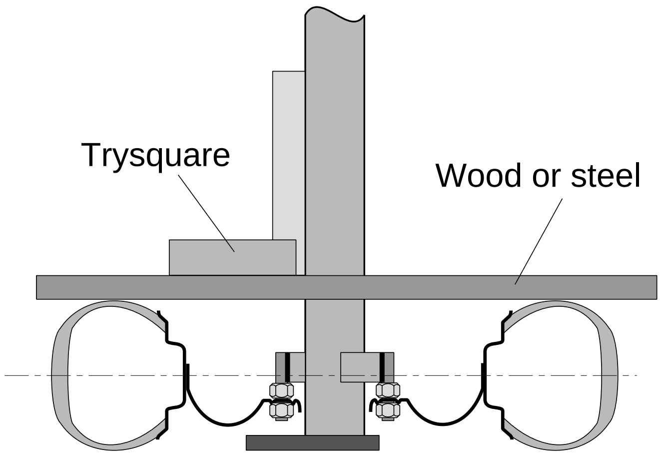

Figure 8: using trysquare to get axle square to wheel.

shows, you can use wooden wedges to hold the axle in place in the rim.) Then weld the struts on properly. Do as much welding as you can without taking the axle out of the wheel because the metal changes size as it heats and cools and it may move out of place.

6) Next make the bearing blocks from 100×25mm timber and 50×25mm timber to the lengths in the cutting list.

7) Cut six 105mm pieces of square tubing for the bearing boxes. Mark the centre of the axle support beam of the cart and put marks on the beam 25mm and 125mm either side of this. You need to weld the 105mm pieces on to the beams as shown in Figure 10.

8) Fit the bearing blocks and fix them in place with loops of 8 to 12mm round bar as shown in Figure 1 and Figure 11.

9) Make four axial thrust washers from 40×6 or 40×3 or similar flat bar like those shown in Figure 12. You must remember to weld on a tag made of a 20mm length of bar to each ring as shown in the drawings. This makes the washers go round with the axle and stops wear in the wrong places.

10) Insert an axle into its large bearing but not its small bearing

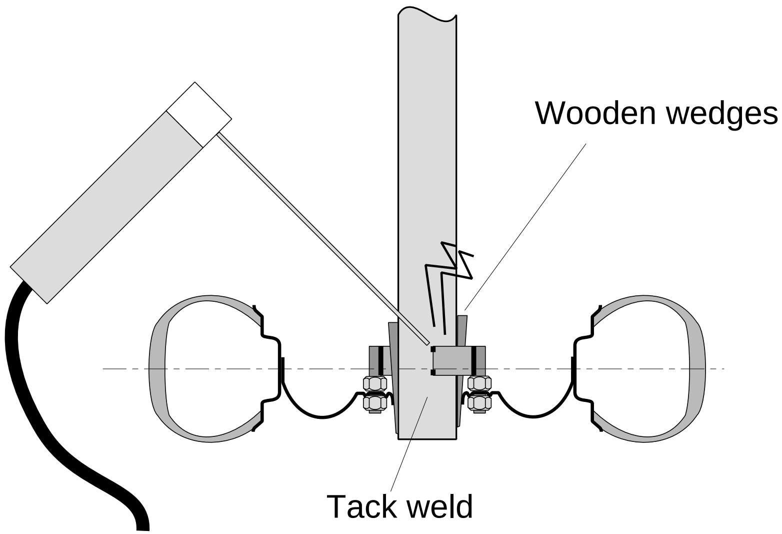

Figure 9: tyre, wheel and axle tube during tack welding stud support struts

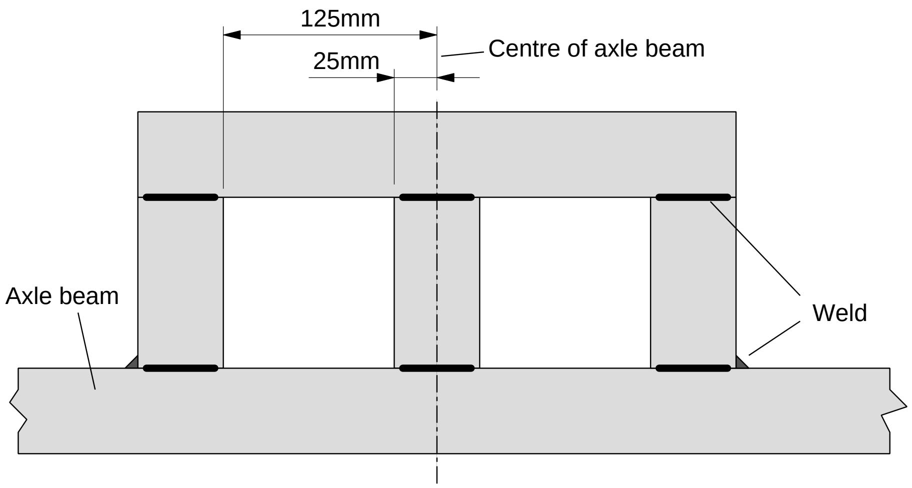

Figure 10: position of bearing support blocks.

and tn put on one of the axial bearing washers with the tag away from the small bearing. Then push the axle all the way through until there is a 20 mm gap between the wheel stud struts and the bearing blocks. Put the second axial ring on to the axle. You should now have an axial washer either side of the small bearing as shown in Figure 13.

11) Now mark the position of the cross bolt holes. Remember that the nuts will have to be turned so do not make the holes too close to the washers - centre about 15mm away is fine. Use the welder to blow the holes.

12) Remove axles from the bearing, apply lots of grease and refit the axles, washers and cross bolts.

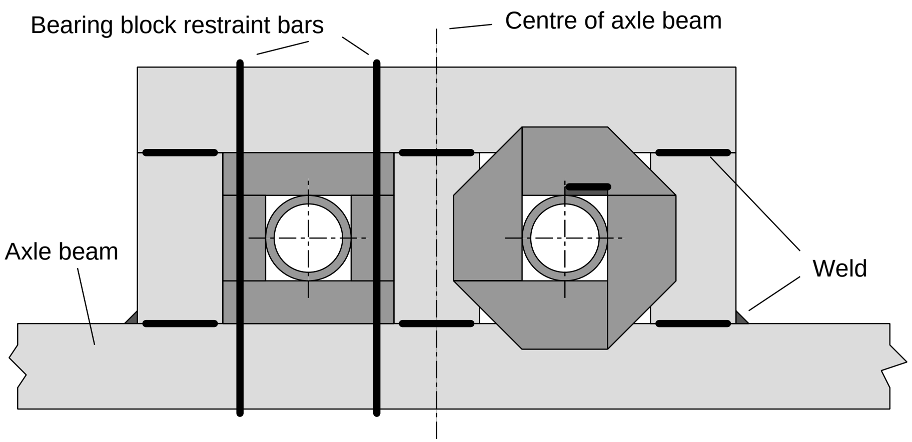

Figure 11: axial bearing washer.

13) Cut the excess axle off about 40mm from the washer. To mark a line around the pipe to cut it square, wrap a strong piece of paper or thin card around the pipe, get the edge in line and use the edge to guide the felt tip pen or scriber as you mark the line.

14) You've finished it!

Other DTU cart developments

The DTU has been working on new designs of wheels, hubs and bearings to bring down their costs and make things more locally manufacturable. It has designs for twin axles with wooden bearings and twin axles with scrap or new ball bearings which do not need any machining. And it has two systems of fixed axle: one with PVC bearings and another

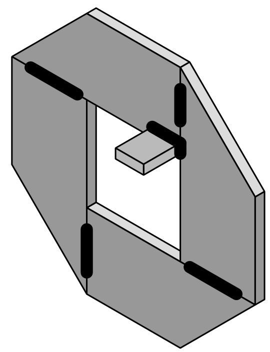

Figure 12: axial bearing washer.

using needle roller bearings which you make yourself. Again for these needle roller bearings no machining is necessary.

Other hub designs using, for example aluminium castings, have been in production in Nigeria and we are trying to reduce or eliminate the machining in these. Also wheel designs in steel sheet, cast aluminium and timber are under development.

The DTU has also been working on a range of cart body types for use with both donkeys and oxen. It has designs for wooden

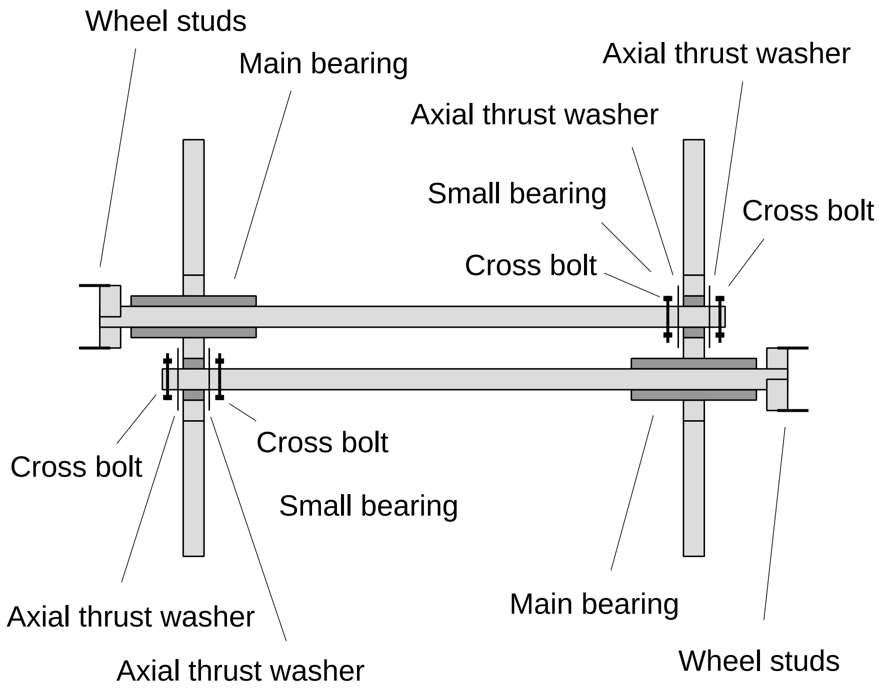

Figure 13: axle and bearing arrangement.

and steel framed types. The wooden types are cheaper in material terms, but the steel framed ones are easier to make because the joints are more straightforward - nevertheless you can make either type of cart in only a few hours, if you are reasonably set up with tools and materials.

Drawings

You will find four drawings on the next pages, the first two give a general section view of the axle. The third gives a view of the components of the axle itself and the fourth a drawing of the thrust washer.

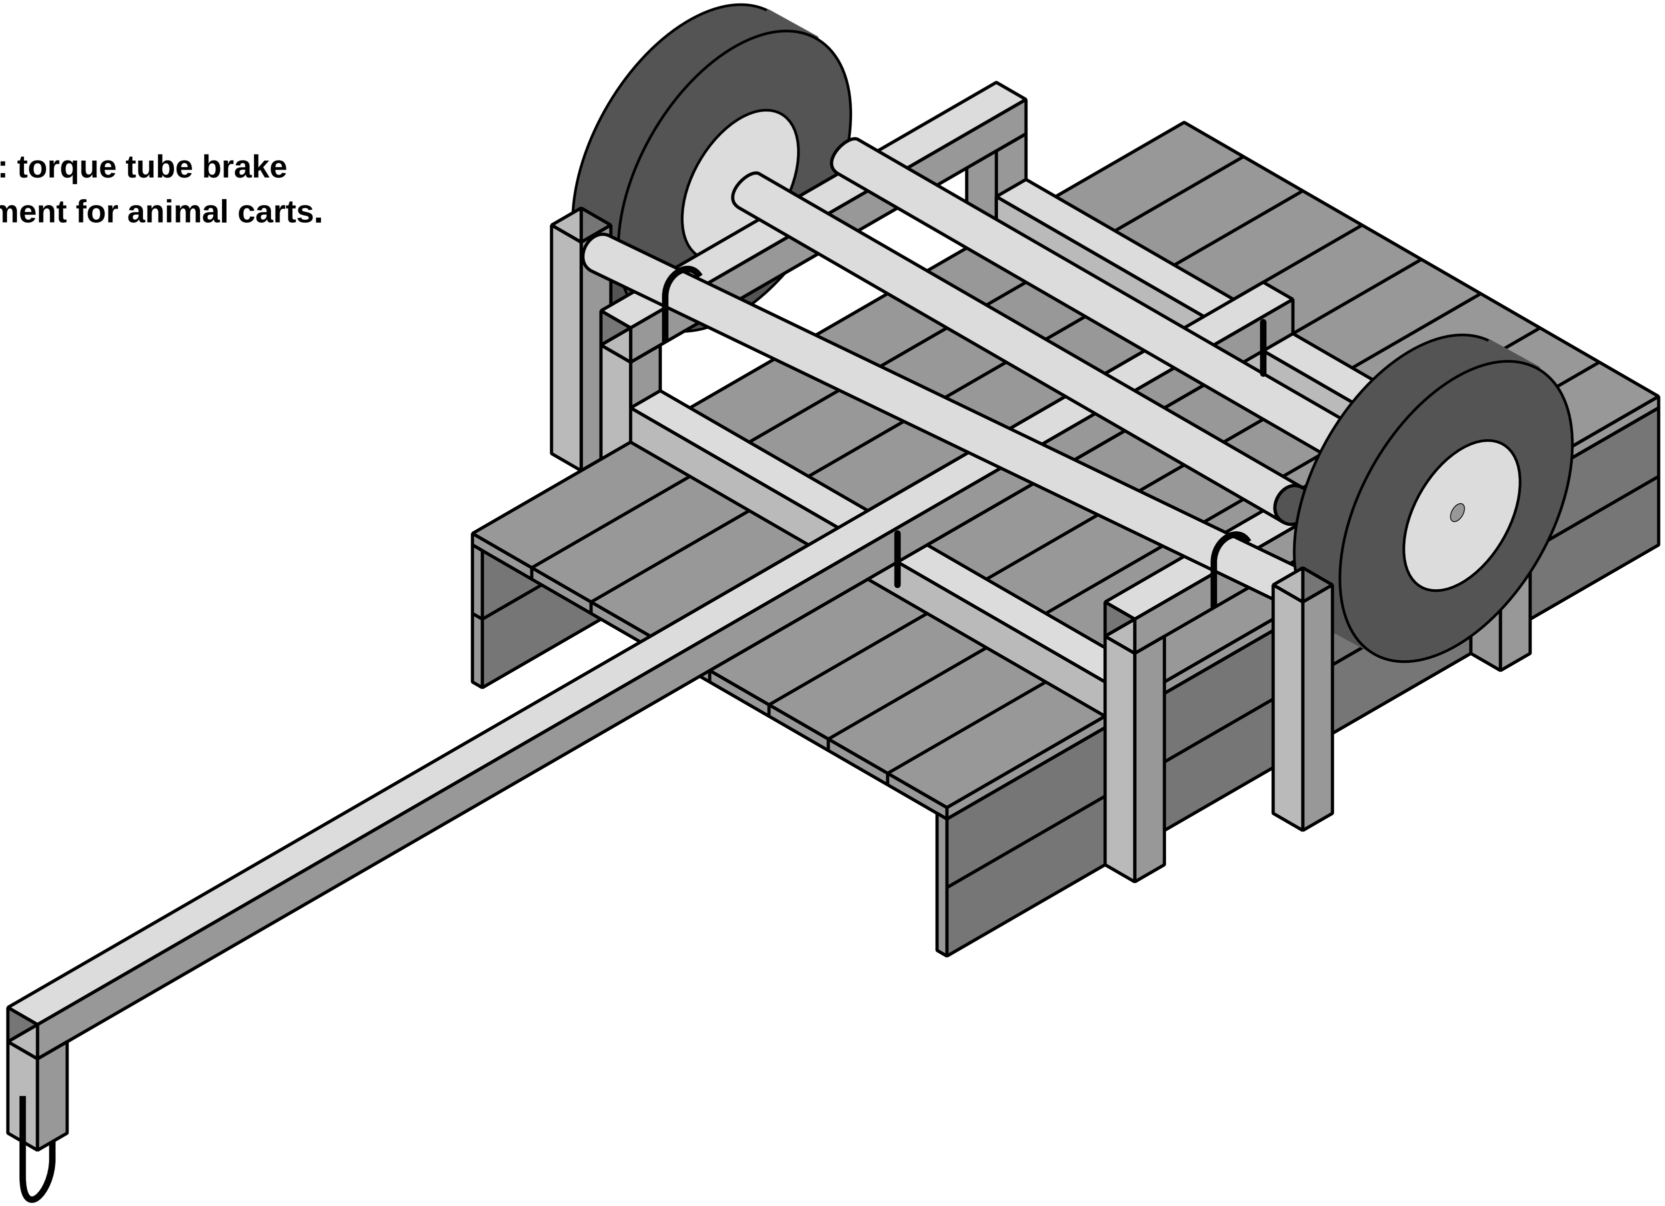
Figure 1: torque tube brake arrangement for animal carts.



Simple low cost torque tube brake for donkey carts.

Introduction

In this booklet we tell you how to make a brake for a steel framed DTU donkey cart from round and square steel tube. The instructions do not cover how to make the cart or the axle - you will need to read other Technical Releases from us to find out how to make these.

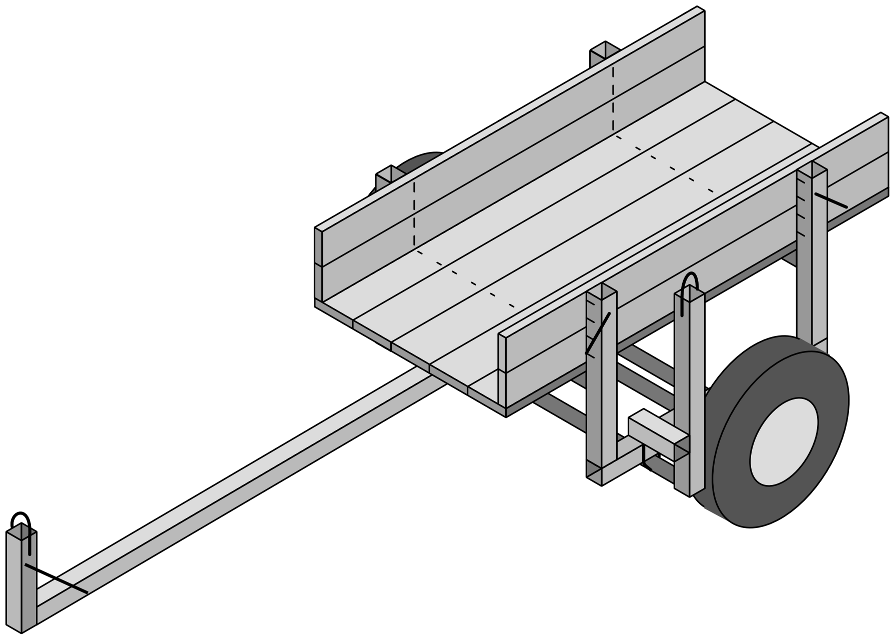


Figure 2: DTU donkey cart fitted with twin axles and simple low-cost brake.

You should find that you can make the brake for about £6. This cost will depend on the cost of the materials and labour. Once you get organised, two men can probably make and fit a brake in an hour.

Easy to make design.

This brake is designed to be constructed without any special tools and jigs, and without any hard-to-get materials. The only tools which you must have are a simple welder, a hacksaw, and a hammer. We have deliberately designed the brake so that drilling is not required.

We have tested these brakes in Kenya and Uganda and we have had only a few criticisms - if the mud is very sticky it jams

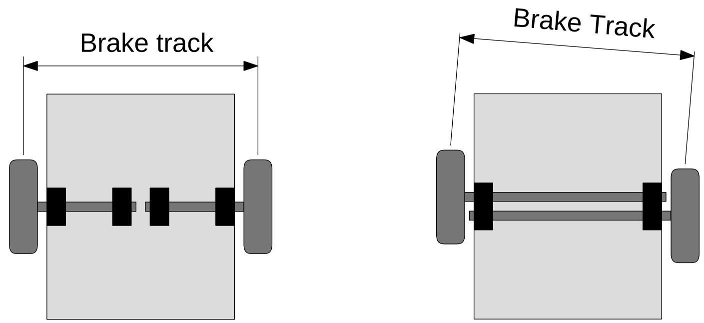

Figure 3: brake track measurement for a conventional half shaft axle and for a twin offset axle.

the brake and makes the cart hard to pull. One modification is to make the brake so it can be removed in bad conditions.

Cutting list and costs

Table 1 shows a cutting list for a brake - Recent prices of materials in Kenya are shown converted into £UK.

Construction step by step

1) The first job, is to get all the material together and clear a space to work. Ideally you will be able to work on a flat area of concrete.

2) Start by measuring the required brake track as shown in Figures 3 and Figure 4.

3) Cut a piece of 1-½" black pipe to this brake track length **minus 50 mm** so for example if the brake track is 1500 mm make the pipe 1450 mm long.

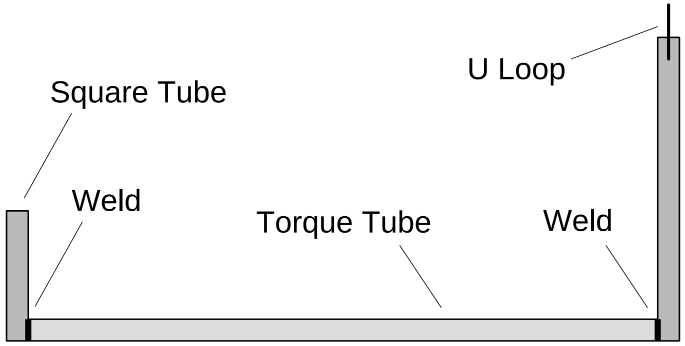

Figure 4: welded brake fabrication.

TABLE 1: materials for torsion tube brake.

component	material	# lengths reqd [#*mm]	total material for one brake [mm]	cost [UK£]
torque tube	1-½"" BSP malleable iron pipe	1 × 1500	1500	3.00
brake pad	50×50 mm square steel tube	1 × 300	300	0.69
brake lever/ pad	50×50 mm square steel tube	1 × 700	700	1.62
brake torque tube loops	R 12 = 12 mm re-bar	4 × 250	1000	0.31
			TOTAL =	5.62

4) Cut a piece of 50 mm × 50 mm × 3 mm wall thickness square tube 300 mm long and another about 700 mm long.

5) Weld the pieces of square tube onto the ends of the round pipe as shown in Figure 5. A trysquare will help you get it square.

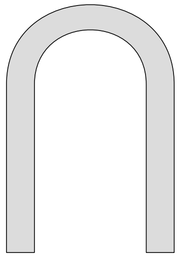

Figure 6: U loop.

6) Make five U shapes from R12 (that is 12 mm round steel bar) each piece 250 mm long as shown in Figure 6.

7) Weld the first U loop onto the end of the 700 mm square tube as shown in Figure 5. A rope tied to this loop can be used to work the brake remotely fo safety.

8) Now turn the cart upside down, put the brake in position and place the remaining four U-loops over the brake torque tube as shown in Figure 7 and Figure 8.

9) Once you have the brake beam in position, tack weld the ends of the loops to the axle support beam, check that the brake can be released clear of the tyres and then weld the loops on properly.

10) Next cut two pieces of R 12 about 25 mm long and weld them to the brake torque tube either side of a support loop so that the brake beam cannot move endwise.

11) You've finished it!

Other DTU cart developments

The DTU has been working on new designs of carts and all their components to bring down their costs and make things more locally manufacturable. It has designs for bodies, wheels, hubs, bearings and animal harness all available from DTU as Technical Releases.

Drawings

You will find two drawings on the next pages, the first gives a general view of the brake and the second gives a view of the components of the brake itself.

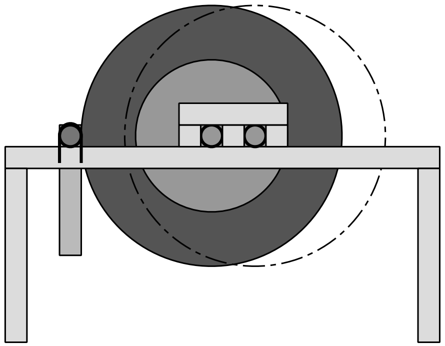

Figure 7: brake beam position.

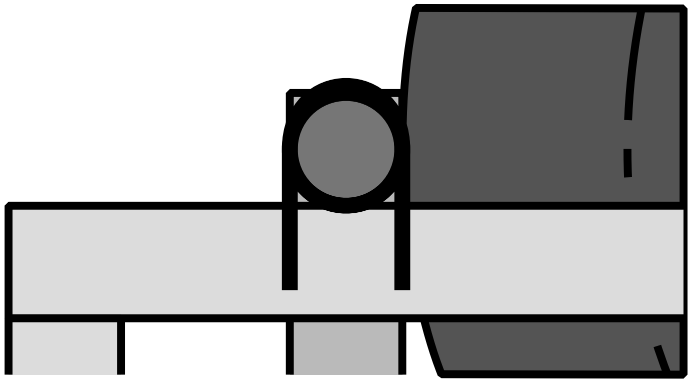

Figure 8: brake beam position - detail.

RELEASE

Steel Wire Rim Wheel for Donkey Carts

Development Technology Unit, Department of Engineering, University of Warwick, Coventry, CV4 7AL UK, tel: +44 (0)203 523523 extn 2339, fax: +44 (0)203 418922, email: esceo@eng.warwick.ac.uk

KENDAT, PO Box 61441, Nairobi, Kenya, tel/fax: +254 2 766939, email: kendat@africaonline.co.ke

Figure 1: wire rim wheel for animal carts.

Steel Wire Rim Wheel for Donkey Carts.

Introduction

In this booklet we tell you how to make steel wire or bar rim wheels for donkey carts. The instructions do not cover how to make the cart or the axle - you will need to read other Technical Releases from us to find out how to make these.

The advantages of this type of wheel are that it cannot be punctured and that it is quite easy to make.

You should find that you can make a wheel for about £12. This cost will depend on the cost of the materials and labour. Once you get organised, two men can probably make a pair of wheels in half a day.

Easy to make design.

This wheel is designed to be constructed without any special tools and jigs, and without any hard-to-get materials. The only tools which you must have are a simple welder, a hacksaw, and a hammer.

Unfortunately we have only tested one of these wheels in Kenya and Uganda but we had no problems. A good modification is to cut the tread from an old tyre and bolt it to the outside of the wheel. Then it is quiet on tarmac roads.

Cutting list and costs

Table 1 shows a cutting list for a wheel - recent prices of materials in Kenya are shown converted into £UK.

Construction step by step

1) The first job, is to get all the material together and clear a space to work. Ideally you will be able to work on a flat area of concrete.

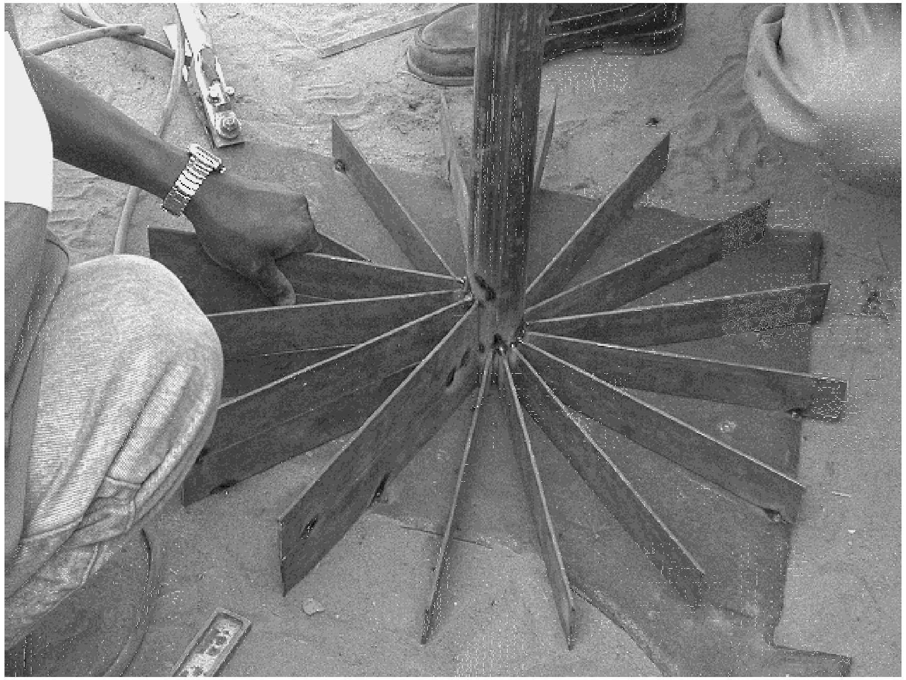

Figure 2: welding spokes to axle.

2) Start by cutting the 16 spokes each of which needs two pieces of flat bar. If you want to make the wheel an exact size subtract the axle radius and the wire diameter from the required radius for example if you want the diameter to be 600 mm ie a redius of 300 mm and the axle is 50 mm diameter and the wire is 10 mm diameter then the spokes should be 300 – 25 – 10 = 265 mm.

3) Next cut the axles from 1-½" black pipe. These will probably need to be about 1500 mm long.

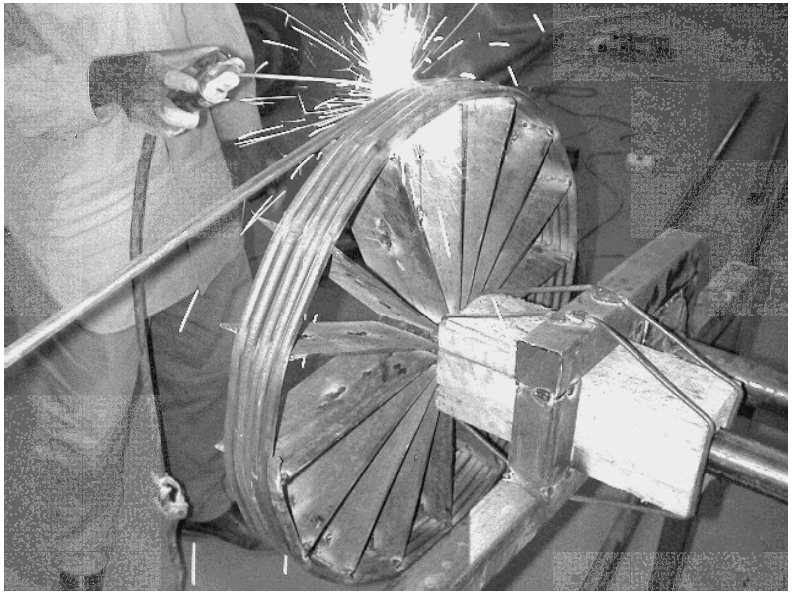

Figure 3: welding steel wire rim wheel for donkey carts. Also shown is wooden bearing.

4) Using a trysquare or a piece of wood or metal to check that the spokes are square to the axle weld the spokes evenly around one end of the axle as shown in Figure 5. Weld one on, then the opposite one, then one at rigth angles to the others, then the one opposite it and so on.

5) Then mount the axle horizontally as shown in Figure 3 so that it can rotate. Straighten the round bar out and then bend about 500 mm of one end so that it fits around the wheel spokes neatly. Weld the end of the wire to the end of a spoke so that it is flush with the outside of the spokes. Weld the wire to the next spoke keeping it flush with the outside of the wheel.

Continue welding the wire to each spoke in turn rotating the wheel as you go. Soon you will start bending the straight part of the wire, but you should find this ok. It is easiest if one person pushes the wire as another welds.

Continue pushing and winding and welding until the wire is the full width of the spokes. You will probably need to start a second length of wire to finish the wheel. Just weld it onto

RELEASE

Double Donkey Harness for Cart Pulling

Development Technology Unit, Department of Engineering, University of Warwick, Coventry, CV4 7AL UK, tel: +44 (0)1203 523523 extn 2339, fax: +44 (0)1203 418922, email: dtu@eng.eng.warwick.ac.uk

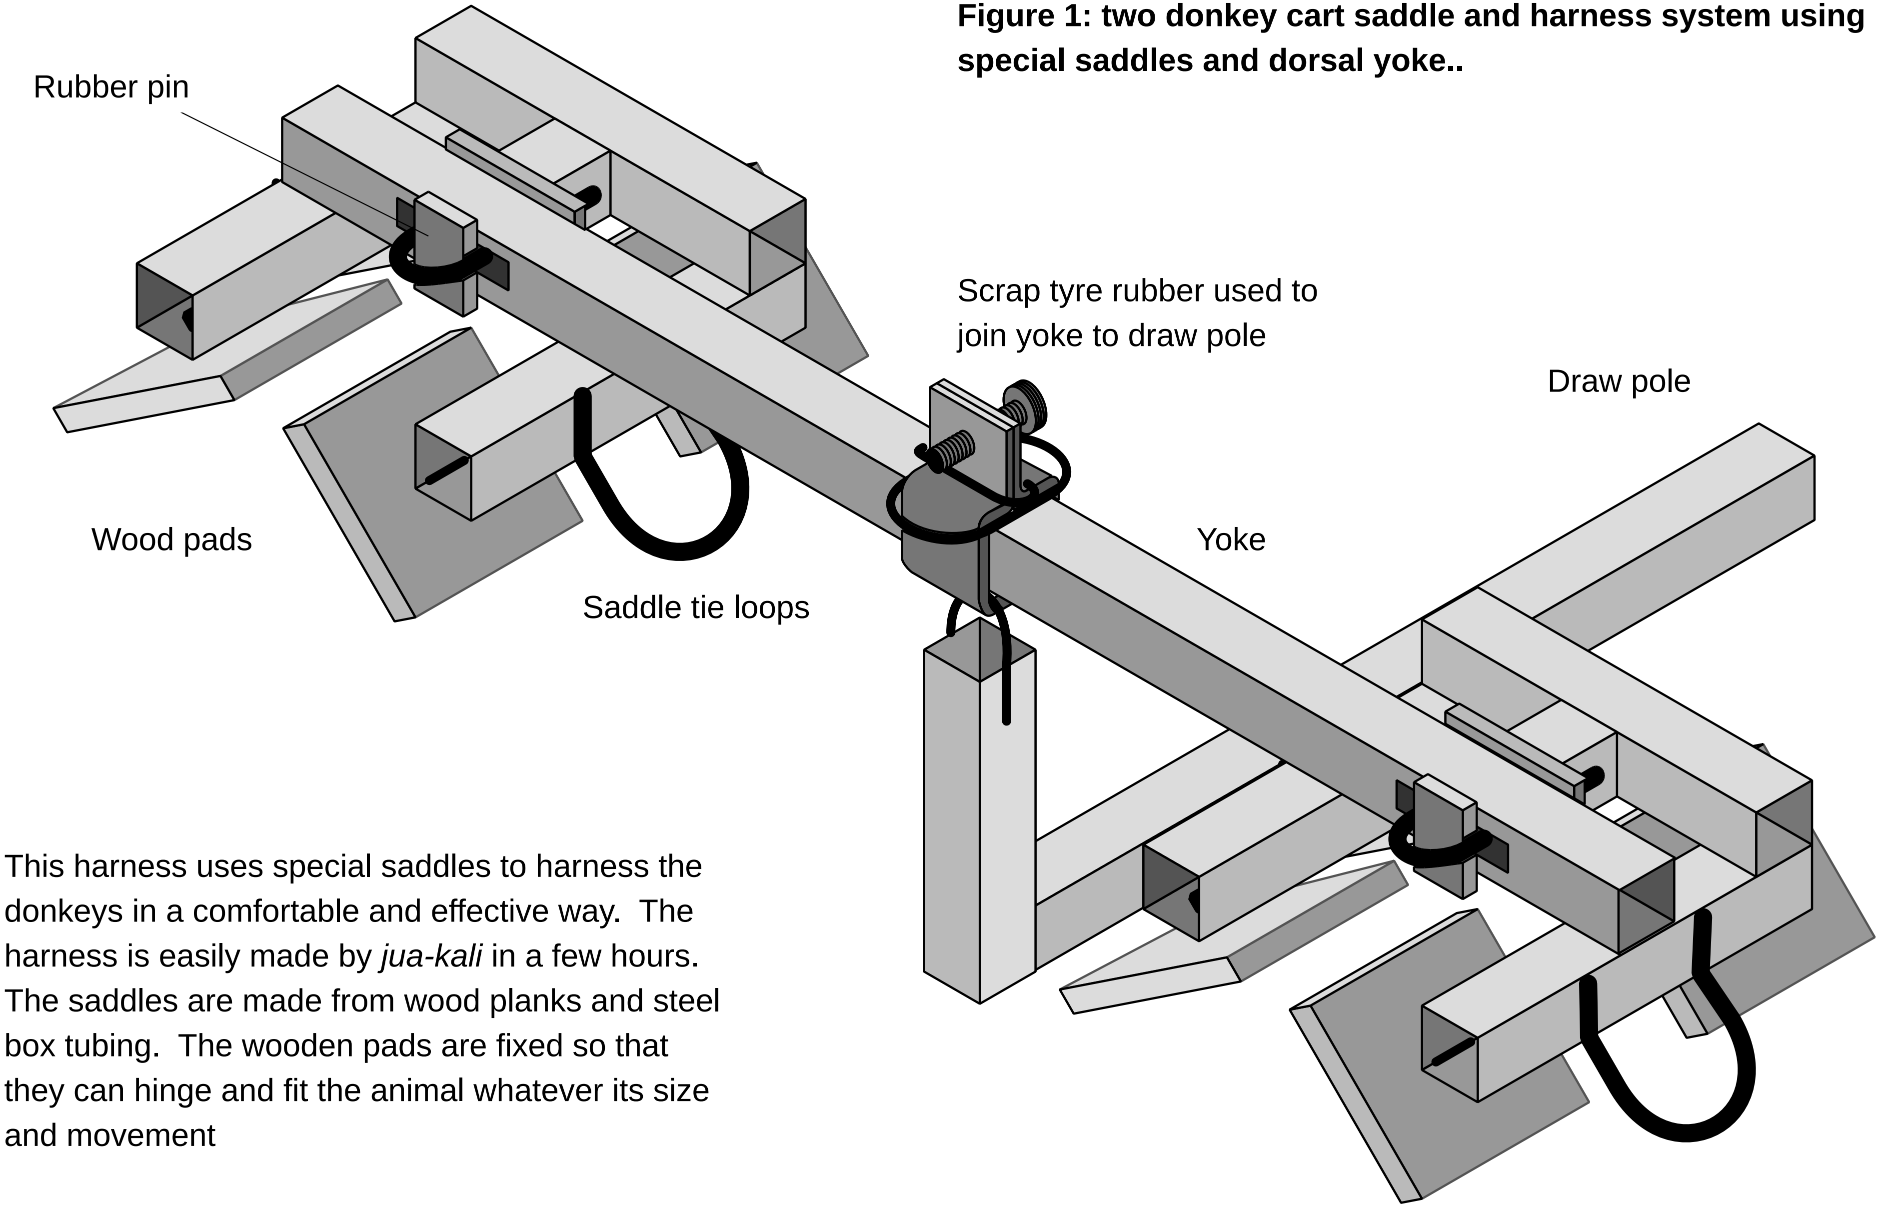
Figure 1: two donkey cart saddle and harness system using special saddles and dorsal yoke..



This harness uses special saddles to harness the donkeys in a comfortable and effective way. The harness is easily made by *jua-kali* in a few hours. The saddles are made from wood planks and steel box tubing. The wooden pads are fixed so that they can hinge and fit the animal whatever its size and movement

Donkey Harness for Carts Made From Steel Box Tubing, Timber and Canvas/ Sacking

Introduction

This Technical release tells you how to make a saddle and harness system for two donkeys to pull a cart with a single draw pole. Another Technical Release tells you how to make a saddle for single animal use.

You should find that you can make the whole harness for two donkeys for less than £$_{UK}$15, depending on the cost of the materials and labour. Once you get organised, two men can probably make a complete set of harness in four hours - we have designed this harness to be easy to make.

Other booklets in this series tell you how to make simple low-cost axles and carts: we have designs for steel framed and wooden framed carts and for many different kinds of axle. All carts and axles can be made without special tools - even drilling metal is not required.

Idea Behind Design

Saddles are used in many countries to hitch animals to carts. Our saddles provide strong points on the animals' backs and a yoke can easily be fixed to them to carry the end of the cart

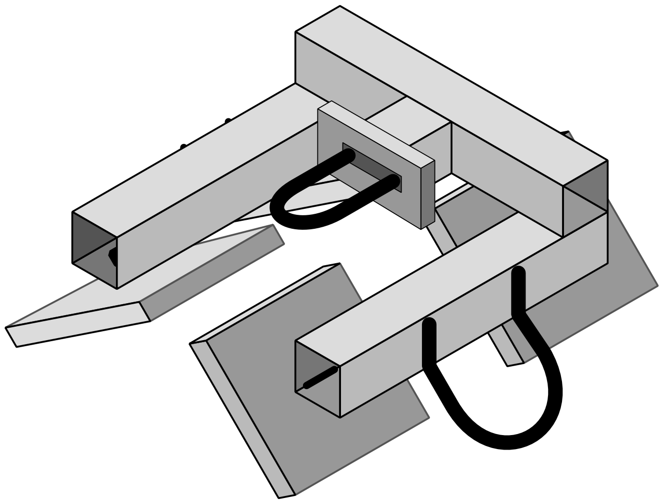


Figure 2: single donkey saddle.

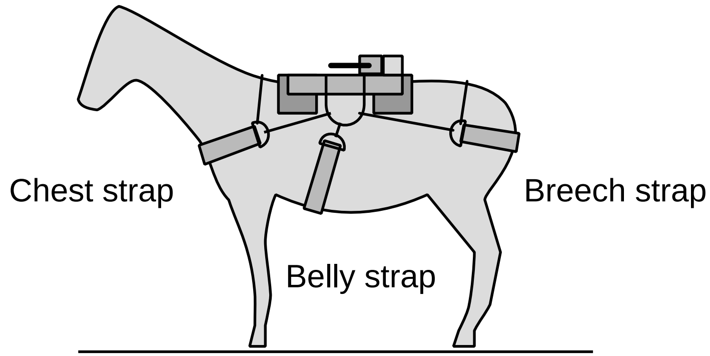

Figure 3: saddle secured to donkey with straps.

draw pole. Using this harnessing method carts can be pulled, steered and braked, and stabilised if the load is too far back on the cart body. This harness allows animals of different sizes to be used together and does not need them to walk exactly side by side. We have even had donkeys jump over a hedge pulling a cart with this harness!

Special tools and jigs and hard-to-get materials are not required. The only tools which you must have are a simple welder, a woodsaw, a hacksaw and a hammer.

The saddle frame is welded and the wooden pads are fixed to the frames with nails which are put through holes in the steel frame and welded so that they are loose and allow the pads to follow the shape of the animal.

These saddles have been tested in Kenya and work well but we would like to test them more. Really we need to test them for a year or two to see how the animals react.

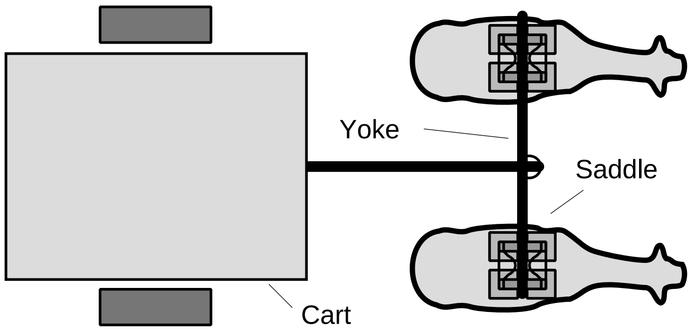

Figure 4: two donkeys harnessed to cart.

Cutting list and costs

Table 1 shows a cutting list for a complete harness - recent prices of materials in Kenya are shown converted into $£_{UK}$.

TABLE 1: harness materials cutting list.

component	material	# components	total mat [mm]	mat cost [$£_{UK}$]
main frames	50×50 box tubing	2×3×300	1800.00	2.11

yoke/ cart attach strap	scrap tyre rubber	1×70×400	400.00	0.50
			TOTAL =	**11.79**

Construction step by step

1) The first job, is to get all the material together and clear a space to work. Ideally you will be able to work on a flat area of concrete.

2) Make up the U-shaped frame as shown in Figure 5. If you have a G clamp you can use it to hold two pieces of the frame together during welding.

3) Then weld the tie loops and the yoke attachment stub and loop onto the U frames so that the frame looks as shown in Figure 6.

4) Next cut the wooden load pads and round off all the edges so that there are no sharp corners to stick into the donkey. Hammer two nails through each of the pads in the positions shown in the drawings. With some timbers you may need to drill holes for the nails to avoid splitting or burn the holes with a hot nail. Then cut the nails so that about 30 mm projects from the timber as shown in Figure 9.

5) Now mark the position of the holes required to accommodate the pad nails in the steel tubing. These holes should be 15 mm and 65 mm from the ends of the square tube as shown in Figure 7. Blow the holes through with the welder at maximum current setting or use an angle grinder or file or hacksaw.

6) Next you can weld on the pad pivots blocks as shown in

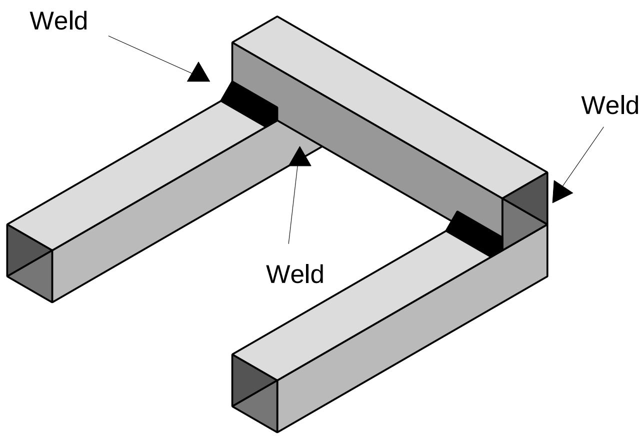

Figure 5: welding of frame cross piece.

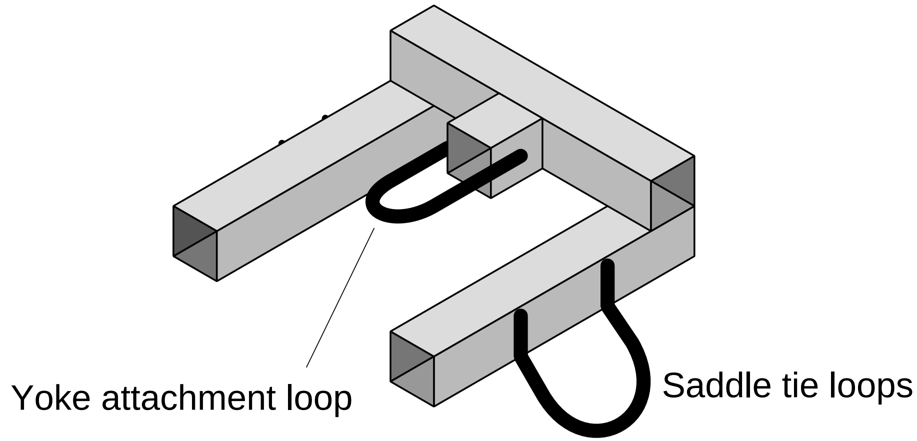

Figure 6: links and yoke loop welded to U- frame.

Figure 7.

7) Now put the nails through the blown holes and weld a piece of nail across the ends of the nails as shown in Figure 10. Welding down inside the tube looks difficult but skilled workers can weld the pads in about one minute.

An alternative way of doing it is to cut slots 70 mm long along the corners where the holes would be as shown in Figure 8. The slots should be 8 mm wide so that the nails are very loose in them. Make up the pads as shown in Figure 9, put the nail loop into the slot in the right place and weld the pad pivot blocks into place across the slot so that they are in the same place as in Figure 7.

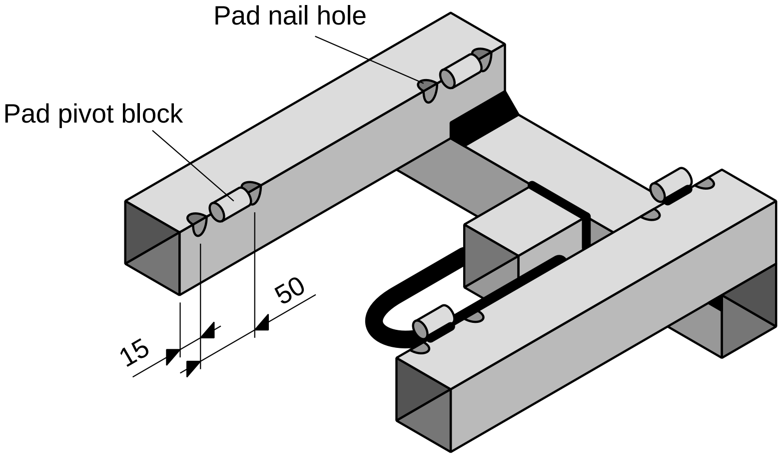

Figure 7: pad nail hole positions and pad pivots.

8) Next you need to make up the six straps to hold the saddles onto the donkeys. The D rings at the end of the straps can be made from 6 mm diameter concrete reinforcing bar as shown in Figure 11. A separate piece of the re-bar is clenched over the strapping using hammer blows to fix the D rings to the ends of the straps as shown.

The straps themselves can be made from heavy canvas or hessian sacking. You should use three or four thicknesses of material for them to make them strong enough and soft enough not to hurt the donkey.

9) Make the strap chain hooks from more 6 mm re-bar as shown in Figure 12 and fit the fixed ends to the saddle tie loops.

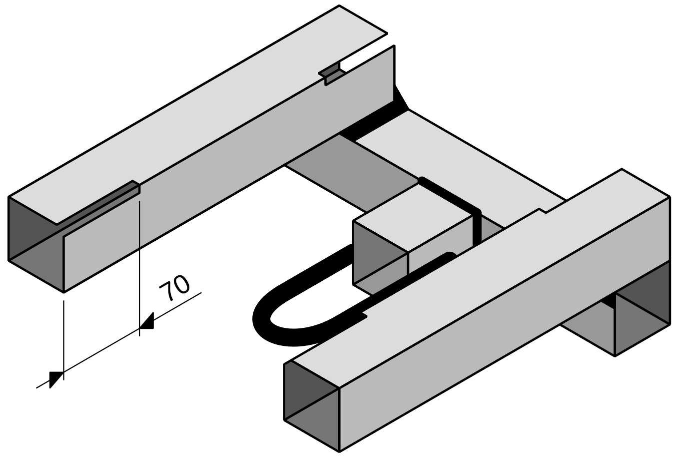

Figure 8: pad nail slots.

10) Cut the yoke to length. You can make the yoke different lengths but we have found that a longer yoke helps the animals turn in a narrow track. Make the slots in the ends with a grinder and welder and file. Weld the central tie loop shown in the drawings.

11) Cut two rubber yoke fixing pins and the buffer pads to the shape shown in the drawings.

12) Cut another piece of scrap tyre rubber about 400 mm long and 70 mm wide. Make a hole about 15 mm diameter about 40 mm from each end. Make a loop of 6 mm diameter steel reinforcing bar about 70 mm long as shown in Figure 14 that will just go over two thicknesses of the rubber strip.

13) Paint and creosote the saddle. You've finished it!

Method of harness use

Harness each animal separately, then fix the yoke to the saddles, then fix the yoke and animals to the cart.

1) First put a blanket or two folded hessian or jute sacks (not plastic) onto each donkey's back to protect them.

   Remember that protecting the donkey will save money because it can work harder if it is comfortable and will not get sick from skin wounds.

2) Put the saddle on so that the fronts of the wood pads are about 100 mm behind the animal's shoulder blades. This

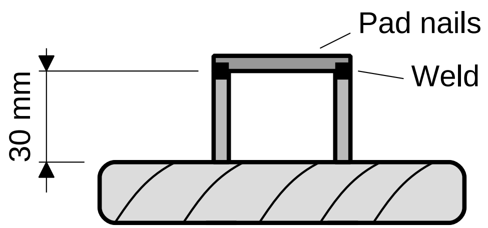

Figure 9: welded pad nails.

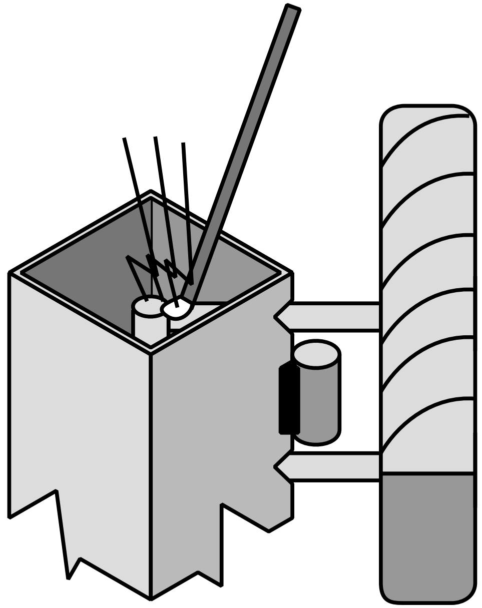

Figure 10: welding re-bar to frames for wooden load pads.

means that the saddle should never come near parts of the animal's back which move.

3) Next hook the breaching strap to the loops hanging from the side of the saddle. It should be tight enough to tend to pull the saddle a little rearwards. Make sure that the breaching strap is pulled up high so that it does not rub the backs of the legs. But it should not be so high that the animal cannot defecate. Tie a piece of thin rope across the animal's back between the rings of the strap to hold the strap up.

4) Now hook the chains for the belly strap onto the hooks fixed to the saddle tie loops. The strap should be 50 mm or 100 mm behind the front legs - check that the legs do not rub on the strap when the animal walks. Tighten the strap so that you can just get a couple of fingers under it between the strap and the animal. This will be much tighter than the other straps.

5) Hook the chest strap to the loop and adjust the tension so that it is a little loose. Use another short piece of rope to hold the chest strap up so that it is just below the wind pipe. The strap goes tight when the animal pulls really hard. We have noticed that the belly strap and breaching strap are nearly enough without the chest strap and so we leave the chest strap a bit loose.

6) Saddle the second animal in the same way. You should be able to saddle an animal in only a few seconds when you

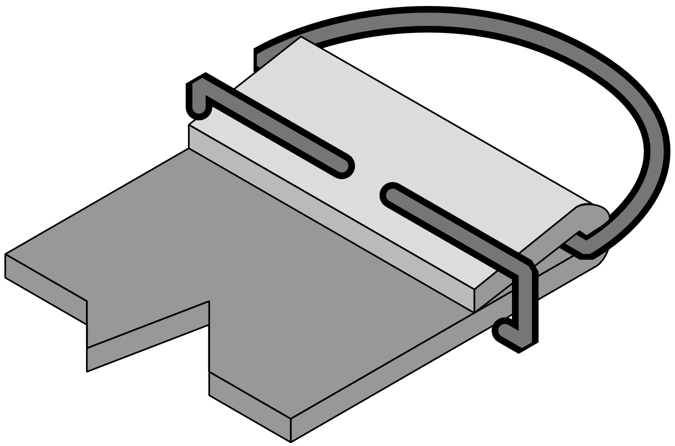

Figure 11: D rings for straps made from re-bar.

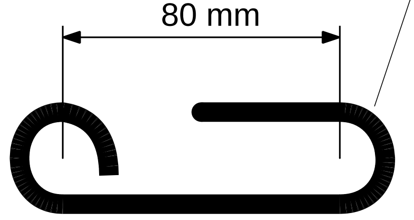

Figure 12: chain hooks for straps.

get practised.

7) Get the two donkeys in position side by side and put the yoke across the two saddles pushing the slots in the yoke over the loops on the saddles as shown in Figure 1. Secure the yoke by pushing the rubber pins into place.

8) Lastly connect the cart to the centre of the yoke using the 400 mm long rubber strap, the 80×15 loop and a bolt as shown in Figure 13.

9) You are ready to go!

Saddle Drawing

You will find drawings of the saddle and yoke on the last pages

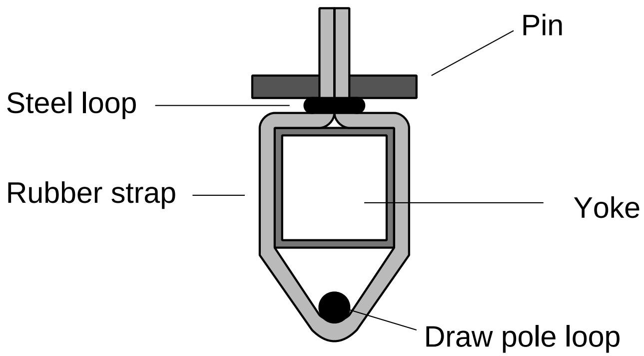

Figure 13: using rubber strap to join cart draw bar loop to yoke.

of this Technical Release.

Other DTU cart developments

The DTU has been working on a range of cart designs for use with both donkeys and oxen. It has designs for wooden and steel framed types. You can make either type of cart in only a few hours, if you are reasonably set up with tools and materials.

The DTU has also been working on new designs of wheels, hubs and bearings to bring down their costs and make things more locally manufacturable. It has a system of axles with bearings made from PVC pipe, another with wooden bearings and a third using scrap ball bearings. None of these axles need machining and they only take two men a day to make.

Novel bearing arrangement for animal carts using scrap (or new) ball-race, running on outside of full width axle. No machining or accurate work required. Bearing may be replaced with different size. Only one bearing per wheel required.

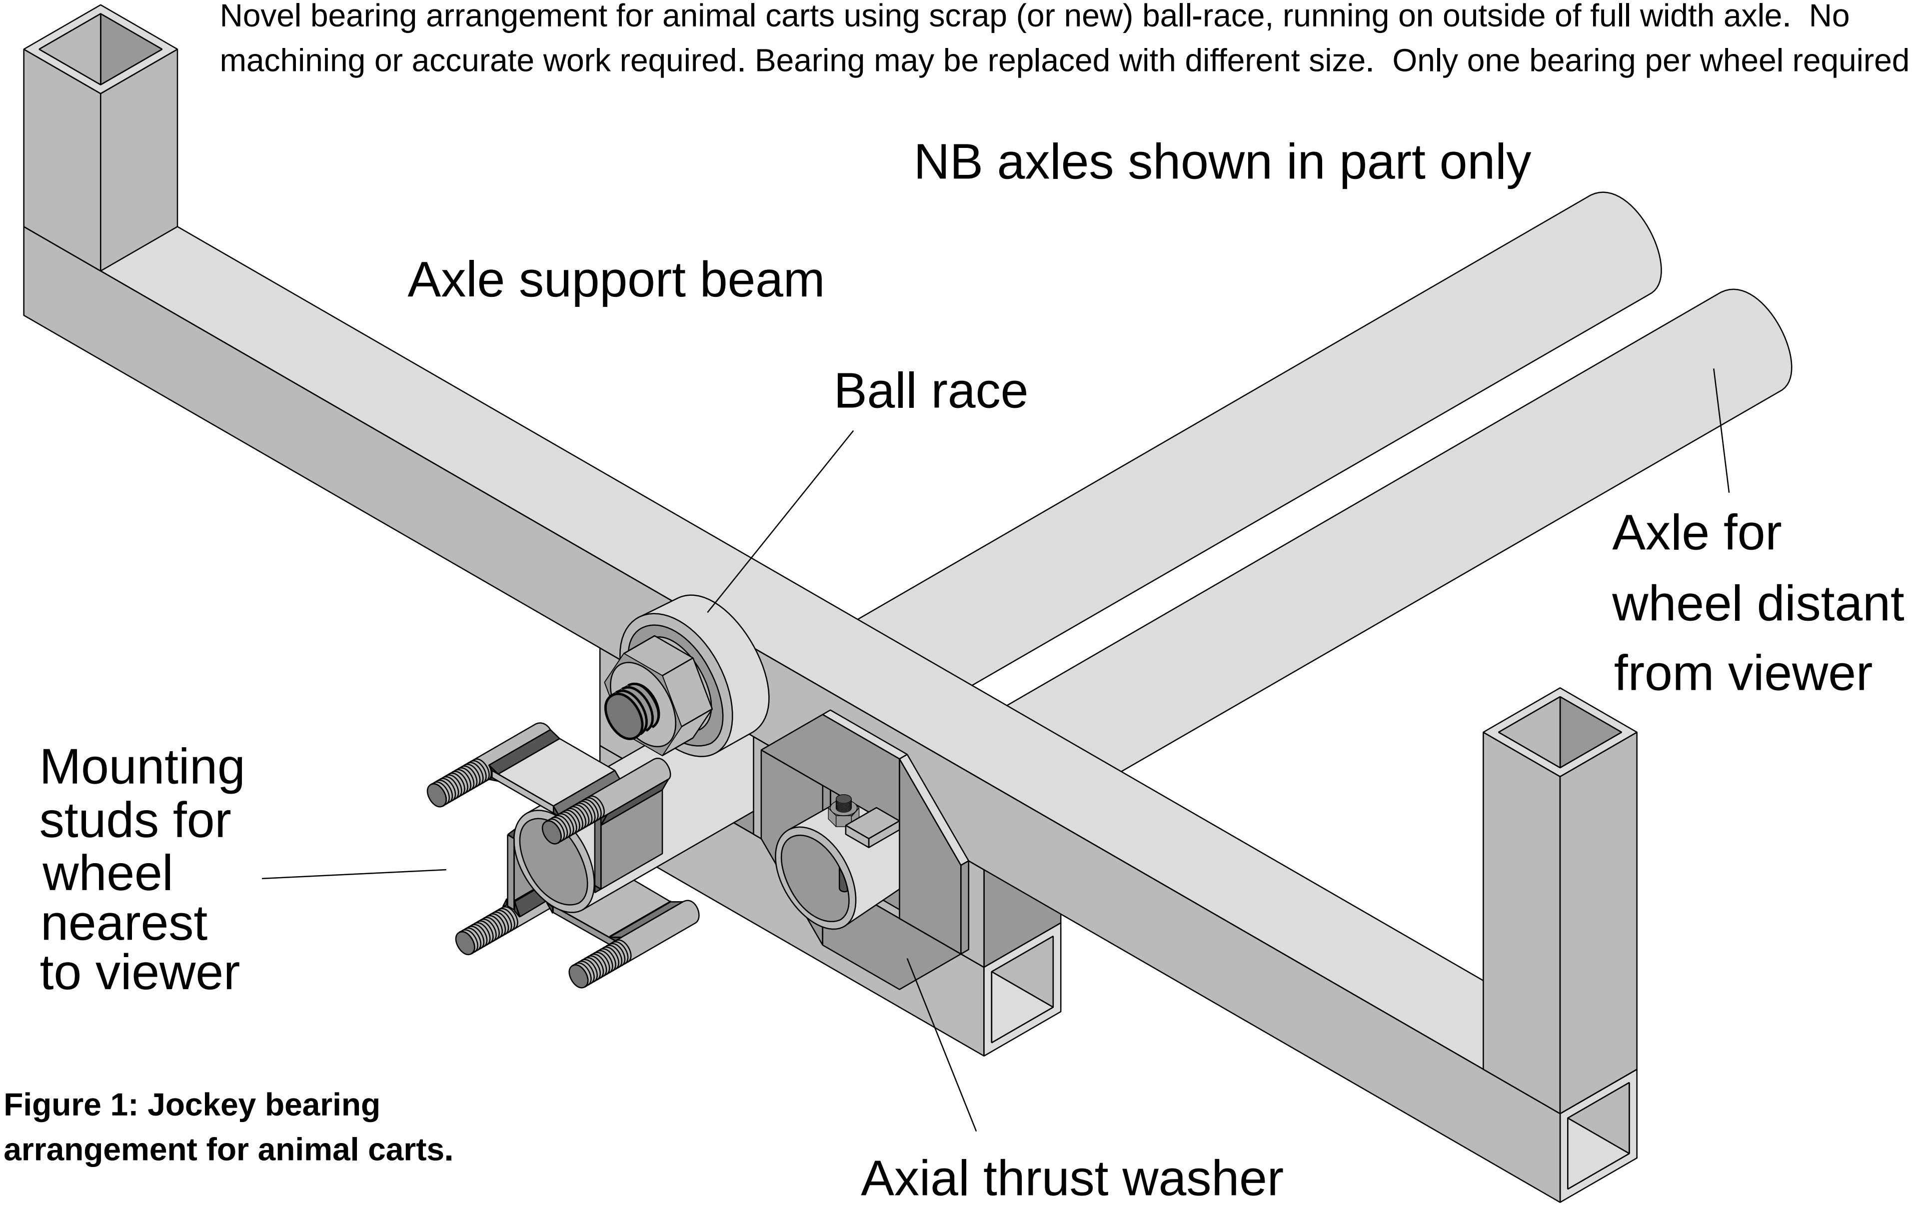

Figure 1: Jockey bearing arrangement for animal carts.

Twin axle system for donkey carts using scrap/ new ball bearings.

Introduction

In this booklet we tell you how to make an axle system for a simple donkey cart from round steel tube and ball bearings. The instructions do not cover how to make the cart itself - you will need to read other Technical Releases from us to find out how to make the carts.

You should find that you can make the axle system for about £40 including the wheels, tubes and tyres. This cost will depend on the cost of the materials and labour. Once you get organised, two men can probably make and fit one cart with axles in half a day. This is quite a lot faster than it takes to find and a scrap car axle and it will be much cheaper.

In other booklets in this series you can find out how to make other low-cost axle systems and carts.

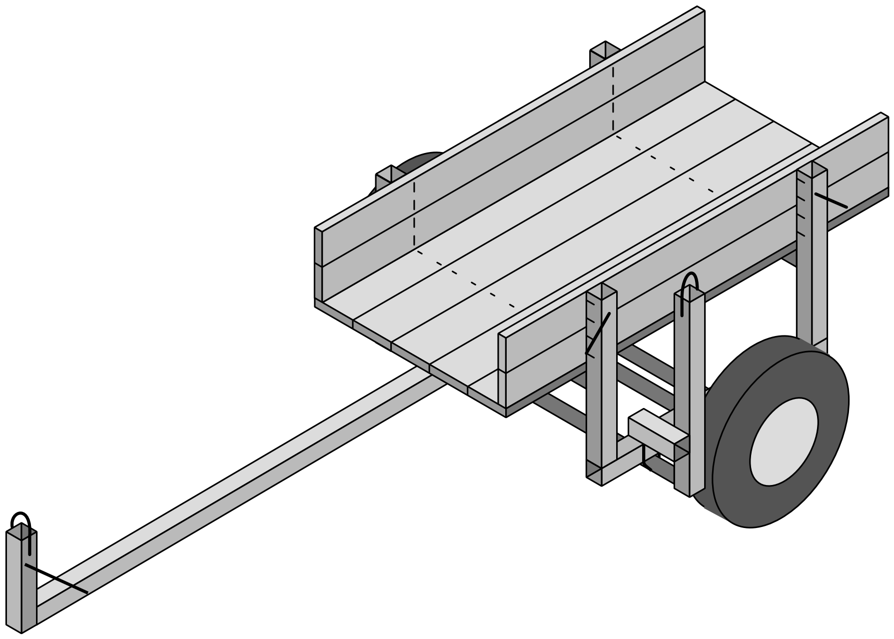

Figure 2: DTU donkey cart fitted with twin axles and PVC bearings.

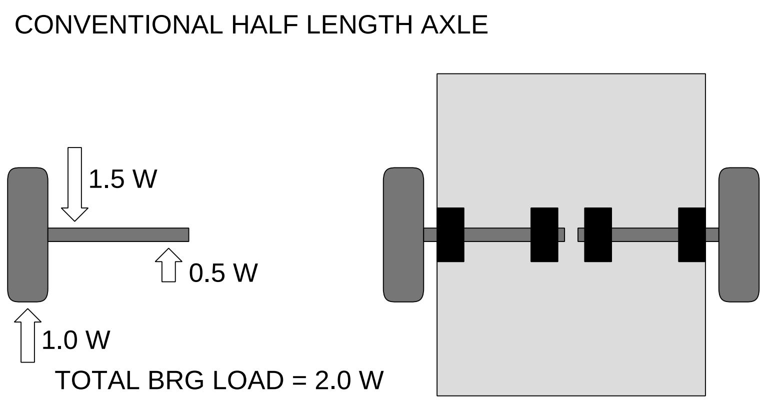

Figure 3: bearing loads in conventional half shaft axle.

Why have twin axles?

There are two types of axle: fixed axles and stub axles. In a stub axle the wheel-hub rotates on a stationary axle. In a live axle arrangement the axle revolves in stationary bearings.

With the stub axle types the bearings must be inside the wheel. This is easy with expensive ball bearings in a machined hub but more difficult to do in a simple workshop. Really you need two ball bearings per wheel as well. You also need to make things quite accurately or make the hubs quite long to stop wheel wobble. Another problem is that the hubs stick out of the wheel and catch on animal and human legs.

If you would really prefer to make a stub axle we have quite a good one using plain bearings made from PVC pipe. This axle also has the advantage that you can take the wheel off without a spanner. We also have a system of making your own roller bearings and we can send you Technical Releases on how to make these axles, but we think the twin axle system here is easier to make and a bit better.

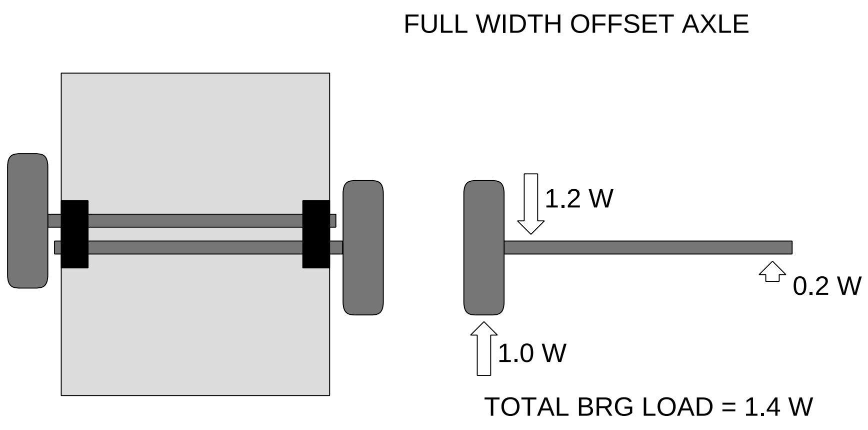

Figure 4: bearing loads in twin offset axles.

Long twin axles reduce bearing loads and require less accurate manufacture. Figure 3 shows the bearing loads of short axles and Figure 4 shows the twin axle method. You will see that bearing loads are about 30% lower. Surprisingly there is no extra steel required either because there would have to be some steel to support the middle bearings anyway.

Easy to make design.

These axles are designed to be constructed without any special tools and jigs, and without any hard-to-get materials. The only tools which you must have are a simple welder, a hacksaw, and

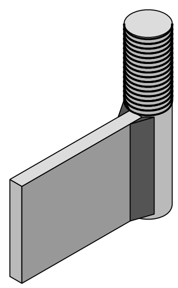

Figure 5: a welded wheel stud and strut fabrication.

a hammer. You might find that a couple of 4" or a 5" G clamps (or something like it) are useful too. We have deliberately designed the axle so that drilling is not required.

We have tested many of these axles in Kenya and Uganda and we have had only a few failures caused by poor welding or incorrect material. We think that they are strong enough, but you can always find someone to break anything. To get a reasonable cost you need to experiment a bit to see how the farmers treat their carts and what they expect them to stand.

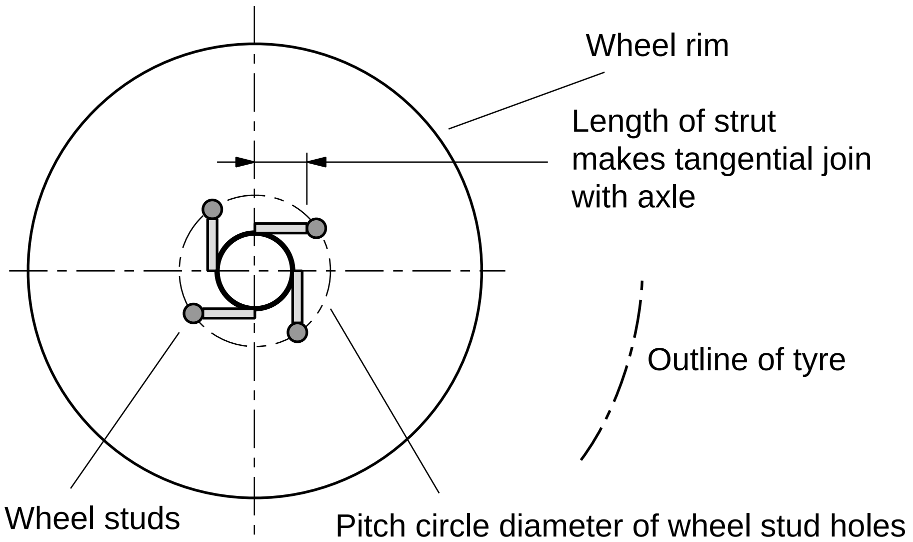

Figure 6: length of wheel strut.

Cutting list and costs

Table 1 shows a cutting list for a complete axle - Recent prices of materials in Kenya are shown converted into £UK.

Construction step by step

1) The first job, is to get all the material together and clear a space to work. Ideally you will be able to work on a flat area of concrete.

2) Start by getting the two ball bearings you want to use and cleaning them. If they have rubber or steel shields it is probably best to leave the shields in place, but if they are open clean the bearings in petrol or diesel fuel or kerosine. Then re-grease them.

TABLE 1: materials for ball bearing twin axle.

component	material	# lengths reqd [#*mm]	total material for one axle [mm]	cost [UK£]
wheel studs	50×M12 nuts and bolts	10	10	2.60
wheel stud struts	6×40 BMS strip	10 × 37	650	0.49
axial thrust washers	6×40 BMS strip	8 × 90	720	0.54
axle cross bolts	75×M12 nuts and bolts	4	4	1.04
axles	1-½" BSP malleable iron pipe	2 × 1500	3000	6.00
axle reinforcements	1-½" BSP malleable iron pipe	2 × 30	60	0.12
main bearing	scrap ball race eg 6205, 6206	2 off reqd	2	5.00
ball bearing mounting bolts	M24×50 or similar	2 off reqd	2	2.00
bearing box sides	50×50×3 mm square steel tube	6 × 53	318	0.73
bearing box top	50×50×3 mm square steel tube	2 × 252	504	1.16
wheel rims, tyres + tubes	na	2	2	25.00
			TOTAL	**44.69**

3) Now you need to get a large nut and bolt for each bearing. Ideally the bolt should just go through the middle of the bearing, but it can be quite loose as long as the bearing can be held very tightly when the nut is tightened.

If you cannot get a nut and bolt you can use a piece of pipe and a welded ring.

4) Next make the wheel stud struts shown in Figure 5. You need to make one of these struts for every stud hole in the wheels you are going to use. Figure 6 shows how to measure the length of the struts. The struts are made from 6×40 flat bar or similar and M12 bolts 50mm or 60mm long. The flat bar should be long enough so that it meets the axle tube tangentially as shown in Figure 6.

5) Once you have made these struts, screw a nut onto each one until it touches the 40×6 metal. Then put the thread through the hole in the rim and screw another nut onto the thread. Tighten this nut lightly with a spanner. Repeat for all the struts so that they all point the same way round the axle, as in Figure 6, and leave a gap for the axle.

6) Now centre the axle in the rim and get it square using a tape measure, a trysquare and a plank or piece of steel resting on the tyre.

Put the wheel rim on the floor and put the axle in place in the middle. You should put something under the end of the pipe to get it in the right position as shown in Figure 7. Get an assistant to hold the top end of the pipe and tell him to

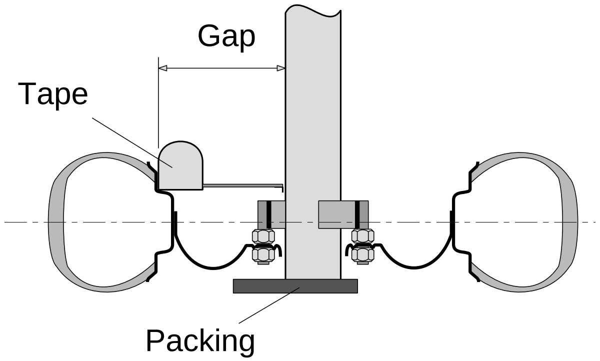

Figure 7: using tape measure to centre axle in wheel.

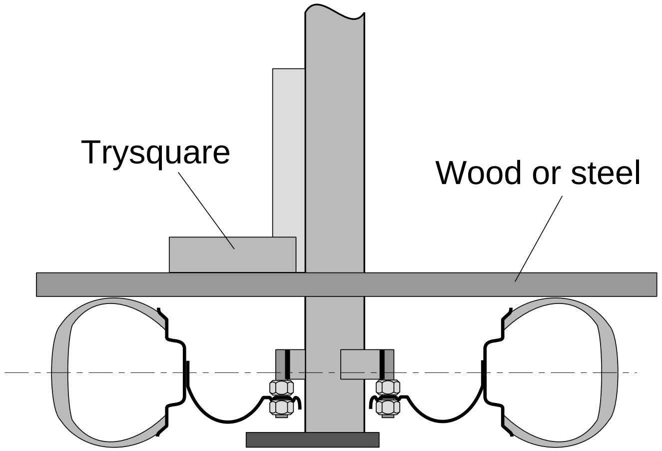

Figure 8: using trysquare to get axle square to wheel.

keep very still! Use your tape to measure from the outside of the pipe to the inside of the rim as Figure 7 shows. Measure in one place and then measure the gap opposite. Move the axle pipe over until it is central. Repeat this for the other direction at right angles. You could use wooden wedges as shown in Figure 9 to hold it.

Now use the trysquare and a piece of wood to get the axle square to the rim as shown in Figure 8. You put the wood on the tyre or rim so that it is flat and you put the trysquare on the wood. You have to move the axle until it is straight with the trysquare and your assistant must hold it without moving. Check it several times - its hard to correct afterwards!

7) Once you have it in position, tack weld the ends of the struts to the axle tube as shown in Figure 9. Then weld the struts on properly. Do as much welding as you can without taking the axle out of the wheel because the metal changes size as it heats and cools and it may move out of place.

8) Next cut six 53 mm pieces of square tubing for the bearing boxes. Mark the centre of the axle support beam of the cart and put marks on the beam 25 mm and 125 mm either side of this. You need to weld the 53 mm pieces on to the axle beams as shown in Figure 10. Weld a 252 mm piece of

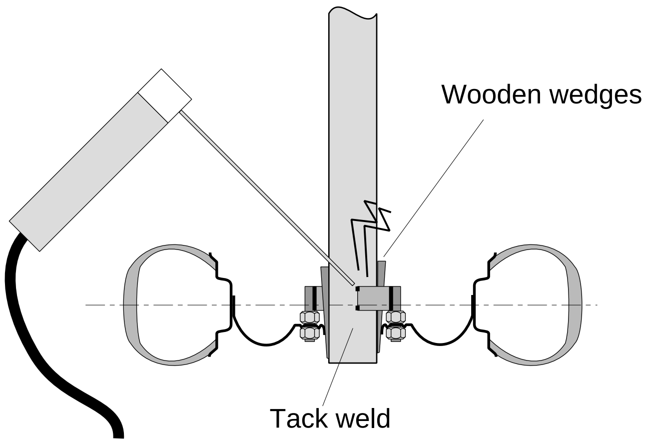

Figure 9: tyre, wheel and axle tube during tack welding stud support struts

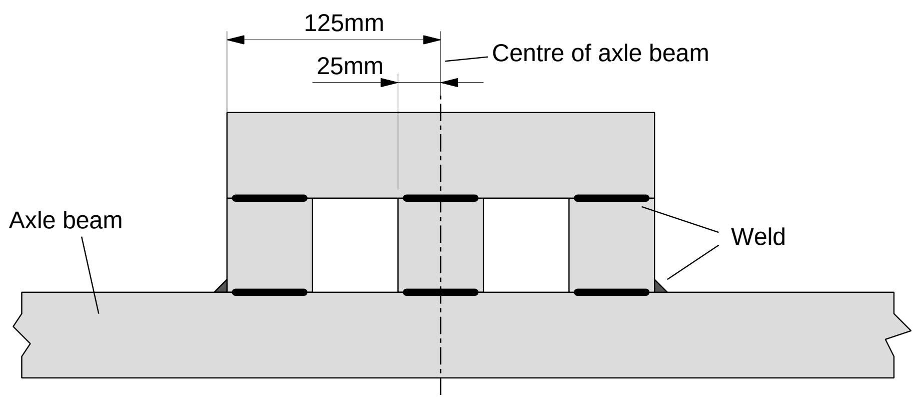

Figure 10: position of bearing support blocks - nb the cart is upside down here.

square tubing across the ends of the 53 mm pieces as shown in Figure 10.

9) Make four axial thrust washers from 40×6 or 40×3 or similar flat bar like those shown in Figure 12. You must remember to weld on a tag made of a 20 mm length of bar to each ring as shown in the drawings. This makes the washers go round with the axle and stops wear in the wrong places.

10) Assemble the axles and thrust washers as shown in Figure 13 but without the crossbolts. Put the wheels onto the axles, lightly tighten the nuts and position the axles so that there are 50 mm gaps between the tyres and the axle beams.

11) Now mark the position of the cross bolt holes. Remember that the nuts will have to be turned so do not make the holes too close to the thrust washers - centre about 15 mm away is fine. Use the welder to blow the holes.

12) Cut the excess axle off about 40 mm from the thrust washer. To mark a line around the pipe to cut it square, wrap a strong piece of paper or thin card around the pipe, get the edge in line and use the edge to guide the felt tip pen or scriber as you mark the line.

13) Mark the place on each axle where the bearing will roll. Cut 30 mm pieces of pipe, slit them so they can be opened and placed on the outside of the axles and weld them in place where you have marked.

14) Now assemble the ball bearings on their bolts and lightly tighten the nut. Position each bearing under the middle of the axle as shown in Figure 11 so that the axle is held 2 or 3 mm away from the axle beam as in General Assembly 1. Then tack or 'spot' weld the ball bearing bolt to the axle beam. Remove the bearings from their bolts and weld fully.

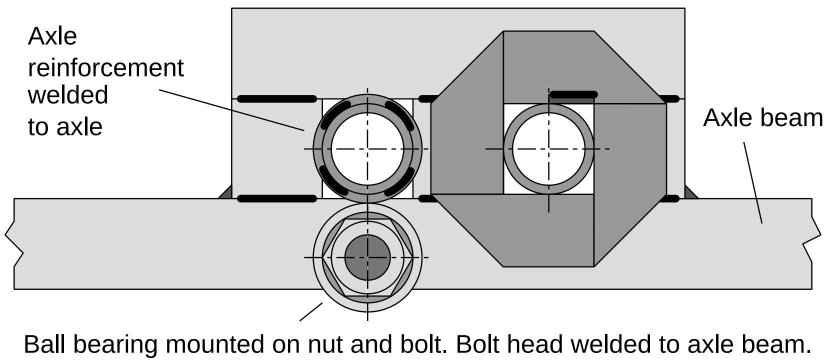

Figure 11: ball bearing mounting and axial bearing washer.

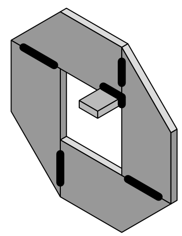

Figure 12: axial bearing washer.

15) Apply grease to the axles where they rub on the axle beams, replace the bearings on their bolts and tighten the nuts, fit the thrust washers and crossbolts and tighten.

16) You've finished it!

Other DTU cart developments

The DTU has been working on new designs of wheels, hubs and bearings to bring down their costs and make things more locally manufacturable. It has designs for twin axles with wooden bearings and twin axles with bearings made from PVC water pipe. And it has two systems of fixed axle: one with PVC bearings and another using needle roller bearings which you can make yourself. No machining is necessary for any of these axles.

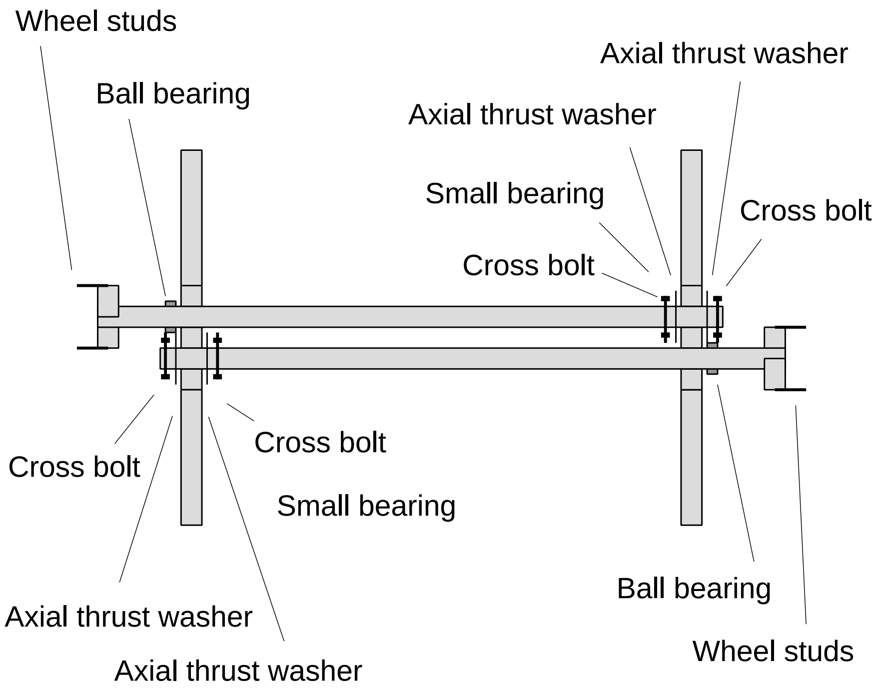

Figure 13: axle and bearing arrangement.

Other hub designs using, for example aluminium castings, have been in production in Nigeria and we are trying to reduce or eliminate the machining in these. Also wheel designs in steel sheet, cast aluminium and timber are under development. We have a design for solid steel rim wheels in which the rim is made from round bar and does not need any hammering.

The DTU has also been working on a range of cart body types for use with both donkeys and oxen. It has designs for wooden and steel framed types. The wooden types are cheaper in material terms, but the steel framed ones are easier to make because the joints are more straightforward - nevertheless you can make either type of cart in only one or two days, if you are reasonably set up with tools and materials.

Drawings

You will find four drawings on the next pages, the first two give a general section view of the axle. The third gives a view of the components of the axle itself and the fourth a drawing of the thrust washer.

Figure 1: woo
wheel for anin
using old rubl
and timber.

Wooden Flexwheel for Donkey Carts.

Introduction

In this booklet we tell you how to make wooden wheels with scrap rubber tyre rims for donkey carts. The idea for these wheels comes from TDAU and Kasisi Mission in Zambia. This type of wheel cannot be punctured and it is quite easy to make. Unfortunately although the wheel itself is made without steel, the fixing to the axle does need welding.

The instructions here do not cover how to make the cart or the axle - you will need to read other Technical Releases from us to find out how to make these.

You should find that you can make a pair of wheels including the bare steel axle pipe for about £30. This cost will depend on the cost of the materials and labour. Once you get organised, two men can probably make a pair of wheels in two days.

Easy to make design.

This wheel is designed to be constructed without any special tools and jigs, and without any hard-to-get materials. The only tools which you must have are a simple welder, a woodsaw, a hacksaw, and a hammer.

Unfortunately we have only tested one of these wheels in Kenya and Uganda but we had no problems.

Cutting list and costs

Table 1 shows a cutting list for a wheel - recent prices of materials in Kenya are shown converted into £UK.

Construction step by step

1) The first job, is to get all the material together and clear a space to work. Ideally you will be able to work on a flat area of concrete.

2) Start by cutting the tyre into two pieces around the centre of the tread. You will not be able to cut a tyre with a steel cord in the tread so avoid the steel type.

3) Measure the diameter of the tyre rim hole accurately. This is likely to be about 325 mm for a 13" tyre, 350 mm for a 14" tyre or 400 mm for a 16" tyre. Measure the diameter five or ten times in several different positions and take an average.

4) Measure the outside diameter of the tyre. This will be about 600 mm for the smaller tyres and 650 to 700 mm for the larger tyres.

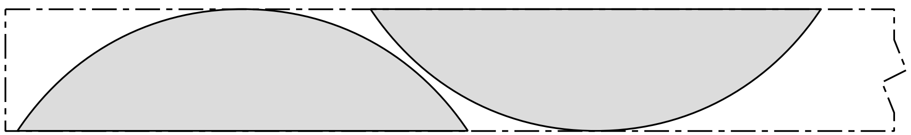

Figure 2: marking out segments to reduce waste.

5) Draw a circle of diameter 30 mm less than the outside diameter of the tyre on a piece of paper or cardboard using a piece of wire to make a compass. On the same centre draw a second circle of diameter equal to the hole diameter. This is to help you mark out the timber, so you should take some trouble over getting it accurate.

6) Now use the cardboard template to mark the timber planks. You can prick through the template into the wood and then join the marks with a pen. Figure 2 shows how to mark out the segments to waste the minimum timber.

7) Cut out the segments. For each wheel you will need to make two of the discs shown in Figure 3. Each disc is three planks thick as you can see. Make sure that the tyre is a snug fit on the single thickness small disc.

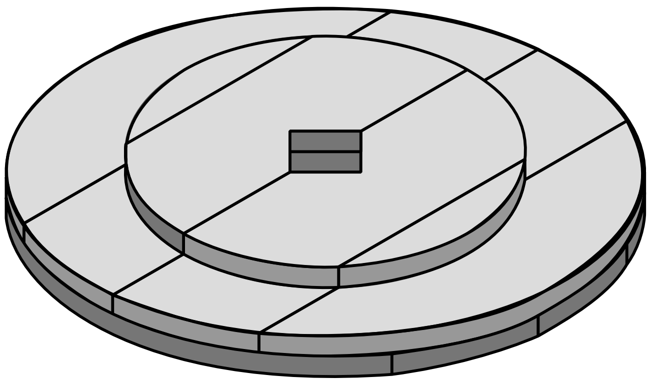

Figure 3: half of one wheel.

8) Nail the segments together with 60 mm nails clenched over. Make sure that the cutouts for the axle all line up - you can put a short piece of pipe into the notch to help align the segments.

9 Carefully mark the position of the bolt holes through the discs and drill the four holes in each disc. It is probably worth making these holes 15 or 16 mm diameter if you are using M12 bolts because it is hard to get all the holes to line up accurately.

10) Cut pieces of 40 × 6 mm steel bar 150 mm long to make the wheel stud struts shown in Figure 4. You will need four for each wheel. To make the long bolts cut the heads off 40 mm bolts and weld on pieces of 12 mm round bar 180 mm long. Check how thick your timber is and change the length here to suit if you need to.

TABLE 1: materials for wooden flexwheels.

component	material	# lengths reqd [#*mm]	total material for two wheels [mm]	cost [UK£]
wheel studs	50×M12 nuts and bolts	8	8	2.08
wheel stud struts	6 × 40 flat bar	8 ×150	1200.00	0.90
axles	1-½" BSP malleable iron pipe	2 × 1500	3000.00	8.23
small timber discs	150×25mm timber	8 × 360 + 8 × 200	4480.00	1.47
large timber discs	150×25mm timber	8 × 580 + 8 × 400	7840.00	2.57
scrap rubber car tyre	size 185×14	2 reqd	2 reqd	4.00
	TOTAL			19.26

11) Next cut the axles from 1-½" black pipe. These will probably need to be about 1600 mm long - it depends on the axle design you are using.

12) Position the axle in a pair of discs without the tyre and fit four stud/ struts. Arrange them to lie around the axle as in drawing 1/3 at the end of this document.

13) Using a trysquare get the axle square to the wheels and get someone to hold it there while you weld the struts to the axle. Make sure that you weld the struts to the axle strongly.

14) Remove the nuts from the studs and the outer wooden disc and fit the two halves of the tyre as shown in drawing 1/3. Replace the nuts and washers and tighten.

15) Repeat for the other wheel. You've finished it!

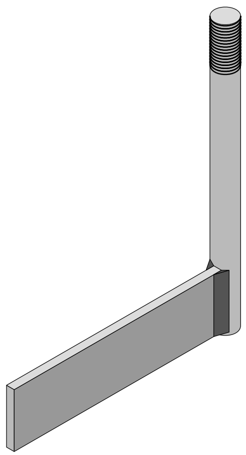

Figure 4: strut and stud fabrications.

Other DTU cart developments

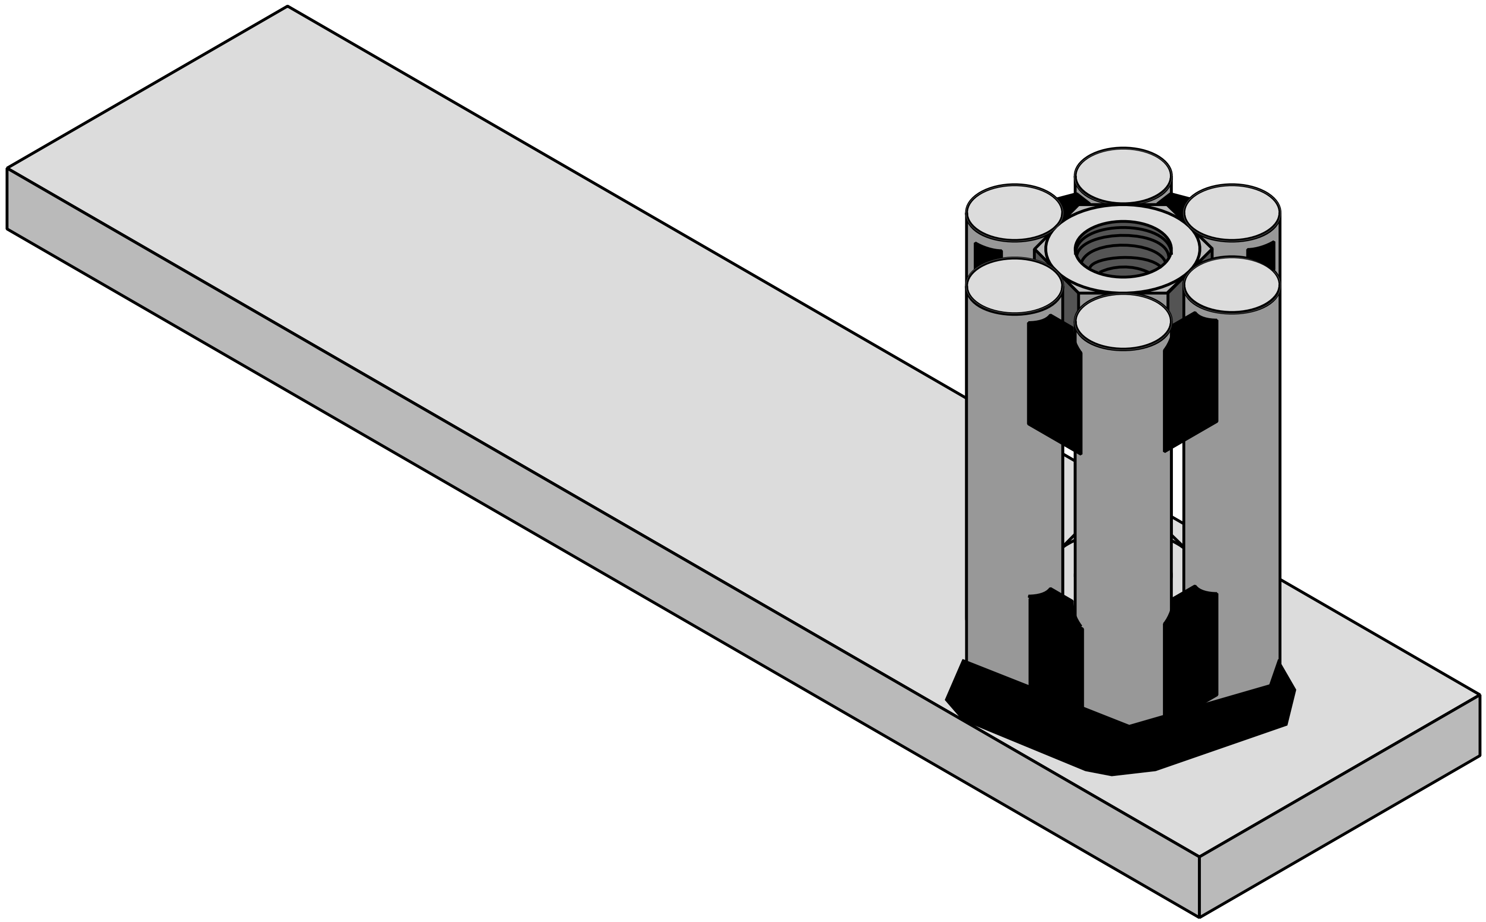
Figure 1: spanner for wheel nuts made from round and flat steel bar and welding.



Wheel Nut Spanner for Animal Carts.

Introduction

In this booklet we tell you how to make a spanner for M12 wheel nuts from round bar and a bit of welding.

You should find that you can make a spanner for less than £1 and you can do it in only an hour or less.

The only tools which you must have are a simple welder, a hacksaw, and a hammer.

Cutting list and costs

Table 1 shows a cutting list for a wheel - recent prices of materials in Kenya are shown converted into £UK.

Construction step by step

1) Cut the round bar into six 50 mm lengths. File the ends square if you are not good a sawing accurately.
2) Cut some strips of thin steel from a tin or drinks can. The strips should be about 65 mm long and 10 mm wide. You will need at least two of them.
3) Wrap one of the strips of thin steel around the six sides of an M12 nut. Bend the steel so that it stays in place without being held.
4) Put the nut and steel strip on a flat surface and arrange the round bars around it as shown in Figure 2.
5) Put a pipe clip around the six rods outside the nut and tighten the clip so that it grips the nut and steel strip tightly inside the rods.you cannot easily get a pipe clip use a piece of wire to bind the rods together.
6) Bend a second steel strip around a nut and put it and the nut inside the rods at the other end. Put another pipe clip around them. Check that all is square and straight.
7) Carefully weld the six rods together using small (tack/ spot) welds. When you have it all joined together you can remove the nuts and steel strip and weld heavily to join it all together strongly. You do not need to weld all the way along the rods, a good weld at each end and on in the middle is all that is needed.

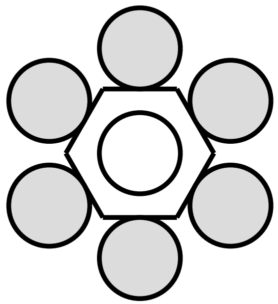


Figure 2: arranging round bars around nut.

8) Make a handle from a piece of flat bar or square pipe and weld it onto one end of the spanner to make a handle.

9) You've finished it!

DTU cart developments

Figure 1: unmachined cast aluminium wheel for animal carts using simple pipe rollers as a low cost roller bearing.

This photograph shows one half only of the wheel. Also missing is the axle - just a piece of 2" pipe (outside diameter 60mm) and the thrust washers.

Note the polish on the rollers and the scuff marks in the aluminium casting where the ends of the rollers rub.

As Cast Aluminium Wheel for Animal Carts.

Introduction

This booklet describes work carried out at Warwick University on as cast aluminium wheels with integral roller bearings for animal carts. This work grew out of work we had performed in Nigeria.

We have made several wheels to the design in the drawings in this document and tested them in a machine which makes them revolve under load. Figure 1 shows one half of one wheel. We ran them for many days and then took them apart to see how much they had worn. We were surprised that they had worn only a little.

We think that they could be used in some countries where scrap aluminium is cheap and where there is good enough communication to allow manufacture in a few workshps around a country and a trade in wheels to develop. Unfortunately we thought that these conditions did not exist in Kenya and Uganda.

We expect that you could make a pair of these wheels including the bare steel axle pipe for about £30. This cost will depend on the cost of the materials and labour.

Easy to cast design.

We have designed this wheel to be easy to cast. You need only to feed the molten aluminium to three or four places around the rim and if you make the gates quite big (about 30 mm by 20 mm) you may be able to avoid using feeders. All the components of the wheels and axle can be made without machine tools though you may need to drill the holes for the bolts joining the two halves of the wheel together if you cannot cast them.

Construction

We have not developed these wheels and so we do not have proper instructions for their casting. We cast our wheels in a special casting laboratory at our university. But we did do some quite complicated casting in Nigeria and we are sure that it would be possible to do this work in most other developing countries. Certainly we identified several companies who could have cast the wheels in Kenya.

Unfortunately therefore you will have to get local expert casting workers to make a suitable wooden pattern from the drawings and then make the castings. After that you can make up the rollers and the rest of the axle yourself.

1) The first job, is to get all the material together including the castings and clear a space to work. Ideally you will be able to work on a flat area of concrete.

2) Clean up the castings and cut off all the excess lumps from the casting process. Remember that the inner tube will press on the casting so you don't want sharp points left to make punctures.

3) Line up two wheel halves and drill six or eight bolt holes through as shown in the drawings. It is probably worth making these holes 13 or 14 mm diameter if you are using M12 bolts because it is hard to get all the holes to line up accurately.

4) Cut lengths of 1/2" steel pipe to act as rollers. You should file the ends of the rollers smooth and square to the length so they revolve smoothly.

5) Make the big washers from 5 mm or 5 mm steel plate. You do not need to make them very accurately but they must go over the axle and they must not have any bumps on the sides. So you could make the hole in the middle with a welder as long as you file the bumps off afterwards.

6) Cut the axle to length and assemble the wheels and washers on it in the right place. You do not need to put the rollers in at this stage. Mark the position of the cross bolts in the axle and blow the holes with an electric welder or drill them.

   A useful way of cutting pipe square at the ends is to wrap a piece of paper or cardboard around the pipe and push it until the edge of the paper is level all the way round and the paper is tight on the pipe. Then mark around with felt tip pen. Finally cut to the line.

7) Next remove the components, clean everything and put it all together with some oil or grease.

8) You've finished it!

Figure 1: straight hame collar for donkeys - wooden version.

Straight Hame Collar Harness for Donkeys made from Steel Tubing, or Timber

Introduction

This technical release covers the manufacture of a straight hame collar for donkeys. Collars allow the highest draught (pull) from a particular animal. Collars can be used to pull carts or agricultural implements. This chapter shows both a steel and a wooden design.

You should find that you can make the wooden collar for one donkey for less than £$_{UK}$1 and the steel one for about £$_{UK}$3, depending on the cost of the materials and labour. Once you get organised, a man can probably make a colar in a few hours.

Idea Behind Design

Collars are used in many countries to harness animals for draught (pull). Most of the designs we have seen have curved hames (the wood or metal parts pressing on the sides of the animal's necks), but some countries have used straight pieces of wood here and our experience suggests that this will work adequately if not well - depending on the shape of the donkey. Most of the donnkeys we have seen in Kenya, Uganda and South Africa would be fine with straight hames.

Special tools and jigs and hard-to-get materials are not required for these designs - the only tools which you must have are a woodsaw and hammer - and for the steel design, a simple welder and hacksaw.

Cutting lists and costs

Tables 1 and 2 show the cutting lists for complete collars -

Figure 2: steel version of straight hame donkey collar.

recent prices of materials in Kenya are shown converted into $£_{UK}$ to assist international comparison.

Construction step by step (steel version)

1) Get all the material together and clear a space to work. Ideally you will be able to work on a flat area of concrete or have access to a bench and vice.

2) Cut two pieces of 50 mm diameter steel pipe 450 mm long.

3) Using a hacksaw, angle grinder or welder set to maximum current, cut the slots for the hame cross bar as shown in Figure 3.

4) Make a top ring for each hame by winding some 8 mm round bar around a piece of the tube and weld it to the top of each hame to close off the end of the slots.

TABLE 1: steel straight hame collar materials cutting list.

component	material	# components	total mat [mm]	mat cost [$£_{UK}$]
main frames	50 round tubing	2*450	900.00	0.97
padding clips	8 mm re bar	2*2*40	160.00	0.02
U loops	8 mm re bar	2*3*125	750.00	0.07
top link	8 mm re bar	2*250	500.00	0.05
strap hooks	8 mm re bar	2*150	300.00	0.03
top link pins	scrap tyre rubber	1*8*70	10.00	0.10
			TOTAL =	**1.25**

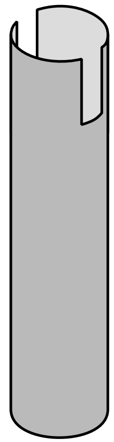

Figure 3: slot cut in top of steel hame.

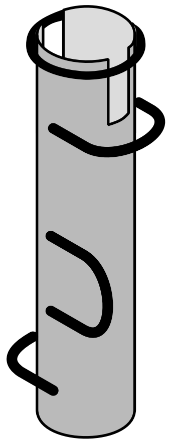

Figure 4: attachment loops and top ring welded to steel hame.

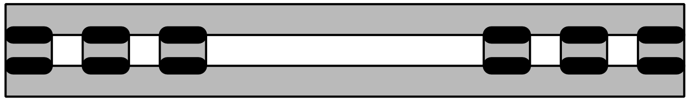

Figure 5: welding of hame cross bar.

5) Make up the hame cross bar shown in Figure 5.

6) Cut some scrap tyre rubber to make pegs to stop the hame cross bar pulling through the hames.

7) Cut 125 mm lengths of 8 mm diameter round steel bar and bend them into U shaped loops.

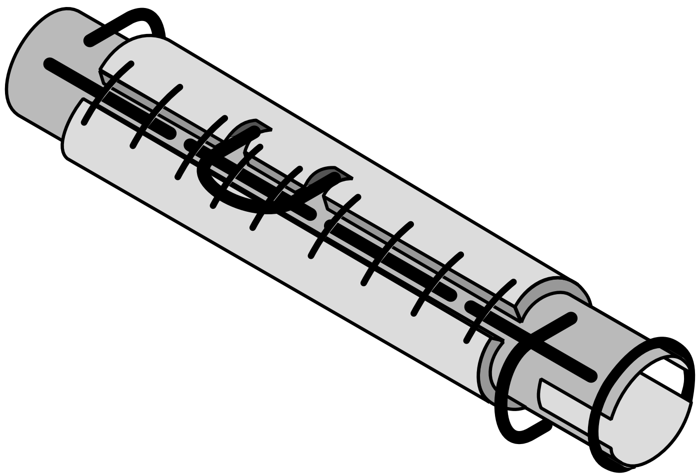

Figure 6: padding tied to hame with wire or cord.

8) Weld the U loops onto the tubes in the places indicated in the drawings.

9) Either:

wind the padding rope around the tube and fix the ends,

or fix padding cloth, blanket or carpet to the hames using wire or cord as shown in Figure 6.

10) Make up some attachment hooks as shown in Figure 8.

Construction step by step (wood version)

1) As always get the material together and clear a space to work. Ideally you will have a flat area of concrete or have access to a bench and vice.

2) Cut two 450 mm long pieces of timber about 50 mm in

TABLE 2: wood straight hame collar materials cutting list.

component	material	# components	total mat [mm]	mat cost [£UK]
hames	50 round timber	2*450	900.00	0.18
padding clips	6mm re bar	2*2*40	160.00	0.02
U loops	6mm re bar	2*3*200	1200.00	0.12
top link	6mm re bar	2*250	500.00	0.05
strap hooks	6mm re bar	2*150	300.00	0.03
top link pins	scrap tyre rubber	1*8*70	10.00	0.10
			TOTAL =	**0.49**

diameter.

3) Make a U-shaped loop from a piece of 8 mm round steel bar for each hame pull loop.

4) In each piece of wood drill an 8mm diameter hole 175 mm from one end and another 225 mm from the same end, making sure that both holes are in line with each other.

5) Hammer the pull loop into each hame and clench over the ends of the loops to hold them into the hame. The clenched ends must be sunk into the timber so they do not press through the padding into the animal.

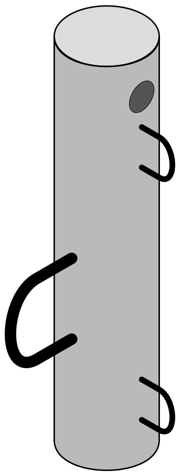

Figure 7: wood hame with hole drilled for bolt type crossbar.

6) Hammer a U-nail into the side of each end of each hame in line with the pull loop as shown in the drawings.

7) Either:

cut a slot in the top ends of the hames for the crossbar and make up the crossbar and two rubber pegs to put through the holes in the crossbar.

or:

drill a hole in each hame 40 mm from the top for a crossbar made from a long bolt (Figure 3·11 shows how a long bolt can be made from a short one) and make the long bolt. Figure 7 shows a wooden hame with a drilled hole before padding has been fixed.

or:

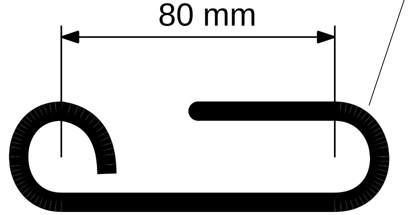

Figure 8: chain hooks for straps.

make up leather straps and buckles as in Figure 1. The leather straps can be put through the U-nails to hold them in place.

8) Cut a piece padding (carpet, blanket cloth etc) and nail to the hame as shown in the drawings.

Collar adjustment and method of use

(Remember that protecting the donkey will save money because it can work harder if it is comfortable and will not get sick from skin wounds.)

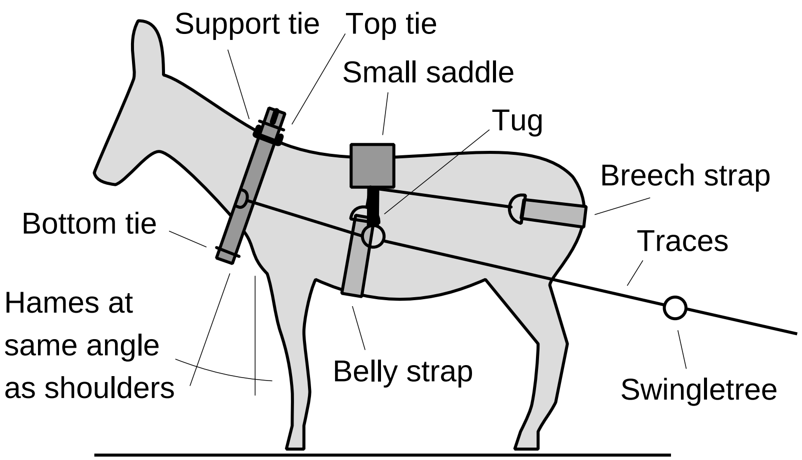

Figure 9: Collar position on donkey with traces pulling at right angles to hames.

1) Adjust the top fixing between the two hames so that it is in approximately the right position (once the collar has been used on a particular donkey this will probably not need further adjustment unless the condition of the donkey changes ie it get fatter or thinner).

2) Slacken or undo the fixing between the bottoms of the two hames.

3) Place the collar over the neck of the donkey and adjust the bottom fixing rope across between the bottoms of the two hames so that it is in approximately the correct position. (If you are using rope for this tie do no tie it properly yet.)

4) Now check and adjust both top and bottom fixings between

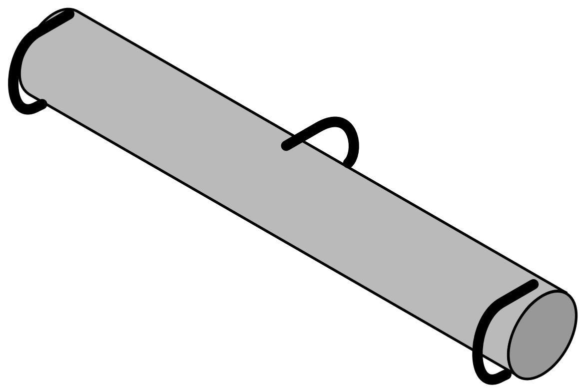

Figure 10: swingletree: the traces will be tied to the ends, and the implement tied to the central loop.

the two hames until the collar is in the right vertical position and the angle between the hames fits the donkey's neck. (If you are using rope for the ties, now make the knot properly.)

5) Tie the top support rope or strap so that it carries the some of the weight of the collar on the donkey's neck.

6) Adjust the lengths of the tugs (the ropes or straps hanging from the saddle if you use one) so that the traces (the ropes or chains which will pull the cart or implement) come back at right angles to the animal's shoulder blades (see Figure 9).

Saddles

With a suitable agricultural implement (plough or weeder etc) It is sometimes possible to pull without using a saddle, but it is usually easier to use a one. This is because ideal angle for the traces is rarely the same as for the implement and using a saddle these can be adjusted independently.

Swingletrees

Whether a saddle is used or not, a swingletree will be needed. A swingletree can be made using the same types of materials as the steel hames. The tube will need to be about 700 mm or 800 mm long depending on how fat the donkey is. You should make sure that the swingletree is long enough so that the traces do not normally rub on the sides of the donkey when they are tight and the donkey is working. Figure 10 shows a steel swingletree. It is also quite easy to make a wooden one.

If you are going to pull a cart you must use a saddle as shown in Figure 9 because the cart will need some up or down force to stabilise it and a donkey's back needs the protection that a saddle gives.

When pulling a cart fix the breeching strap and the tugs to the shafts. Lead the traces to a swingletree on the front of the cart.

Other DTU cart and harness developments

The DTU has been working on a range of cart designs for use with both donkeys and oxen. It has designs for wooden and steel framed types. You can make either type of cart in only a few hours, if you are reasonably set up with tools and materials.

The DTU has also been working on new designs of wheels, hubs and bearings to bring down their costs and make things more locally manufacturable. It has a system of axles with bearings made from PVC pipe, another with wooden bearings and a third using scrap ball bearings. None of these axles need machining and they only take two men a day to make.

Acknowledgements

Initial trials with these collars were suggested and greatly assisted by Dr Dag Austbo and Mr Martin Aeshlimann from the National Agricultural University of Norway and were hosted by Dr Bruce Joubert in South Africa.

The DTU would also like to thank Dr Pascal Kaumbutho of KENDAT in Kenya and Mr Joseph Mugaga of TOCIDA in Tororo, Uganda for their very considerable help with this project. A large number of other people and organisations have contributed to the success of the project, most notably Mr Anthony Ndungu in Kajiado Kenya, Mr JD Kimani in Kikuyu Kenya and Mr Joseph Gitari in Wanguru Kenya in whose workshops most of the development work of this project was performed. Thanks are due also to Mr Stanley Lameria in Kajaido, Mr Patrick Gitari in Wanguru and Mr Mathew Masai in Machakos for their assistance.

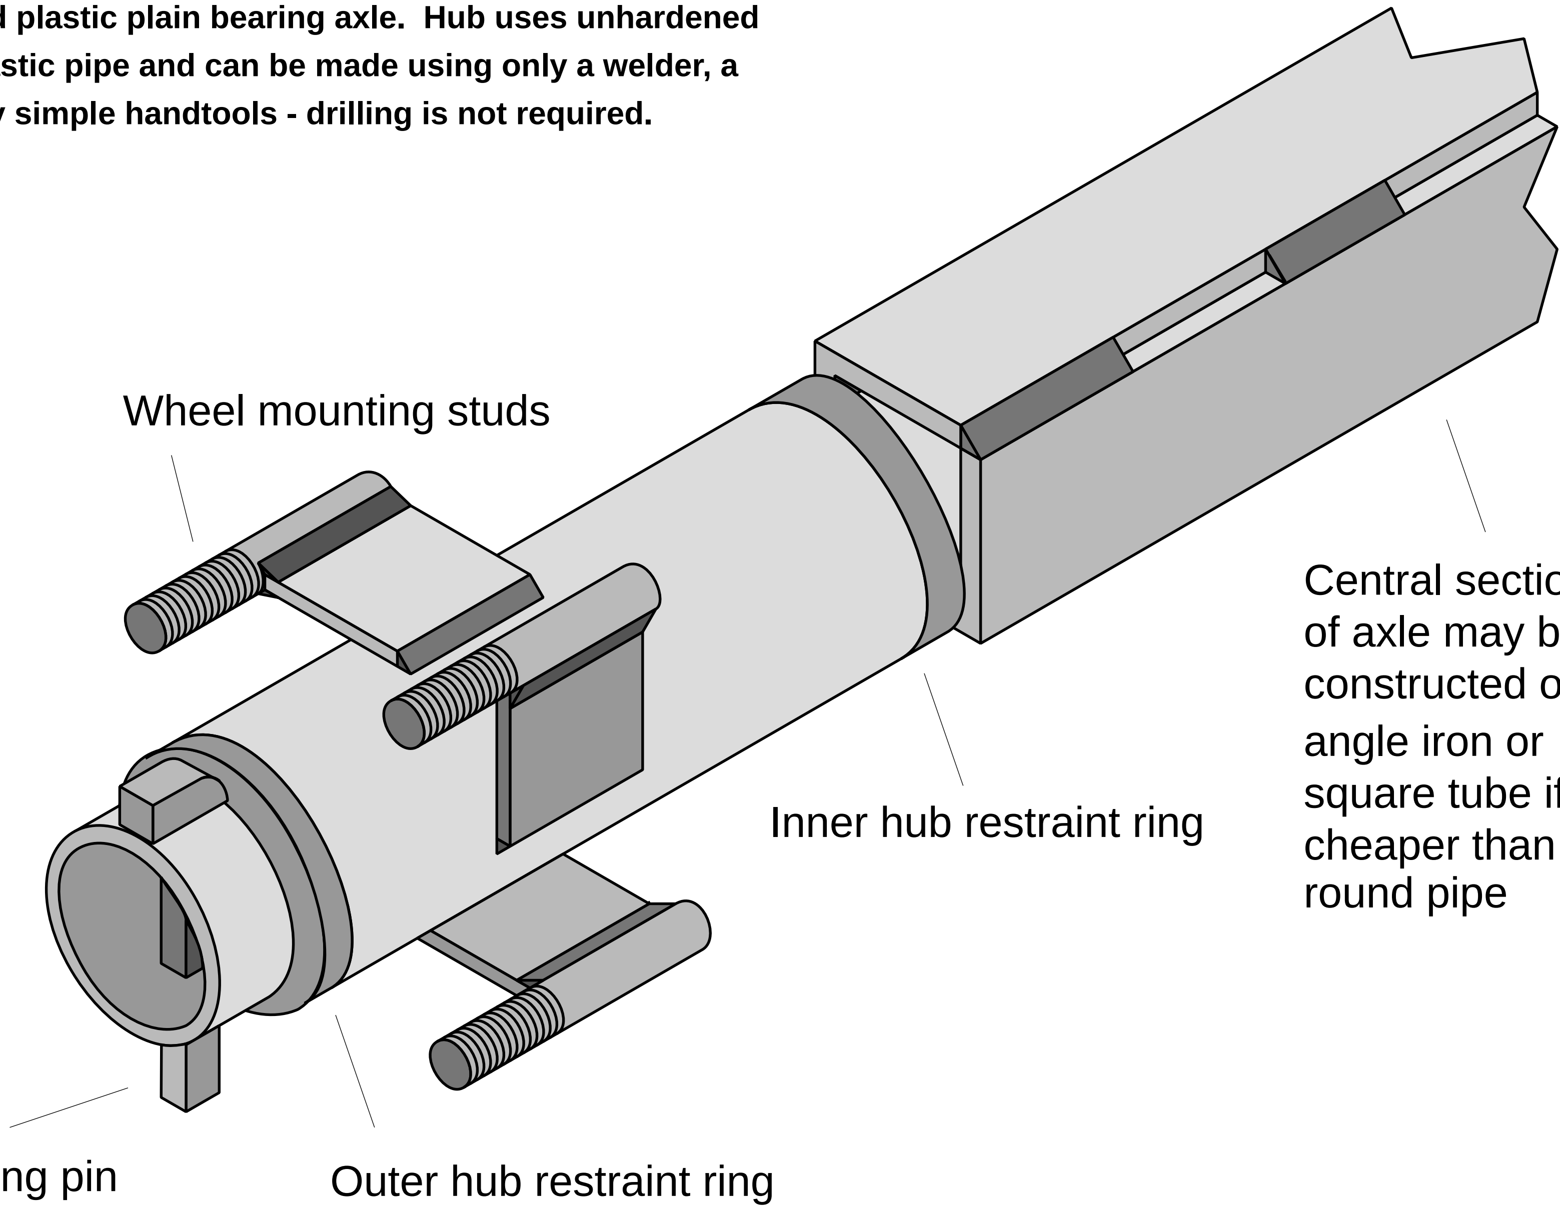
Figure 1: pipe and plastic plain bearing axle. Hub uses unhardened mild steel and plastic pipe and can be made using only a welder, a hacksaw and very simple handtools - drilling is not required.



PVC Plain Bearing Ox-Cart Axle

Introduction

Not enough farmers in Africa have animal carts. Those who have carts can take their produce to places where they can get the best prices. They can also get into town and buy fertilizer and better seeds and move things around their farm easier. The trouble is that carts are too expensive for many farmers. The question is what can be done about it?

Carts are made in many different places. Some carts are made in factories in industrial countries and some are made in factories in Africa, but most are made by local blacksmiths or carpenters using scrap car and 4WD axles. In many countries these people cannot get enough axles to meet the demand so the price is high. Another problem is that the axles are often so worn that they do not last long. Lots of farmers take the (differential) unit out of the axle too, which makes the axle break sooner and lets the dirt in.

What you need is an axle which blacksmiths and fabricators can make with fairly simple tools - without having to get parts machined. There are usually blacksmiths and fabricators in the small market towns used by the farmers. Experts think that having the cart maker close to the farmer is a good thing because they can talk to each other easily and sort out any problems. And of course if the cart is made locally, it can be repaired locally, so there will not be problems with spare parts.

Idea behind design

The idea behind the design of axle described in this technical release is to allow construction without the use of machine tools (drills, lathes and milling machines), and to use materials which should be readily available. The materials can be used 'as bought' - no hardening of any of the components is needed. The only tools which you must have are a welder and a hacksaw, but a file and a vice are also very handy. Of course if you do have power tools - especially a power hacksaw or angle grinder with cutoff wheel - things can be made much faster. This axle is suitable for a wide range of production methods so that if you have to make many of them you can make special tools to make it quicker.

The hubs in this design use 2½" BSP pipe on 2" BSP axles so that they will fit many scrap 4WD wheels. Most wheels have a hole in the middle about 75 mm diameter, or a bit bigger. Sometimes the holes are smaller and the wheel will not fit on the hub, but you can sometimes saw or file the hole bigger if you have to. Another way of avoiding the hole in the wheel problem is to use live axles as described in Technical Releases 36, 37 and 41.

It is best to make these axles with a plastic pipe sleeve bearing between the axle and the hub tube. The best plastic is probably polythene, but this is hard to get in short lengths so we have used PVC in Kenya. Search around the stores in your area to see what is available. If the only steel pipes you can find for the axle and hub tube do not have enough gap between them for a plastic bearing then you can still get good performance without using the plastic sleeve, but the axle will wear a bit faster and the cart will be a little harder to pull. Alternatively you can enlarge the hub tube a little see the **modifications** section.

You will see from Figure 1 that the wheels are fixed to the axles by struts rather than by thick metal discs as on most axles. Putting the fixing studs on struts like this is much easier and cheaper. It also means that you might be able to fit a slightly different wheel by bending the struts a bit to fit. Or if that does not work you can even cut nearly through the welds and then weld them in the right place. You could even cut the struts right off and weld on a different number if your wheels have a different number of holes.

Performance

Many farmers and water carriers in Kenya have used axles similar to these axles on their carts for three years or more without even a plastic bearing. Of course you need to clean the axle and hubs out and re-grease them every month at least and if you use them heavily you should grease them every day. Actually this is easy because all you need to do is remove the hub restraint pin through the end of the axle, take the wheel and hub off, put some grease on the axle and replace everything. It should only take a few seconds.

Length of axle

You need to decide how long to make your axle. Of course you can make the axle any length you like to suit your cart, but most carts will need an overall axle length of between 1500 to 1800 mm. You will need to make the track of the wheels so that the wheels do not rub on anything. You should keep the wheels and tyres about 50mm away from any part of the cart. If the cart

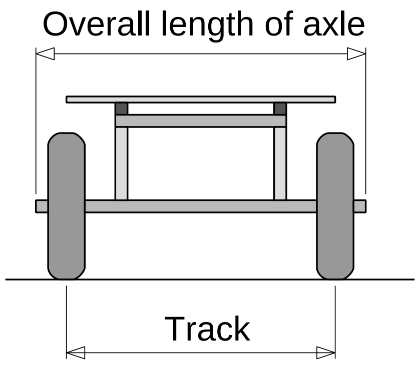


Figure 2: track width of cart.

is to use roads with deep ruts in them it may be a good idea to make the track of the cart the same as the ruts so that the cart stays level on these roads.

In the **cutting list and cost** section you will see that you can make the axle with a central section of some other material than the 2" BSP if this is very expensive. We have assumed that you will use square box tubing but you could use two pieces of angle iron to make a square tube.

To calculate how long to make the axle decide how big you want the **track** to be (see Figure 2) and add 310 mm. This distance will now be the **overall length of the axle** (see Figure 2 for this also). If you are going to use square box tubing or angle iron for the central section of the axle then you should subtract 300 mm from the **track** and make the central section this long (we have shown this to be 1200 mm long in the cuting list but you will probably find you need to make it a little different).

Table 1: materials and costs.

component	material	number & length reqd [#× mm]	materials cost in Kenya [£UK]
central axle	60 mm square box tubing	1×1200	3.82
hub stub axles	2" BSP malleable iron pipe	2×350	2.37
hub outer tube	2½" BSP malleable iron pipe	2×200	2.50
PVC plastic brg	2" PVC plastic pipe	2×250	0.47
axial thrust rings	10mm or 12mm square bar	4×154	0.52
thrust ring tags	10mm or 12mm square bar	4×154	0.02
hub restraint pegs	10mm or 12mm square bar	90×2	0.10
wheel studs	M12 × 50 mm bolts	10×50	5.00
wheel stud struts	6×40 steel flat bar	8×37	0.47
TOTAL COST =			14.80

Cutting list and costs

The table shows a cutting list for a complete axle - two wheel hubs with stub axles joined by a square tube section in the middle. We have shown this way because round pipe is very expensive in some countries. But if pipe is reasonably cheap where you are then make the whole axle out of one piece of pipe.

Recent prices of materials in Kenya for the axle are shown in $£_{UK}$. The 2" BSP (British Standard Pipe) is about 61mm outside diameter, or a bit less, with a wall thickness of about 3.6mm. The 2½" BSP is about 76mm outside diameter, with a wall thickness of about 3.6mm.

These instructions deal with making an axle to the design shown in the drawings. If you find that you cannot get the right sizes of material you might still be able to make an axle with other sizes. See the **Modifications** section later in this booklet.

Construction step by step

1. The first and probably most difficult job, is to get some suitable pipes. Then get everything else togerther and clear a space to work - ideally on concrete.

2. You will probably find that no plastic pipe fits properly between the axle pipe and the hub tube but all you need to do is slit a piece along its length and open it up a bit or close it down until it fits. A better way is to make a helical saw cut in the plastic pipe so it is like a spring. Then it will open up or close down to the size easily and it will not tend to wear the area around the slit.

3. When you have got the right pipe sizes, you can cut the two hub pipes each 250 mm long and the axle pipe about 1500 mm or 1600 mm long, or if you are going to do it with a central section in square pipe or angle iron, you need to cut the central section about 1200 mm long plus the two stub axles each about 500mm long. If you need to support a simple one piece pipe axle an easy way is to weld short pieces of round bar onto it as shown in Figure 4. If you make these about 300 mm long they will strengthen the axle quite a lot as well.

   Figure 5 shows how you can weld the stub axle tube into the square box tubing. You will need to cut slots in the sides of the square tube so that it can bend in or out to accept the stub-axles. When you are welding the stub axles in, make sure you tack weld them in first and check that they are straight before you do the final weld.

4. Next you need to make a hole near each end of the axle pipe for the hub restraint pin. To do this without using a drill cut a slot in each side of each end of the axle. Make the slots about 30 mm long to start with and about 10 mm wide. You want the slots just the right length so that with the hub

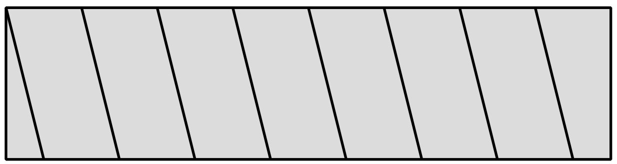

Figure 3: helical sawn cut in plastic pipe bearing sleeve.

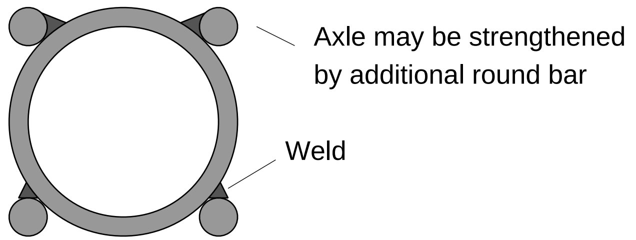

Figure 4: method of adding round bar to support pipe axle and strengthen it if needed.

restraint pins in place the hub tubes are not pinched tight. It does not matter of they are a bit loose.

5. The next step is to weld the stud bolts or bits of threaded rod onto the struts. If you have a vice it makes welding the bits together easier because you can clamp the pieces together while you tack weld them. You need to make one strut for each wheel stud unless you are using five or six stud wheels on a single donkey cart. If so you could use only three studs per wheel if the cart user wants only light

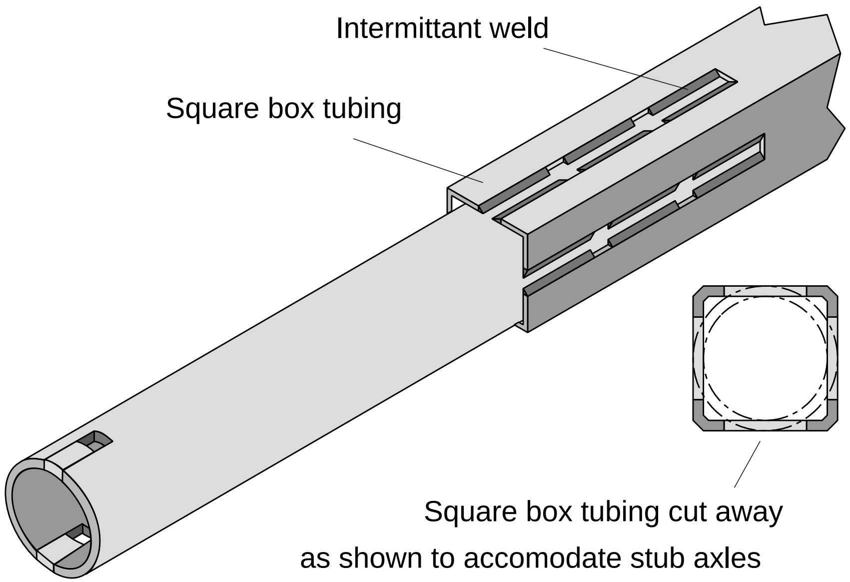

Figure 5: method of welding stub axles into square tube.

use from the cart.

We have used this method of fixing wheels successfully with the old VW wheels which have very large holes in the middle.

When you've made up the struts you can put a nut on each stud and then put the studs through the wheels, and put a second nut on each stud. Then get everything even and straight with the hub pipe in place as well in preparation for welding the struts to the hub tube. You want to get the middle of hub pipe level with the middle of the tyre, as is shown in Figure 7. Most wheels need the studs to be about 60mm offset and this is what is on the drawings.

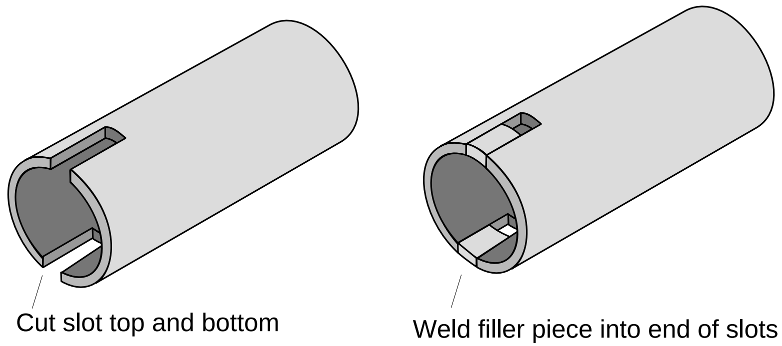

Figure 6: method of making hole for hub restraint pin without drilling.

wedges as shown in Figure 8 is a good way to do it.

When you are happy, tack weld the struts to the hub pipe. Then remove the wheel and wedges so you've got room and finish the welding of the struts to the hub tube. Repeat this for the other hub. If you are going to make several axles you can make up a simple jig, rather than the wedges, to hold everything for welding. We have used a piece of plywood with a central hole to fit snugly over the hub tube and four holes for the studs. In other words its a bit like a dummy wheel.

It is best to check that the hubs, and stub-axles still go together when you've finished welding because sometimes weld contraction can pull it all out of shape and make it all too tight. You might need to file off some high spots inside the hub. If you can get it together without a hammer you'll be ok because it will wear to the right shape.

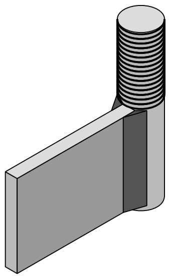

Figure 7: stud welded to the wheel struts.

6. Nearly there! Now take the wheels off the hubs and make up four rings (called hub restraint rings on the drawing) from 6 mm or 8 mm square steel bar (or round bar if you cannot find square). One ring must be welded about 230 mm from each end of the axle pipe or from the ends of the stub axles to stop the hubs going too near the centre of the axle.

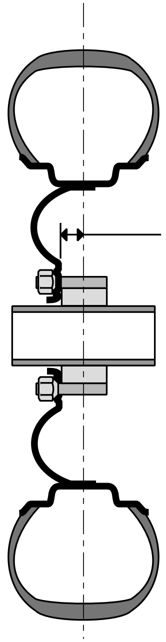

Figure 8: cross section of tyre wheel and hub tube showing centering of hub tube in wheel.

7. Now put it together! Smear some grease onto the plastic bearing pipe (if you are using one) and onto the axle and put the hub tube and plastic bearing onto the axle. Then put the outer hub restraint ring on and secure it with the hub restraint pin. Do the same for the other hub.
8. Paint everything!
9. You've done it!

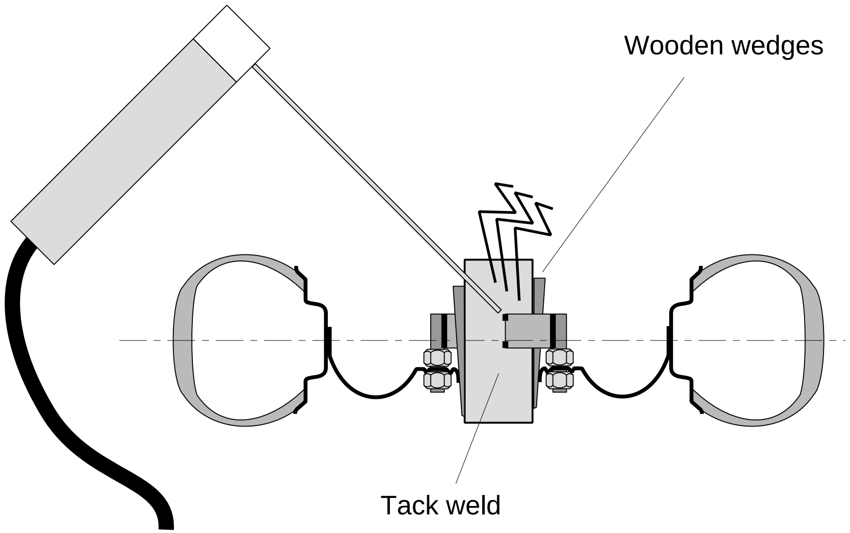

Figure 9: cross section of tyre wheel and hub tube during tack welding of stud support struts

Modifications

Obviously the axle has to be strong enough to carry the cart, so it should be made from pipe bigger than about 50mm outside diameter. You must also make sure that the pipe has a wall thickness of more than about 2.5 mm.

The hub pipe also must have a wall thickness of 2.5mm or more. And it must have a bore (or inside diameter), which goes easily over the axle with enough room for the plastic bearing and some grease. There can be quite a lot of clearance (slackness or looseness) between the hub and the axle (say up to 3mm) - it does not have to be tight. If you cannot get steel pipes with enough clearance for a plastic pipe bearing then the axle will work quite well without it, but you should grease it more often.

Pipes can be made slightly bigger (up to 1mm bigger) by forcing a short piece of round bar of the right diameter through them with a press. Another way to do it is to saw the pipe along its length and open it up to the right size and then weld it. You can also make it a bit smaller like this by cutting a wider slot and squashing the pipe down. Try to clean the weld back flush with the tube using a file if you can as this will give longer life. It does not matter if

If you find that you cannot get anything like the materials talked about in the cutting list then maybe you can adapt the design a bit. If the hole in the middle of the wheels is big then you stand a better chance of finding a combination of pipes and rollers that will fit. You can often cut a bit out of the middle of the wheel to make the hole bigger. The hole in Land Rover wheels is big and you can get 4" pipe into them. Of course the shaft does not have to be a pipe - it could be solid and then it could be a bit smaller, say 30mm diameter if the steel is high quality.

Another idea that we have tried is to use a hardwood as the hub and even the wheel. If you think about it, the wear on something which is rolling must be less than when something is sliding over it, so a wooden bearing should be better than a sliding one. Some bearings we have tried have had a steel ring fitted inside so that the rollers roll on this steel. We have also tried making these rings from round bar like wire so that it's like the rollers roll on the inside of a spring. This seemed to work quite well.

Other DTU cart developments

Other methods of hub design using aluminium castings, for example, which might need no machining, are under development at Warwick and wheel designs in steel sheet, cast aluminium and timber are also in manufacture or under development. A range of designs for donkey and ox carts made of steel and wood, is also available, some of which are in production in Kenya and Uganda.

Acknowledgements

The DTU is grateful to the DFID (British Government) for the financial support necessary to carry out the research and development project under which this product was developed.

The DTU would also like to thank Dr Pascal Kaumbutho of KENDAT in Kenya and Mr Joseph Mugaga of TOCIDA in Tororo, Uganda for their very considerable help with this project. A large number of other people and organisations have contributed to the success of the project, most notably Mr Anthony Ndungu in Kajiado Kenya, Mr JD Kimani in Kikuyu Kenya and Mr Joseph Gitari in Wanguru Kenya in whose workshops most of the development work of this project was performed. Thanks are due also to Mr Stanley Lameria in Kajiado, Mr Patrick Gitari in Wanguru and Mr Mathew Masai in Machakos for their assistance.

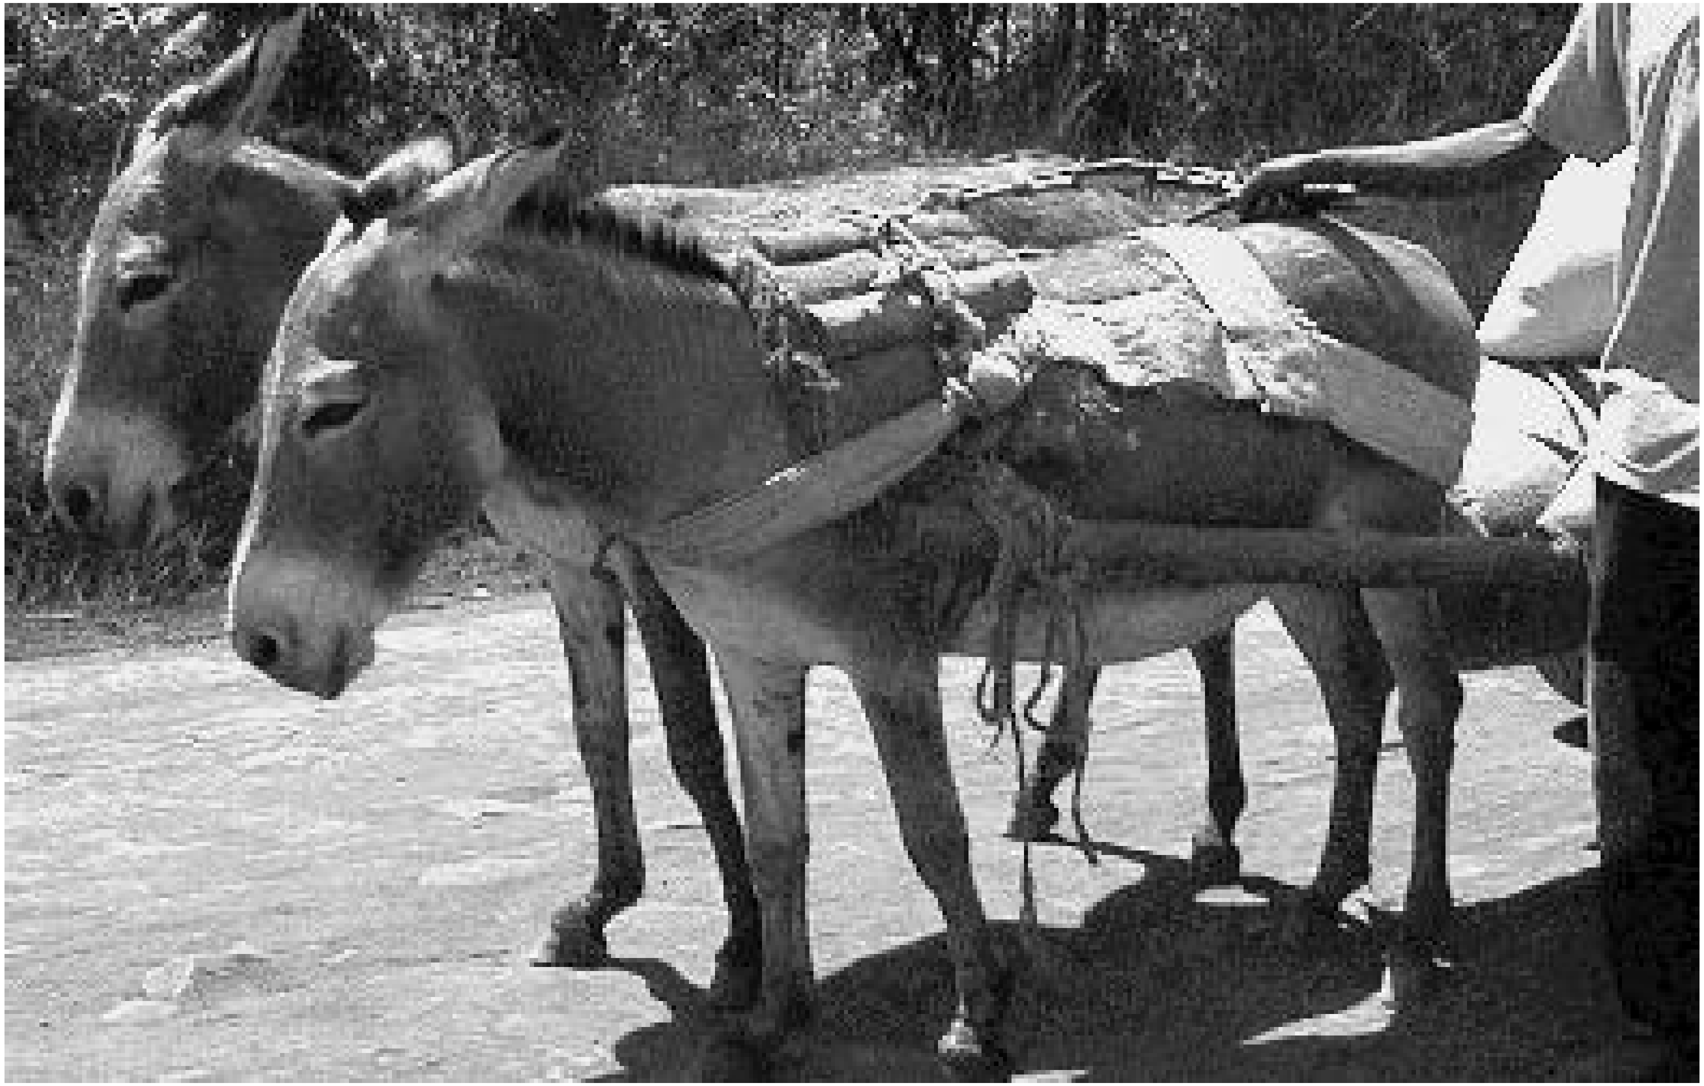
Figure 1: locally made chain and wood block saddle for donkeys.



Chain and wood block saddle for donkeys.

Introduction

This chapter covers a simple but effective saddle design for donkeys pulling carts, though it can be used for other purposes as Figure 2 shows. Saddles are necessary in a cart harness because vertical loads must be applied by the animal to stabilise the cart. We have adapted the saddle shown here only slightly from a design used by many farmers in the Mwea area in Kenya.

This saddle is extremely easy to make. All you need is some light chain (made from 2mm or 4mm steel wire) some wood and some fencing nails (U-nails). The only tools which you must have are a woodsaw and hammer. You will probably find that you can make the saddle for one donkey for about £$_{UK}$3 for a version for use with agricultural implements or about £$_{UK}$6 if you need to make up the belly and breeching straps for use with carts. You can probably make a saddle in only a couple of hours.

Idea behind chain saddles

Saddles are used to apply downwards load from a cart or from an agricultural implement onto donkeys. Saddles must be used because donkeys' backs are easily damaged by things put on them. Fat donkeys will be much more resistant to injury, but donkeys in poor condition have much thinner muscles on their backs and this tends to expose their backbones. Any hard object (even a strap) just stretched over their backs can cause damage as the skin over their backbone is compressed. After some time this pressure will damage the skin and infection can start which can kill the donkey.

Figure 2: simple version of chain saddle used with steel version of straight hame donkey collar.

A properly shaped saddle will protect the vulnerable area of skin and put the load onto the muscles which cover part of its back. Figure 3 represents an animal in good condition and Figure 4 shows the vulnerable area of skin above the backbone. A saddle must be shaped on the underside to keep clear of this vulnerable skin.

Cutting list and costs

Tables 1 shows a cutting list for a saddle with recent prices of materials in Kenya converted into $£_{UK}$.

TABLE 1: steel straight hame collar materials cutting list.

component	material	# components	mat cost [$£_{UK}$]
chain	dog or round wire chain	1	1.40
wooden blocks	100 × 50 mm roughsawn	4 × 250	0.40
padding	blanket/ sacks	2	0.80
U-nails	U-nails	¼ kg	0.60
strap hooks	6mm re bar	2×150	0.03
strap rings	6mm re bar	6×180	0.11
strap clenchers	6mm re bar	6×120	0.07
strap hooks	6mm re bar	6×150	0.09
straps	CC5 canvas	3×4×65	1.97
strap chains	dog chain	3×300	0.70
		TOTAL =	**6.14**

Construction step by step

1) Get all the material together and clear a space to work. Ideally you will be able to work on a flat area of concrete or have access to a bench and vice. It is also easiest if you have the donkey standing by to try the saddle fitting out and position things.

2) Cut four pieces of 100 × 50 roughsawn timber 250 mm long and round off all the corners with a file or carpenter's plane.

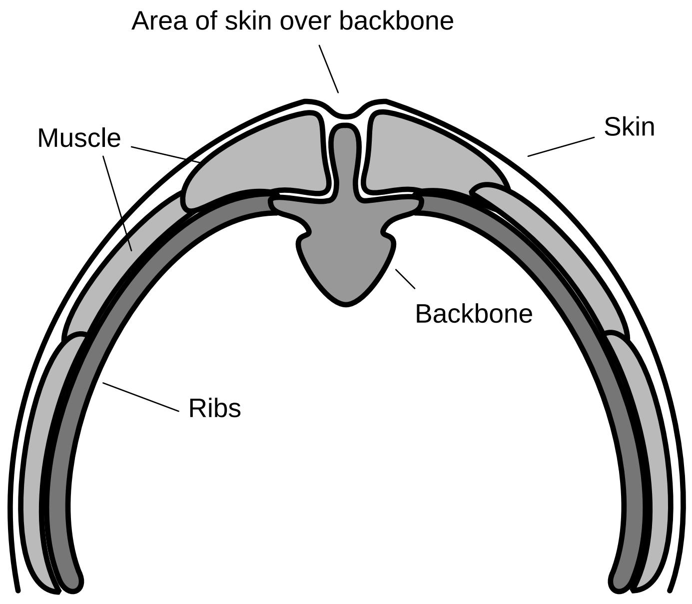


Figure 3: skin over the backbone of donkey in good condition is not vulnerable.

3) Using U-nails, fix each of the top wooden blocks 75 mm either side of the centre of the chain and the other two blocks a further 75 mm away from them as shown in Figure 5.

4) Make up the padding from blanket or natural fibre sacks (DO NOT USE PLASTIC SACKS). You can either leave this padding separate from the saddle or you can nail it on to the wooden blocks. If you nail it, you must use another layer of cloth under the the nailed padding to make sure the nails do not touch the animal.

5) It may be easier to fix the saddle to the rest of the harness if you make up two of the hooks shown in Figure 6 and fit one to each end of the chain.

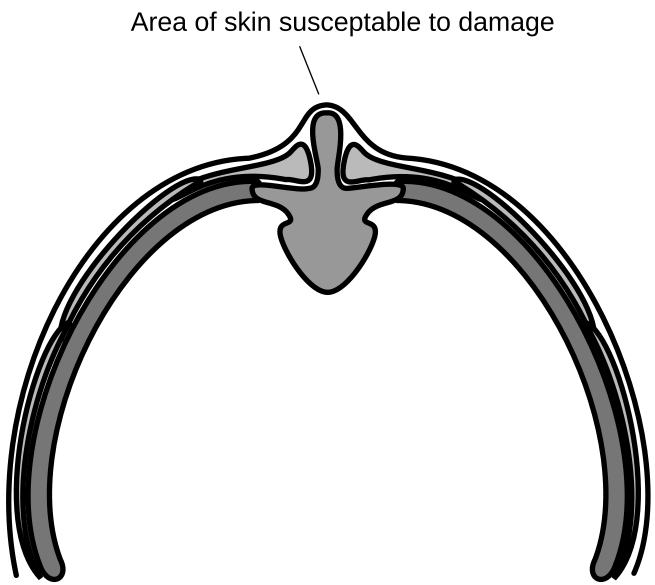

Figure 4: skin over backbone of donkey in poor condition is very vulnerable.

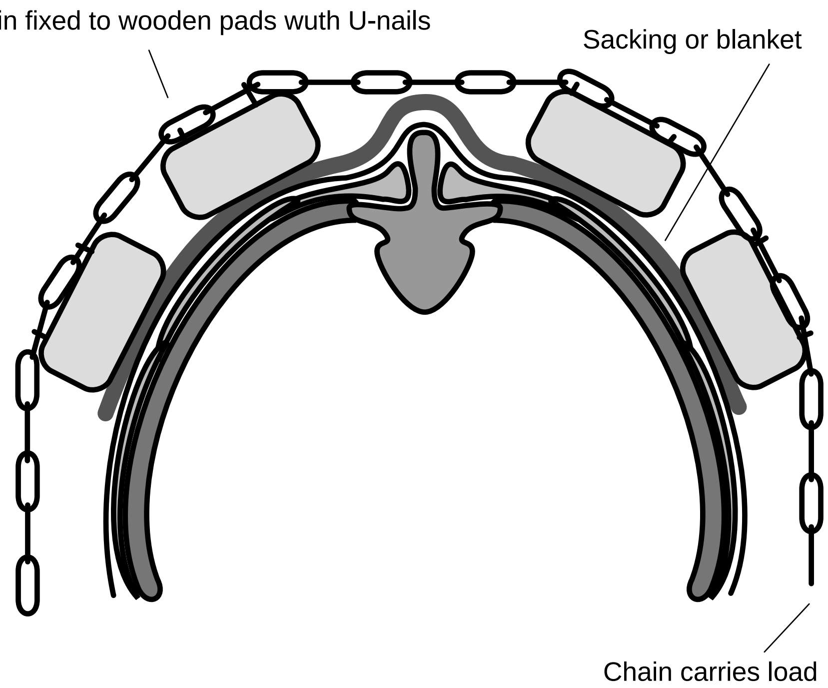

Figure 5: height of wooden blocks keeps chain away from backbone. Note sacking/ blanket padding.

6) If you are going to use belly, breeching and breast straps for cart use, make up six more of these hooks and fit one to the chain between the wooden blocks on each side, and one to the chain just below the lower wooden blocks, as shown in Figure 7.

7) If you are going to use the saddle for pulling carts make up a belly strap, a breeching strap and a breast strap to hold the saddles onto the donkeys. The D rings at the end of the straps can be made from 6 mm diameter concrete reinforcing bar as shown in Figure 8. A separate piece of the re-bar is clenched over the strapping using hammer blows to fix the D rings to the ends of the straps as shown.

   The straps themselves can be made from heavy canvas or hessian sacking. You should use three or four thicknesses of material for them to make them strong enough and soft enough not to hurt the donkey.

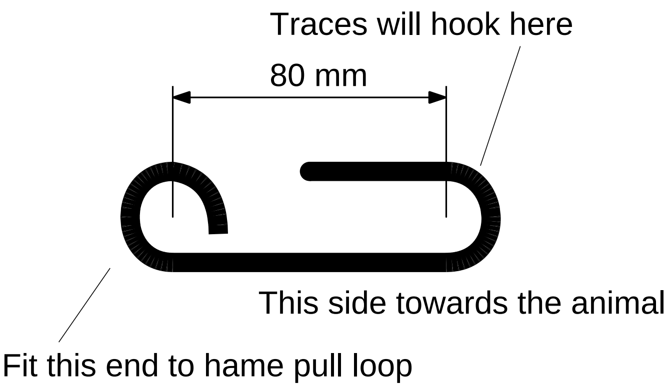

Figure 6: chain hooks for straps.

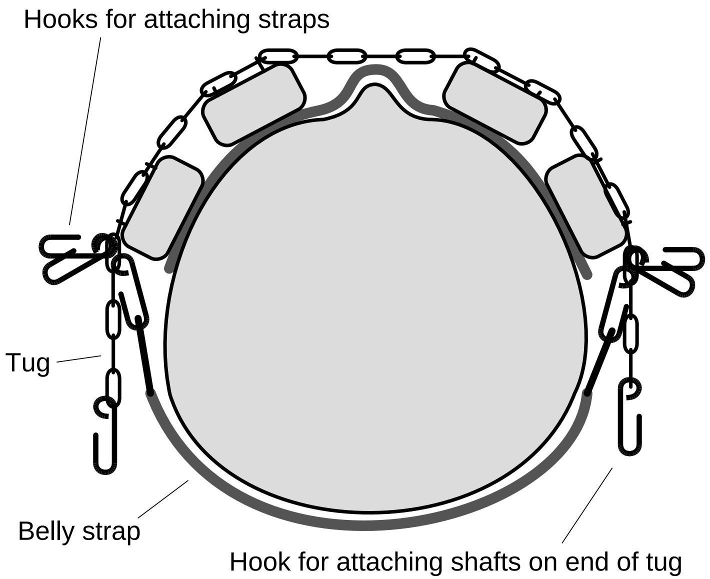

Figure 7: arrangement of attachment hooks for straps and shafts on saddle chain.

Using the saddle with agricultural implements

(Remember that protecting the donkey will save money because it can work harder if it is comfortable and will not get sick from skin wounds.)

Agricultural implements normally demand high draught and this is usually only available using a collar harness of the type described in our Technical Release 46. Breast straps are difficult to use with most donkeys because their chest are poorly proportioned for this work. It is even worse if you want them to pull hard.

It is usually easier to use a saddle with agricultural implements (plough or weeder etc) because the ideal angle for the traces is rarely the same as the ideal angle for the implement and, using a saddle, these can be adjusted independently. Figure 9 shows the general layout of harness when using the saddle with a collar.

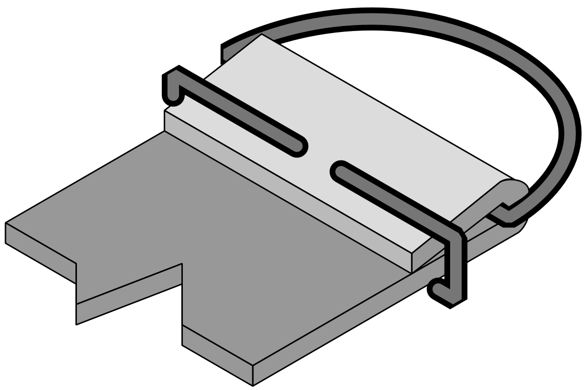

Figure 8: D rings for straps made from re-bar.

1) Place the saddle on the donkey's back using a separate piece of blanket or sacking under any nailed on padding.

2) Check that there is plenty of room under the chain you must be able to get two fingers under the chain - it MUST NOT TOUCH THE DONKEY'S BACK! Figure 10 shows a poorly arranged saddle with one of the wooden blocks nearly over the backbone.

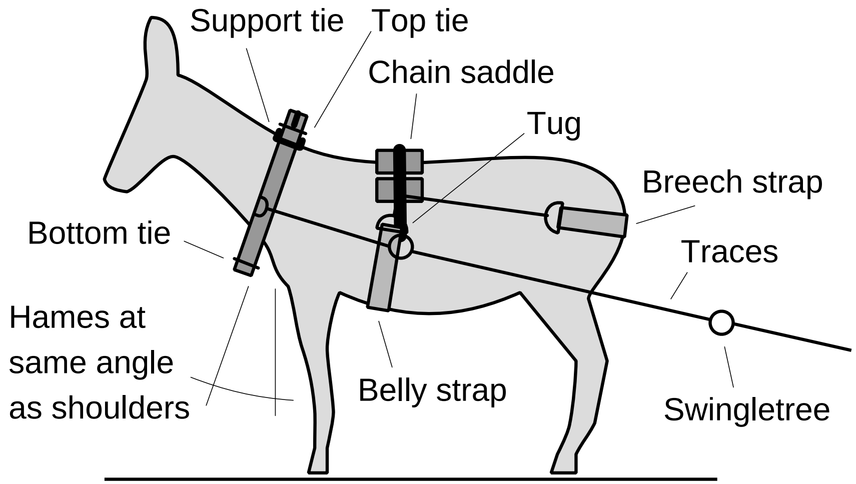

Figure 9: saddle and collar position on donkey with traces pulling at right angles to hames.

3) Adjust the lengths of the tugs (the ropes or straps hanging from the saddle if you use one) so that the traces (the ropes or chains which will pull the cart or implement) come back at right angles to the animal's shoulder blades (see Figure 9).

4) Fit the breeching strap if you find that the saddle rides forward as you work, but you will usually find that the backward pull on the tugs keeps it in place.

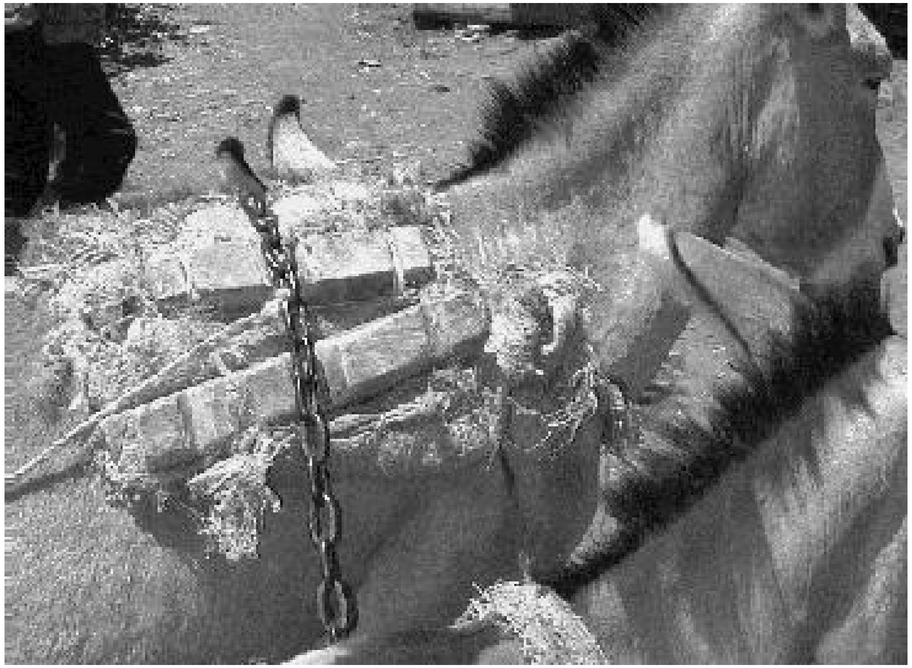

Figure 10: inadequate height of wooden blocks and poor positioning endangers skin over backbone. The sacking/ padding is also poor.

Saddle use with carts

(Remember that protecting the donkey will save money because it can work harder if it is comfortable and will not get sick from skin wounds.)

If you are going to pull a cart you must use a saddle because the cart will need some up or down force to stabilise it. A donkey's back needs the protection that a saddle gives against this force. If people just use neck yokes in your area you will usually see damage on the necks and shoulders of their donkeys.

Figure 11 shows a typical arrangement of breast band, saddle,

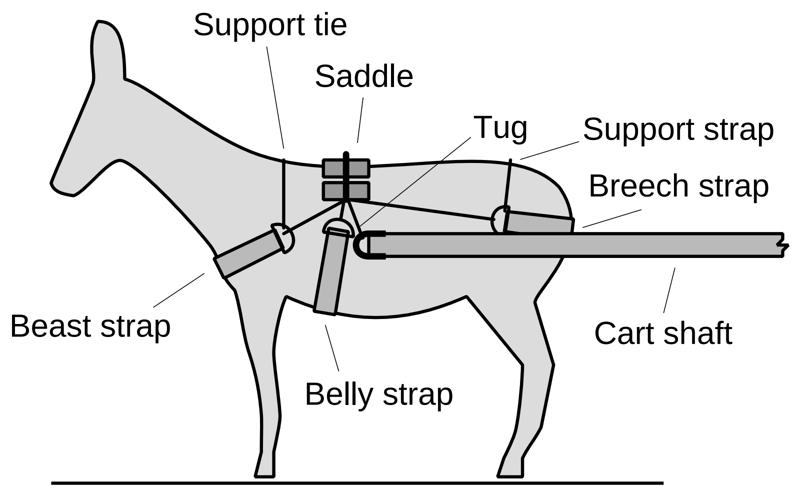

Figure 11: attachment of saddle to cart and use of breast strap.

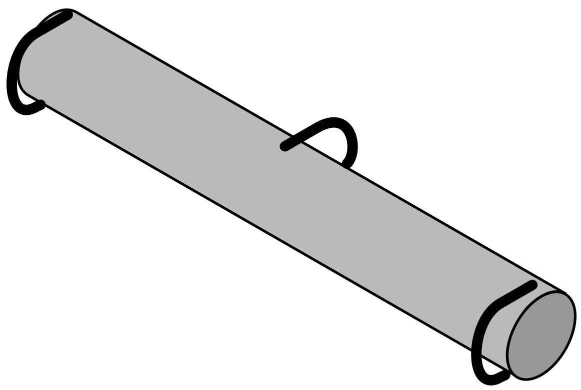

Figure 12: swingletree: the traces will be tied to the ends, and the cart or implement tied to the central loop.

belly strap, breeching strap, tugs and cart shafts.

Using a breast band to pull the cart is usually acceptable, but if the cart is very heavy then you should use the collar described in our Technical Release 46.

1) Place the saddle on the donkey's back using a separate piece of blanket or sacking under any nailed-on padding.

2) Using two of the hooks shown in Figure 6 attach the belly strap. It should be quite tight so that it does not move during work.

3) Check that there is plenty of room under the chain over the backbone: you must be able to get two fingers under the chain - it MUST NOT TOUCH THE DONKEY'S BACK!

4) Attach the breeching strap to two of the hooks just below the lower wooden blocks. Tie a piece of rope or cord across from the D-ring in one end of the breeching strap to the D-ring of the other so that the strap will not fall out of position if the strap goes slack. The breeching strap will be nearly loose.

5) Now bring the shafts of the cart either side of the donkey and attach the tugs to the shafts so that the cart is level.

6) Lastly attach the breast band to another pair of hooks below the wooden blocks of the saddle or lead traces (pieces of rope or chain) from the ends of the breast strap to a swingletree on the front of the cart. A swingletree is shown in Figure 12. Use of the swingle tree is kinder to the animal because it allows a little movement of the breast strap with the movement of the animals chest as it moves. Make sure that the traces do not rub against the sides of the animal.

Design of Rainwater Storage Tanks for use in Developing Countries

Stephen Turner

EDAT Year Four

Department of Engineering
University of Warwick

27th April 2000

SUMMARY

This project is to investigate the problems associated with ferrocemnet water storage tanks in developing countries, with the aim of giving the engineer a series of practical tips that will help with tank construction in the field. Using the findings of the project a series of a construction rules have been produced. The aim is to overcome the problems that are particular to constructing ferrocement water tanks in hot dry climates.

In rural areas of many developing countries, there is a scarcity of water. Traditionally, rainwater collection has provided valuable source household water. Therefore there is a need to provide simple, economical storage facilities that can be constructed with semi or unskilled labour. Approximately 80% of the cost of a ferrocement tank is the construction material. Due to the high cost the majority of water tanks are financed through donor funding. To enable self-sufficient production material costs need to be reduced. This project looks at efficient ways of reducing material inputs.

The first stage is to carry out structural analysis. For this thin shell theory has been used. Excel spreadsheets have been produced to allow the designer to vary the range of tank configurations and material characteristics. Initial findings from the analysis show that cylindrical tanks with curved walls can withstand greater loads than cylindrical tanks with vertical walls. Comparing a Thai jar (figure 2.7(b)) style water tank to standard cylindrical tank (figure 2.7(a)) of a similar volume material inputs can be reduced by approximately 30% (assuming the material is homogeneous).

Little is known about the mechanics of shrinkage, therefore this has been the focus of the experimental work carried out on ferrocement tanks. The author's new physical test shows how shrinkage can be reduced through the use of reinforcing. A range of reinforcing systems has been tested and results show that a thin-wire steel square mesh is the most effective of the three examined.

The report investigates how the environment in which the tank is constructed plays an important role in the degree of shrinkage and cracking. It is shown that tanks constructed in a hot and dry environment and tanks that are allowed to set at different rates are much more susceptible to cracking.

NOTATION

E	Youngs modulus
g	Gravity
h	Tank height
H_o	Edge loads consisting of shear forces at tank base
M_o	Edge loads consisting of bending moments at tank base
M_x	Bending moment
N_q	Hoop force in tank wall
N_f	Meridional force in tank
PR	Poisson's ratio (used in spreadsheet)
P_c	Portion of the load retrained by cantilever
P_r	Portion of the load retrained by hoop stresses and radial constraints
P_x	Total outward pressure load to be restrained
p_r	Pressure of fluid
Q_x	Shear force
r	Tank radius
r_1	Radius of curvature of the meridian in doubly curved tank
r_2	Radius of curvature of the second principal curve in doubly curved tank
S	Surface area of doubly curved tank
t	Tank wall thickness
v	Poisson's ratio
V	Volume of tank
w	Radial deflection
x	Intermediate point on the tank wall
D_H	Horizontal deflection around the diameter of tank
e_f	Strain in plane of the meridional force
e_q	Strain in plane of the hoop force
g	Intermediate point on tank wall in the x direction
r	Fluid density
x	Intermediate point on tank wall in the y direction

1.0 INTRODUCTION

1.1 A Brief Introduction to Rainwater Harvesting

A good quality RainWater Harvesting (RWH) system provides people with access to an on-site water supply, either next to their homes or at local public buildings such as schools and health centres. Rainwater has been collected and used for drinking water throughout the centuries, but in recent years they have fallen out of favour as they are considered old-fashioned. Ideally, the RWH collection system should involve basic construction techniques, be inexpensive to maintain, and have a long functional life span (Pacey 1986). If the system is designed well, it should provide a good safe source of drinking water at a relatively low cost when compared to the mains supply.

The RWH system provides a good alternative water supply option, especially for rural areas, where the following characteristics apply:

– it operates independently, and therefore gives people access to drinking water without them being dependent on a grid supply which can be unreliable,

– alternate sources of water do not provide sufficient quantities of potable water,

– the available sources of water are of a poor quality, such that the construction and maintenance of expensive treatment plants would be prohibitive,

– the cost of supplying grid water is too high,

– rainwater catchment area i.e. roofs, tend to be larger per capita in rural areas compared to urban,

– pollution levels in rural areas tend to be lower when compared to the towns and cities, making the water more suitable for direct human consumption without treatment.

Other benefits of RWH include:

– it reduces soil erosion (especially in the hilly areas)

– it requires a reduced amount of valuable energy inputs compared to the grid supply,

– it localises the process of water collection, which results in a reduction of the amount of civil engineering works compared to grid connection.

There are many aspects to RWH, each of which must be studied and managed correctly, if the overall system is going to run efficiently. They may be classed as follows;

– water usage management,

– water quality and other health issues,

– water collection hardware (storage tanks),

– financial considerations.

In many 'westernised' countries the most common way of obtaining a rainwater storage tank is to purchase it ready-made from the factory. When looking at rainwater harvesting from the perspective of the rural poor, the factory made tanks are unlikely to be a realistic due to their high cost and transportation difficulties. The problem should be looked at from a self-help emphasis within the community. However, since tank construction is a skilled task, any self-help effort must involve specially trained individuals, even if the most basic tasks are left to the householders themselves.

Assistance should not only be in the form of technical skills, but also in the supply of raw materials and help in the method of payment. Several approaches to the development of necessary skills have been used in rainwater projects. Training may be offered to the village craftsmen, as in Kenya (Pacey and Cullis 1986), or to community workers or individuals chosen at village meetings who are given special training as 'village technicians' (Ichikawa 1995).

The design of the rainwater storage tank is not merely an abstract engineering problem, it is related to the type of assistance, the sort of materials and other resources that are locally available. In places where satisfactory rainwater storage jars or tanks are already available, assistance may come in other forms, such as, offering advice on what type of tank to buy, financial advice, health, or other hardware advice such as gutter construction.

Self-sustainability should be the ultimate aim of any RHW project, and where possible it should be independent of any external subsidy. Ideally the storage tank should be able to be constructed by local craftsmen, where possible using locally available materials, and funded by either the individual or community. Self-sustainability is not only the ability of individuals or communities to pay for and build their own tanks, but also to maintain them, so that the benefit the tank offers is permanent.

Once the tank is constructed, its performance should be monitored. Attention must be paid to deficiencies in maintenance, such as keeping gutters clean, as well as any other defect the tank may develop. As well as practical advice on tank construction and maintenance, other factors should be addressed such as water management and health issues regarding the stored water.

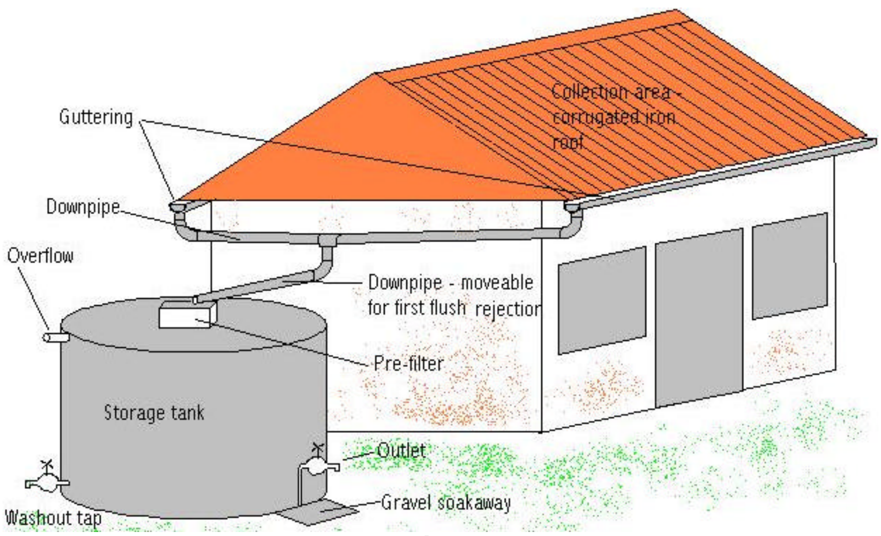

Fig. 1.0 Domestic rainwater harvesting system (DTU 1998).

From the engineering perspective, there are a number of RWH technologies that can be improved upon. These technologies, which involve the water collection and storage side of RWH, can be divided up into a number of key elements (see figure 1.0).

Tank sizes vary depending on ownership, domestic water storage tanks range from 1 to 10m^3 see figure 1.1, community water tanks vary from 10 to over 100m^3 (figure1.2). The main size limiting factor for domestic tanks is cost. For community tanks cost is a factor, but they are also size limited by catchment area and rainfall patterns. For typical ferrocement tanks constructed in Kenya costs vary from 50$US\$/m^3$ for a 11m^3 tank to 26$US\$/m^3$ for a 46m^3 tank (Gould 1999).

Fig. 1.1 A 8m^3 domestic ferrocement storage tank in Sri Lanka

Fig. 1.2 A 46m^3 community ferrocement storage tank in Uganda

As well as the above factors, ease of manufacture is an essential part of any good design. The majority of RWH projects are in rural areas, which may lack the resources and infrastructure that is available to the urban designer. Levels of construction skills may also be limited. This being so, ease of manufacture is a very important area, where possible the tank should be manufactured using a limited range of materials and tooling.

1.2 The Project

The project will investigate the problems associated with building water storage tanks in developing countries, with the final aim of giving the engineer a series of practical tips that will help with tank construction in the field.

The project will only investigate water storage tanks built above ground, where all the forces are carried by the tank walls. Water storage tanks can be constructed from a multitude of materials, but this project will concentrate on ferrocement. Ferrocement is a form of thin cement mortar reinforced with layers of continuous and relatively small diameter mesh. It is usually made from a mortar of Portland cement and sand applied to steel reinforcement which is often provided in the form of small aperture wire mesh, typically 15*mm* x 15*mm*, see figure 1.3. Ferrocement is a low-level technology and is labour intensive, it is therefore ideally suited for water tanks in rural areas of developing countries. Ferrocement is well suited for thin wall structures such as water tanks because the distribution and dispersion of reinforcement provides good cracking resistance, higher tensile strength-to-height ratio, ductility, and impact resistance.

Fig 1.3 Ferrocement tank under construction

The materials, which are usually imported into the area from nearby towns, can be relatively expensive. The cost of this material often puts water storage tanks out of reach of many people in the rural sector. It is therefore important for the designer to investigate where and how construction materials can be reduced. To reduce material inputs it is important to know how large the forces are and where they act and also to know if it can be constructed from local available materials.

Section two of the project investigates how structural analysis can be carried out to establish the forces in the tank. To achieve this the theory of thin walled shells is used. Also, in section two, an Excel spreadsheet has been developed to allow the designer to study any range of tank shapes and construction materials.

A reduction in construction material through reduced wall and base thickness makes the tank more susceptible to additional problems which include shrinkage. Section three investigates the different types of shrinkage and how they effect cement based materials. It also looks into the degree to which shrinkage may be aggravated in less developed countries where the environment tends to be harsher. As well as dry weather, developing countries often suffer with a shortage of construction skills and poor quality raw materials. Different ways to reduce the additional stresses which shrinkage induces will be examined. This includes looking at tank design and education in the appropriate use of the raw materials.

Section four examines the mechanics and development of cracks in ferrocement and how they effect the durability of the tank. There is a limited amount of literature on the mechanical properties of ferrocement, so in section five a series of practical experiments are carried out to investigate some of these properties. It is essential to ascertain the tensile strength of the materials as well as looking into the effects of cracking caused by shrinkage, therefore three tests will be performed. They are,

- Tensile strength testing,
- Unrestrained (free) shrinkage,
- Restrained shrinkage.

Section six discusses the significance of the findings, section seven offers practical tips for tank construction and in section eight there are recommendations for future work.

2.0 STRUCTURAL ANALYSIS

The aim of this section is to study the theory of how stresses develop in structures and then to use the theory to write a spreadsheet to give ‘real’ results.

When analysing the loading on a water tank, it can be considered as a thin walled shell structure because the overall radius is large compared to the wall thickness, usually the ratio is greater than 10:1. These shell structures can be classified as shown in figures 2.0(a) and 2.0(b),

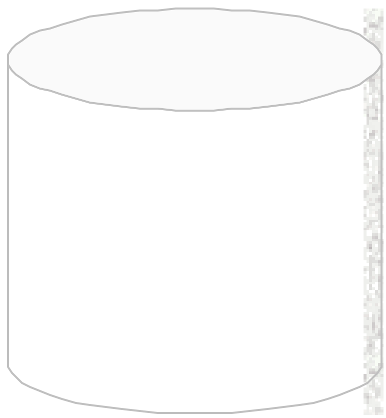

Fig 2.0(a) Singly curved shells

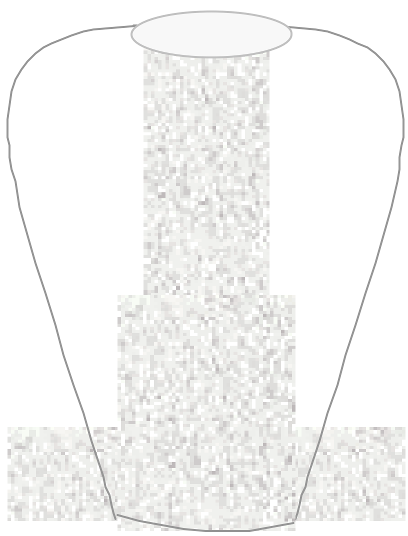

Fig 2.0(b) Doubly curved shells

The two main theories used when dealing with thin shells are,

- Membrane theory,
- Bending theory.

This project uses both membrane and bending theory. Initially the membrane theory will be used to calculate the stresses in the tank wall when there are no boundary conditions i.e. the tank walls are free to move, see figure 2.1(a).

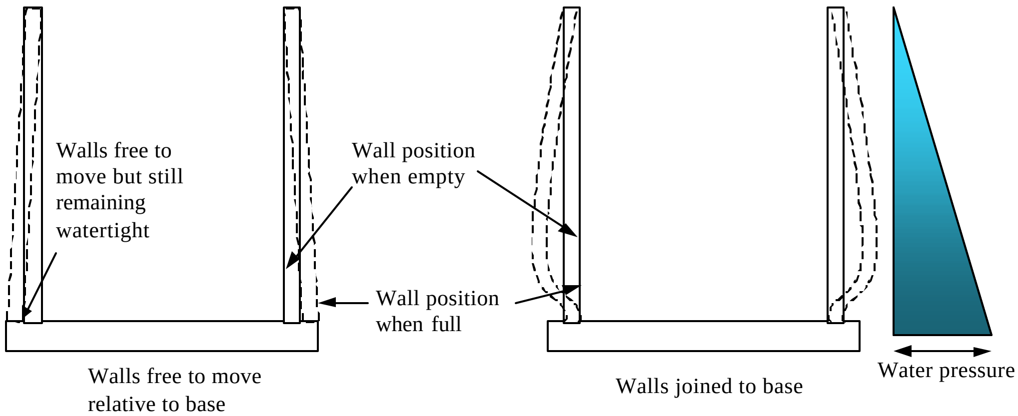

Fig. 2.1(a) Membrane theory

Fig. 2.1(b) Combined membrane and bending theory

In figure 2.1(b), the wall and base are monolithic i.e. the wall and base are continuous. As the wall is restrained bending stresses are set up in the wall. There now exists a complex combination of bending, shear and hoop stresses. Gray and Manning (1960) state that if the wall is not free to move at its base, then the loading caused by the water pressure is counteracted by a combination of hoop and cantilever resistance. It can be seen in figure 2.1(c) that as the base of the wall is restrained the hoop stress at the base is zero and the maximum hoop stress is now experienced higher up the wall. Bending theory is used to calculate this additional loading on the tank wall. The profile of the load distribution line is governed by the profile of the tank.

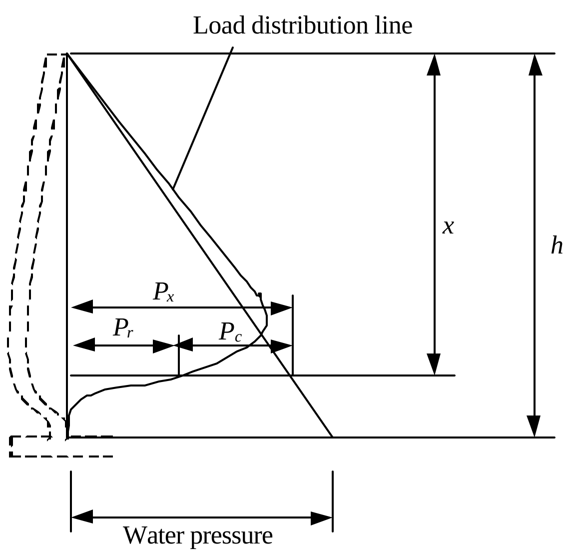

Fig 2.1(c) Typical load distribution for tank with a monolithic base (Gray and Manning 1960)

These theories are further simplified as only axisymmetric loading is considered. These loads are assumed to act at only the middle surface of the shell (wall), i.e. they pass through the centre of the structure. It is also assumed that the construction material is homogenous, isotropic, and linearly elastic, obeying Hooke's law.

2.1 Singly curved shells

Membrane theory

The governing equation for stress in singly curved shells, is;

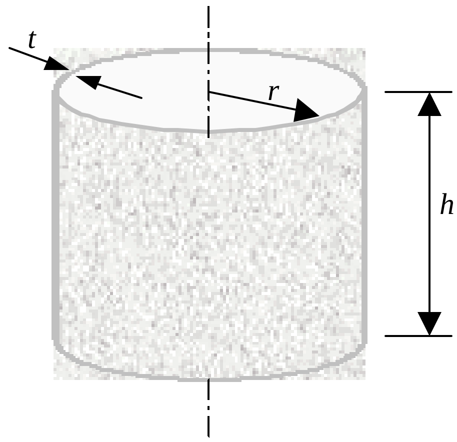

Fig. 2.2 Hoop force in singularly curved shell

$$N_q = p_r.r \tag{1}$$

To find the hoop stress (s), the hoop force is divided by the wall thickness (t) (Shigley 1983),

$$s_q = \frac{p_r.r}{t} \tag{2}$$

In this type of shell all the forces are resisted by the 'hoop' forces in one plane.

Tanks designed with singly curved shells, are probably the most common style of tank in current use as they are relatively easy to design and construct. Their main disadvantage is their weakness, they can only resist loads on one axis i.e. hoop forces.

Bending theory

As previously stated the membrane solution alone could not satisfy compatibility conditions at the boundaries. Bending theory can be further simplified by assuming that the base is solid and does not deflect. Using the spreadsheet it is possible to calculate the minimum depth which the base needs in order for it to be assumed to be solid and inflexible. The effects of edge loads have to be superimposed on the membrane solution. For both singly and doubly curved shells, these edge loads consist of shear forces (H_o) and bending moments (M_o).

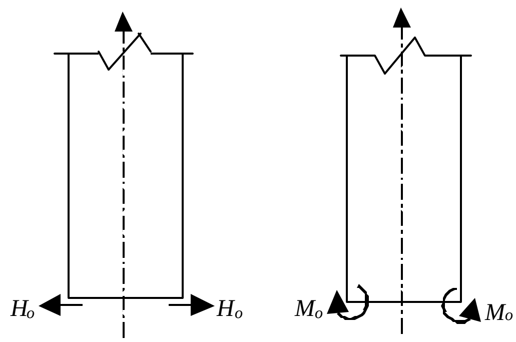

Fig. 2.3 Edge loads, H_o shear and M_o moments

These edge loads induce additional forces,

- M_x is the bending moment,
- Q_x is the shear force,
- $N_{\boldsymbol{q}}$ is the hoop force,
- w is the radial deflection.

these can be calculated from;

$$N_q = \boldsymbol{r} r \left[h - x - he^{-lx/r} \cos \frac{\boldsymbol{l}x}{r} + \left(\frac{r}{\boldsymbol{l}} - h \right) e^{-lx/r} \sin \frac{\boldsymbol{l}x}{r} \right] \qquad (3)$$

$$M_x = -\frac{\boldsymbol{r} rt}{\sqrt{12\left(1-\boldsymbol{n}^2\right)}} \left[\left(\frac{r}{\boldsymbol{l}} - h \right) e^{-lx/r} \cos \frac{\boldsymbol{l}x}{r} + he^{-lx/r} \sin \frac{\boldsymbol{l}x}{r} \right] \qquad (4)$$

$$Q_x = \frac{\boldsymbol{r}\, t\, \boldsymbol{l}}{\sqrt{12\left(1-\boldsymbol{n}^2\right)}} \left[\left(\frac{r}{\boldsymbol{l}} - 2h \right) e^{-lx/r} \cos \frac{\boldsymbol{l}x}{a} + \frac{r}{\boldsymbol{l}} e^{-lx/r} \sin \frac{\boldsymbol{l}x}{r} \right] \qquad (5)$$

$$w = \frac{\boldsymbol{r}\, r^2}{Et}\left[h - x - he^{-lx/r}\cos\frac{\boldsymbol{l}x}{r} + \left(\frac{r}{\boldsymbol{l}} - h\right)e^{-lx/r}\sin\frac{\boldsymbol{l}x}{r}\right] \qquad (6)$$

where;

$$l^4 = 3\left(1 - n^2\right)\left(\frac{r}{t}\right)^2$$

The effects of the additional loading forces are localised around the shell wall/base intersection. All the equations contain a multiplication term $e^{-l x/r}$, which means the effect will decay exponentially with distance moved away from the base. For a full derivation of the formulae see Flügge (1967).

2.2 Doubly curved shells

The structural analysis for doubly curved shells is more complicated than that of the singly curved shell. These shells have curvature in two planes, figure 2.4. This allows them to resist loads by generation of forces in the two planes. They are generally more efficient than singly curved shells. The two main forces are,

- the meridional force (N_f),
- the hoop force (N_q).

And the two main radii of curvature are,

- radius of curvature of the meridian (r_1),
- radius of curvature of the second principal curve (r_2).

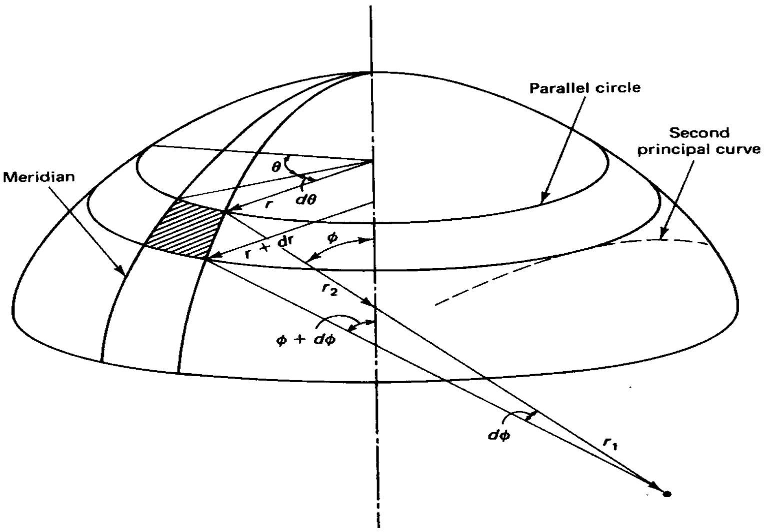

Fig. 2.4 Doubly curved shell, showing the parallel circle, principal curves, and shell element (Kelkar and *Sewell1987*)

The main equation governing the forces in a doubly curved shell is;

$$\frac{N_f}{r_1} + \frac{N_q}{r_2} = p_r \qquad (7)$$

Where p_r is the pressure at a particular point.

Equation (7) is rearranged to find the hoop force N_q;

$$N_q = r_1\, p_r - \frac{r_1}{r_2} N_f \qquad (8)$$

After some mathematical manipulation the general solution for the meridional force N_f can be found as follows;

$$N_f = \frac{1}{r_2 \sin^2 f}\left[\int \left(p_r \cos f - p_f \sin f\right) r_1 r_2 \sin f \, d f + k\right] \qquad (9)$$

where k is a constant of integration to be obtained from an appropriate boundary condition.

The next step is to find the geometric parameters for the shell. The shell's profile can be described as a curve, where $y = f(x)$. The principal radius of curvature of the surface in the meridional plane, r_1, and the second principal radius of curvature, r_2, are given by;

$$r_1 = \frac{\left\{1+\left[f^{'}(x)\right]^2\right\}^{3/2}}{f''(x)} \tag{10}$$

$$r_2 = \frac{x}{\sin f} \tag{11}$$

where $f'(x)$ and $f''(x)$ denote first and second derivatives of $f(x)$ with respect to x. By sketching a right-angled triangle it can be seen that;

$$r_2 = \frac{x\left\{1+\left[f^{'}(x)\right]^2\right\}^{1/2}}{f'(x)} \tag{12}$$

and angle f is;

$$\sin f = \frac{f'(x)}{\left\{1+\left[f^{'}(x)\right]^2\right\}^{1/2}} \tag{13}$$

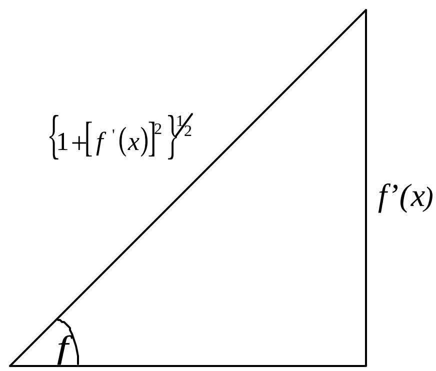

Fig. 2.5 Trigonometric interpretation of the equations

To calculate the stress resultants, figure 2.6 shows a shell of revolution generated by a rotation of a curve $y = f(x)$ about the y axis, filled with liquid of density r, to a depth $h = f\left(x_H\right)$. The pressure p_r acting in direction normal to the shell at height $g = f(x)$ above the bottom of the tank is given by;

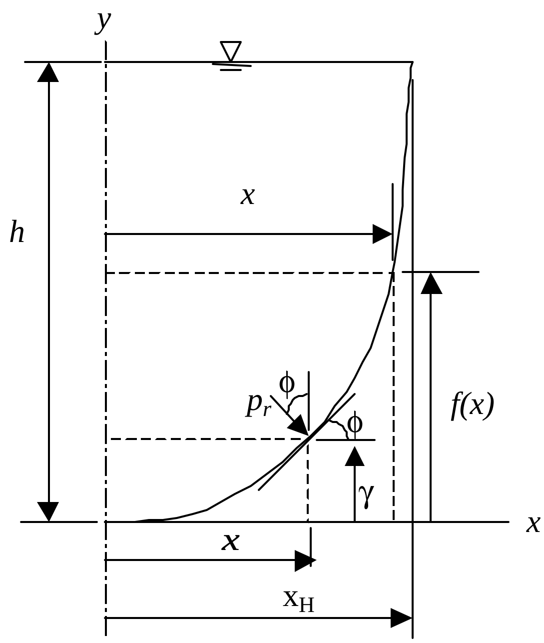

Fig 2.6 Liquid shell of revolution (Zingoni 1997)

$$p_r = \rho g(h-\gamma) = \rho g\{f(x_H) - f(\xi)\} \tag{14}$$

The net vertical resultant *W(x)* of the pressure acting on the shell whose edges are defined by *(x,(f(x))* is obtained by integration, as follows;

$$W(x) = 2\pi\rho g\left\{\frac{x^2}{2} f(x_H) - \int_0^x \xi f(\xi)\,d\xi\right\} \tag{15}$$

The meridional stress N_ϕ can be found by resolving forces in the vertical direction;

$$2\pi x N_\phi \sin\phi = W(x) \tag{16}$$

Form (16) and using the expression for *W(x)* from (15), and the expression for $\sin\phi$ given in (13), N_ϕ is found as follows;

$$N_\phi = \rho g \frac{\{1+[f'(x)]^2\}^{1/2}}{x f'(x)}\left\{\frac{x^2}{2} f(x_H) - \int_0^x \xi f(\xi)\,d\xi\right\} \tag{17}$$

As seen previously the hoop stress N_θ is given by (2).

The total volume *V* of the tank is obtained from (15), by dividing the total weight of the liquid, this is equal to $(W(x_H))$, by the unit weight ρg, thus;

$$V = 2\pi\left\{\frac{x^2}{2} f(x_H) - \int_0^{x_H} \xi f(\xi)\,d\xi\right\} \tag{18}$$

The total surface area S of the (constant thickness) tank is obtained by rotating the curve $y = f(x)$ about the y axis[2].

$$S = 2\pi \int_0^{x_H} \left\{1 + \left[f'(x)\right]^2\right\}^{1/2} dx \qquad (19)$$

To find out how much the tank walls deflect under load the strain is required. Since both N_θ and N_ϕ have already been found using membrane theory, the following relationship can be used to find the strains;

$$\varepsilon_\phi = \frac{1}{Et}\left(N_\phi - \nu N_\theta\right) \quad \& \quad \varepsilon_\theta = \frac{1}{Et}\left(N_\theta - \nu N_\phi\right) \qquad (20)\ \&\ (21)$$

Generally only the horizontal deflection Δ_H is required (Kelkar and Sewell 1987), i.e. the increase in size around the diameter of the tank;

$$\Delta_H = r\varepsilon_\theta = \frac{r}{Et}\left(N_\theta - \nu N_\phi\right) \qquad (22)$$

In the following section the formulae will be have been substituted into two Excel spreadsheets, one for singly curved shells and the other for doubly curved shells.

Due to the complexity of bending theory for shells of general revolution, it will not be incorporated. The solution given by the membrane theory gives good results for many practical problems, (Kelkar and Sewell 1987).

There are a number of good books that cover the full derivation of all these formulae, such as, ‘Shell Structures’ by Zingoni (1997) or ‘Analysis and Design of Shell Structures’ by Kelkar and Sewell (1987).

2.3 The Excel spreadsheets

The most common shape is the cylindrical tank, this style of tank resists all its applied loads in one plane. These loads vary linearly from a minimum at the top to a maximum at the base. Tanks are usually constructed with a constant wall thickness, which has to resist the maximum load at the bottom of the tank. This means that above this point the material is under utilised, and therefore wasted. To overcome this problem the tank shape may be varied, it could be made conical or tank thickness could be varied from top to bottom.

It is a well known fact that that certain shapes resist loads better than others, for example, if constructed of similar materials, a domed roof is stronger than a flat roof. Therefore it is important to investigate stresses in more unconventional tank shapes, such as the 'pumpkin' tank shown in figure 2.7(a) or the jar shaped in figure 2.7(b).

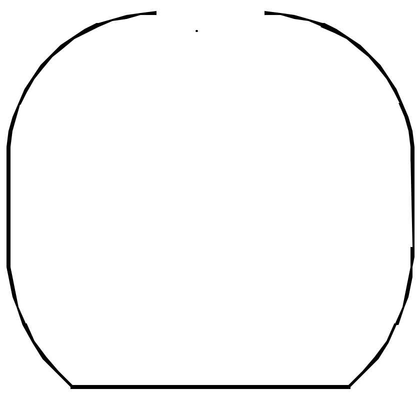

Fig 2.7(a) Pumpkin tank

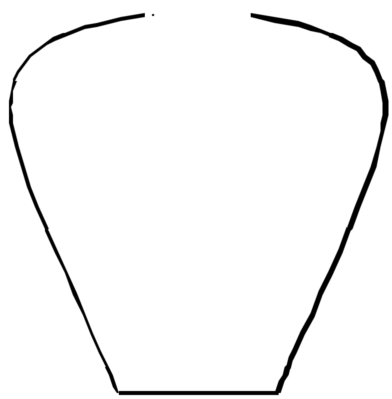

Fig. 2.7(b) 'Thai' Jar tank

The Excel spreadsheet lets the designer experiment with various shapes of tank and calculate where the maximum forces occur. These forces include shear, hoop and meridional force intestines, and bending moments, as well as tank wall deflection. The spreadsheet used to analyse the forces in the singly curved shells takes into account additional forces caused by the tank wall/base intersection (bending theory). The spreadsheet can be used to help with material optimisation as it can work out the ratio of construction material to water storage capacity.

The spreadsheet used to calculate forces in singly curved shells has already been used by the Development Technology Unit to aid in the design of a rammed earth water tank.

There are two spreadsheets, the first one analyses singly curved tanks and the second doubly curved tanks.

Singly Curved tanks

To start the operation a number of INPUTS are entered including material yield tensile strength, tank volume, base and lid thickness; and a suitable safety factor, see figure 2.8.

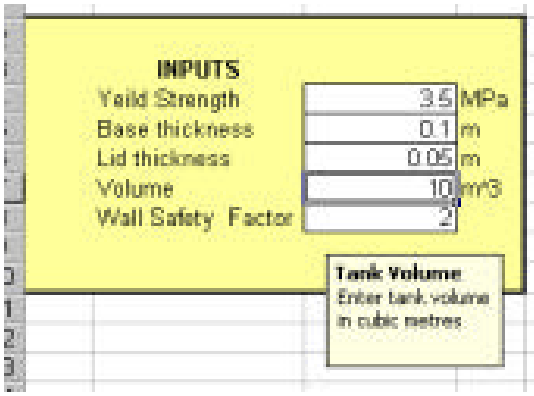

Fig. 2.8 Input parameters

The yield strength of the material can be found from literature but if unconventional materials are being used, i.e. ferrocement, it may be necessary to carry out some form of mechanical strength testing. The material yield strength used in this example was found using experimental methods (see section 5.0). The results given by the numerical model are only as accurate as the material property data therefore it is vital at this stage to enter data that is as close as possible to realistic figures.

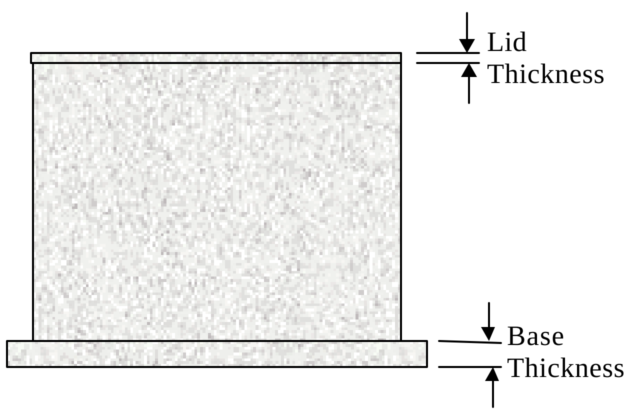

Fig. 2.9 Tank base and top geometry

The thickness of the base and lid (see figure 2.9) are used when calculating the amount of tank construction material needed to make the tank. The base thickness is also used in calculating the base rigidity (to be discussed later). The safety factor can be chosen by the designer, this may depend on a number of factors. Examples include uncertainty on the quality of raw materials, climatic and geological conditions, as well as unusual loading such as wind.

For this example, the tank volume is $10m^3$ with the data given in figure 2.8, a range of tank sizes and amount of raw material required for construction is calculated, see figure 2.10.

Diameter	height	Wall thickness		Material	
0	#DIV/0!	#DIV/0!	m	#DIV/0!	m^3
0.2	318.31	0.178	m	67.53	m^3

Fig. 2.11 Inputs used to calculate tank wall and base rigidity

For the shell theory discussed in section 2.1 to be valid, it is assumed that the tank base is totally solid with no deflection. To calculate the base and wall flexibility the Youngs modulus (*E*), Poisson's ratio (*PR*) and volume fraction are required. Ferrocement is a composite of two materials, in the spreadsheet the cement mortar is called the matrix and reinforcement is called the fibre. The volume fraction is the volume of reinforcement per unit volume of ferrocement.

The spreadsheet is also capable of finding the minimum base thickness that is required to make a totally rigid base. It can be seen in figure 2.12 that for this particular tank, it can be seen that the base is totally rigid if its thickness is greater than 15*cm*, making the base any thicker than this will just be a waste of material.

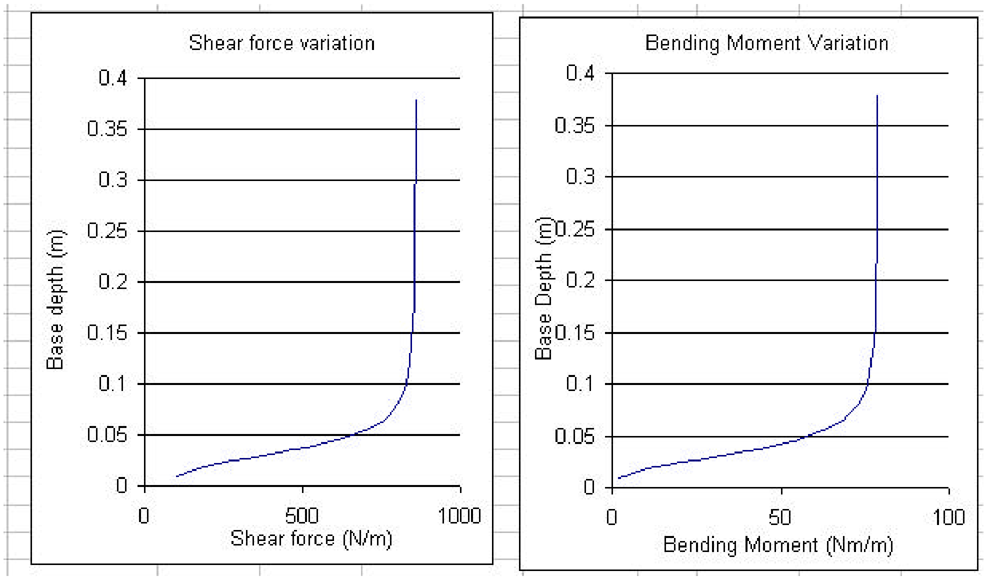

Fig. 2.12 Variation in shear force and bending moment

The spreadsheet calculates the maximum stresses, deflection and bending moment and at what point they are greatest, see figure 2.13. The ratio of construction material to water storage capacity is another deliverable. A full print out of the spreadsheet can be found in Appendix V

3.6E-10 17

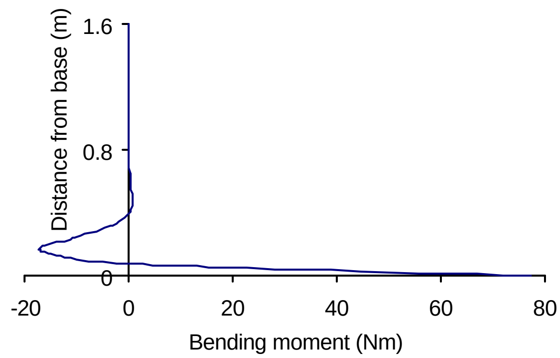

Figure 2.14(d) Variation in bending moment

The spreadsheet also allows the user to calculate the hoop stress in the tank wall if the wall is free to move, i.e. not connected to the base as shown in figure 2.1(a).

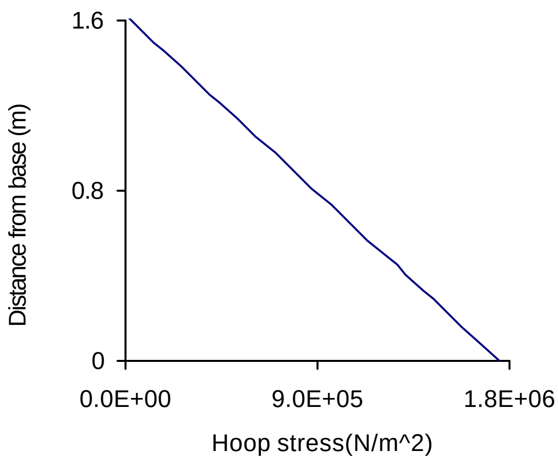

Fig. 2.15 Variation in hoop stress with floating base

Doubly curved shells

This spreadsheet is used to calculate the forces in the doubly curved shells. It is not as user friendly as the spreadsheet used for the singly curved format. As before, the material characteristics including: Young's modulus, Poisson's ratio, volume fraction and wall thickness, are entered.

For the tank profile shown in figure 2.17, the following data has been entered.

1						
2			Input			
3						
4	E wall matrix	35	Gpa	PR wall matrix	0.1

Fig 2.18 Results for doubly curved tank

The spreadsheet calculates the maximum deflection, hoop stress, and meridional stress and at which point from the base of the tank they are the greatest. It also calculates the volume, surface area, the amount of raw materials required in construction and the ratio of raw materials to water storage capacity.

The variation in meridional and hoop stress is displayed in figure 2.19.

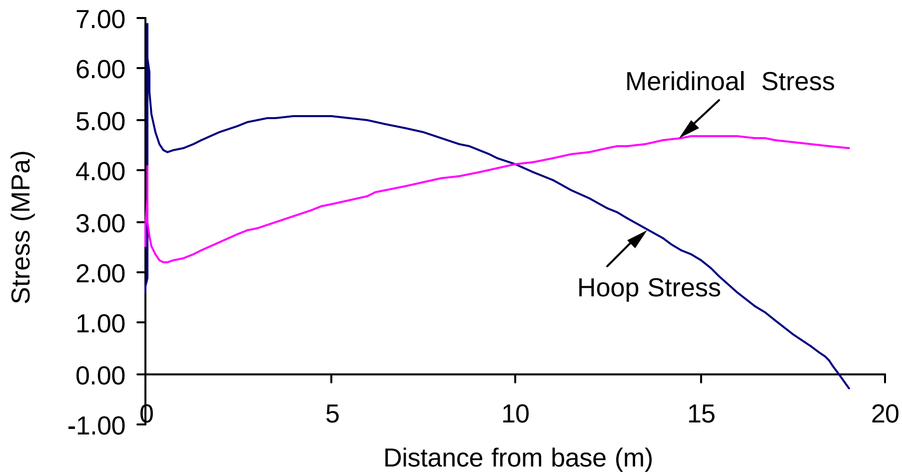

Fig 2.19 Variation in membrane stress

Variations in stress near the base of the tank can be ignored, this is due to the breakdown of the membrane hypothesis. The tank wall deflection, i.e. the increase in tank radius, can be seen in figure 2.20.

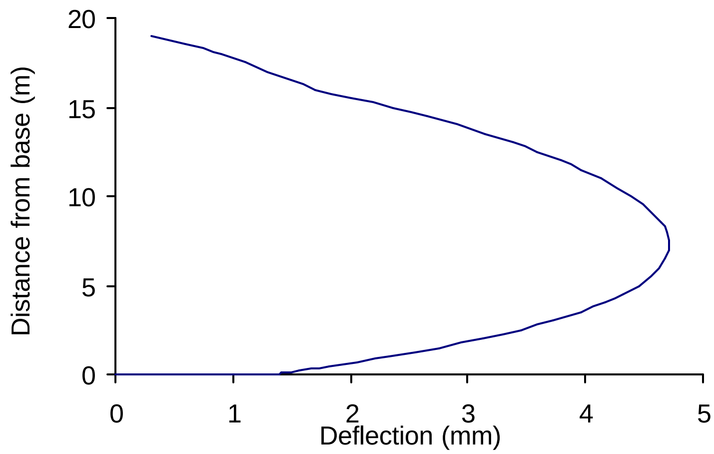

Fig. 2.19 Variation in Deflection

Discussion

The spreadsheets are to be used as tools to aid in the designing and construction of water storage tanks. They give the designer an opportunity to experiment with many shapes of tank, as well as material properties. The designer can enter any required tank specification, the spreadsheet is then run and the results are given. Changes to the tank specification can be made immediately. This process allows iterations to be made quickly and easily. The program results can be plotted out, this gives the designer a graphical representation of the forces. The visualisation of these forces will help with the design process.

From the results for the singly curved tank, figures 2.14a-c, it can be seen that the greatest load is near the base of the tank. In figure 2.15, for the tank whose wall is not attached to the base, the maximum force is at the bottom of the tank. For the doubly curved tank, see figure 2.19, the forces are more uniformly distributed over the whole tank wall. These results show the designer that if they require a tank of uniform wall thickness and hence a uniform wall strength, the doubly curved tank is the most suitable, as the forces are distributed evenly over the whole tank. It can also be seen that if a uniform wall is used to construct a singly curved tank, the construction material used in the upper part of the tank is not fully utilised and therefore wasted. Other factors have to be taken into consideration such as construction difficulties, a greater degree of skill is required to construct a doubly curved tank compared to a singly curved tank.

It is assumed that the designer is using a homogenous construction material which can withstand forces equally well in both a vertical and horizontal direction, a characteristic of ferrocement. The results and theory show that for singly curved tanks the majority of force is on the horizontal plane but for the doubly curved tanks, the force is on both vertical and horizontal planes. This means that the construction material is used to its full potential for the doubly curved tank.

It can be seen from figure 2.15, which if the wall is free to move relative to the base, the maximum stress and therefore wall deflection, is at the bottom of the tank wall. When the bottom of the wall is restricted from moving, as in figure 2.14(a-c), the maximum hoop force and wall deflection are a small distance from the base. This distance depends on the size of the tank and the characteristics of the construction materials used. Using these results the designer can decide where to position any extra reinforcing.

To overcome the problem of additional forces that are generated by the base wall interface it is possible to construct a tank so that the wall is free to expand. The Development Technology Unit is currently examining this construction technique at Warwick University. It is achieved by positioning two polythene strips between the wall and base, see figure 2.21. This reduces the sliding friction between the two surfaces, and therefore the wall is relatively free to expand, eliminating the additional forces.

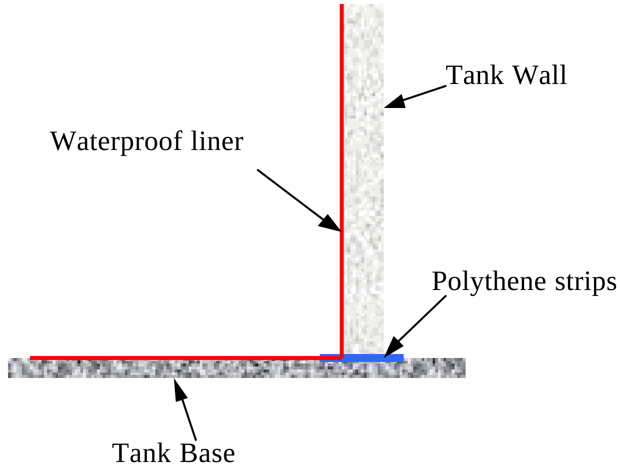

Fig 2.21 Experimental tank with sliding wall

The designer is also free to experiment with safety factors, these will vary according to raw material, climatic and ground conditions.

3.0 SHRINKAGE

This section of the project will concentrate of the effects shrinkage has on water tanks constructed from ferrocement. The mechanics of shrinkage in cement is a complicated subject and will not be fully explored in this report. Further information on the mechanics of shrinkage can be found in a number of books, including 'Proprieties of Concrete' by Neville (1995) and 'Concrete Technology' by White (1991).

3.1 Classes of Shrinkage

Shrinkage can be divided into three main categories. They are,

- Plastic,
- Autogenous,
- Drying.

Plastic Shrinkage

This takes place when the concrete is still in the plastic state. The volume change is small, in the order of 1% of the absolute volume of dry cement (American Concrete Institute). Although the mechanics of plastic shrinkage are not fully understood, it is known that it can lead to surface cracking. The amount of shrinkage is related to the rate of evaporation. One practical conclusion is that thin sections, such as tank walls, should not be cast under hot and dry conditions.

Autogenous Shrinkage

Autogenous shrinkage results in volume change without the loss of moisture. The magnitude of the strain induced is in the order of $40x10^{-6}$ at the age of one month and $100x10^{-6}$ after 5 years (Davis 1940). The contraction is relatively small and of significance only in large mass structures. This project only deals with thin walled structures therefore this type of shrinkage can be ignored as it very low compared to drying shrinkage.

Drying Shrinkage

As the cement sets it looses moisture, this loss of moisture causes shrinkage. This type of shrinkage has the greatest effect on the water tank. Shrinkage in the order of 2,000 x 10^{-6} has been observed (Singh 1989). The finer the grain size in the mix the greater the shrinkage, cement for example will have a greater degree of shrinkage compared to concrete. The rate at which the shrinkage occurs depends on the speed of water loss, therefore in hot, dry and windy climates rates of shrinkage will be high.

3.2 Differential shrinkage

The problems that shrinkage creates are worsened by the effects of differential shrinkage. Differential shrinkage occurs if water loss from one area is greater than another, this is especially so in the early stages of curing. This type of shrinkage has a tendency to induce internal stresses in the structure and can lead to cracking. Differential shrinkage occurs in all cement-based products but to what extent depends greatly on the size and shape. It can be seen from figure 3.0 that the thinner the section the greater the shrinkage, this is because the moisture loss is faster. Therefore structures that have large surface areas compared to volume, a characteristic of water tanks, will have a tendency to display a high degree of shrinkage. For practical purposes shrinkage cannot be considered as purely an inherent property of the cement without reference to the geometry of the structure.

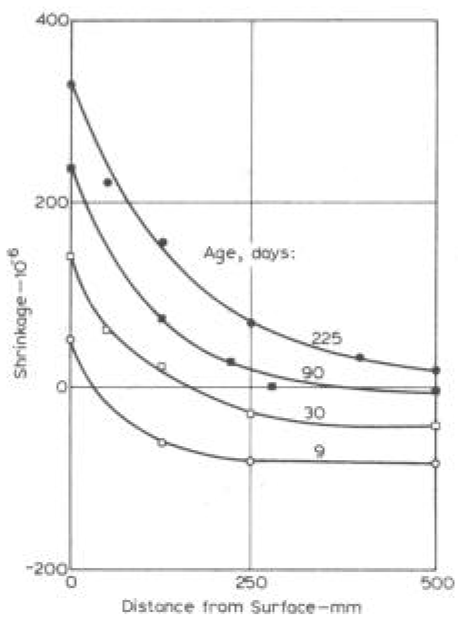

Fig.3.0 Effect of dimensions on shrinkage (Neville 1995)

There are a number of ways to help reduce the problems caused by differential shrinkage when building tanks in a hot climate;

- The wall thickness should be kept constant throughout the tank this will reduce the build up of internal stress.
- Ideally, the tank should be constructed in a shaded area, this will reduce water loss.
- The tank should be constructed in the coolest part of the day, ideally in the morning so the construction materials have had the opportunity to cool down overnight.
- The tank should not be constructed so it is half shaded, again this will cause internal stress to be built up.
- The application of cement mortar should be as continuous as possible. Rendering wet mortar onto dry should be avoided, as stresses will build up between the layers.
- A good curing regime is required, such as the use of wet hessian and plastic covers.

3.3 Restrained Shrinkage

The effects of shrinkage are only really a problem if the stresses they induce are not able to release themselves. If strains due to shrinkage cannot develop freely, large internal stresses are developed. If these tensile stresses are greater than the tensile strength of the material, cracking and sometimes total failure may occur. Shrinkage in any form weakens the structure as it acts as a preload this may lead to unexpected failure even under low loads. The effect of restrained shrinkage is shown in figure 3.1, the ends of the cement mortar specimen are held and as the cement shrinks, cracks start to form, usually at the weakest point.

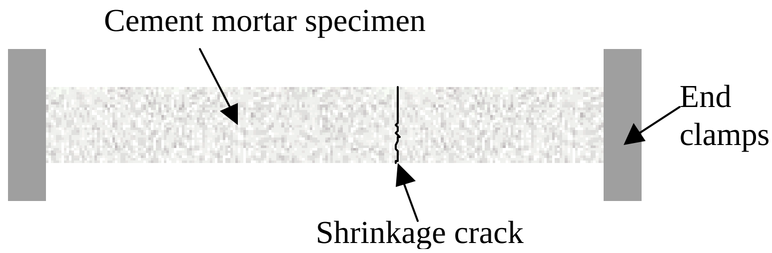

Fig. 3.1 Cracking caused by shrinkage

In the case of the water tank in figure 3.2, the bottom of the structure is usually cast earlier than the walls, consequently the shrinkage strains at the bottom ε_{base} and the walls ε_{wall} may be very different. Since the base of the wall cannot move freely additional bending moments and forces develop at the base/wall interface.

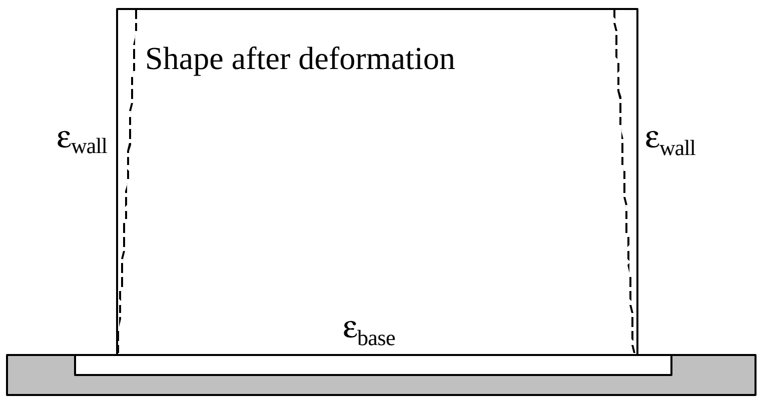

Fig. 3.2 Effect of shrinkage on the tank wall

3.4 Further factors that influence shrinkage

There are number of other factors that effect the degree and rate of shrinkage. They include,

- Water/cement ratio,
- Curing and storage conditions,
- Aggregate.

Water/cement ratio

In general, the higher the water/cement ratio the higher the degree of shrinkage. It has been demonstrated that shrinkage is directly proportional to the water/cement ratio between values of about 0.2 to 0.6 (Neville 1995). At higher water/cement ratios, the additional water is removed upon drying without resulting in shrinkage. A minimum water/cement ratio of 0.4 is required for the cement to reach its full strength, as the water/cement ratio increases the strength is adversely effected. In practice, this value of 0.4 is rarely achieved because of difficulties in working of with such a dry mix.

Curing and storage conditions

Curing is the name given to the method used for promoting the hydration of cement. It consists of the control of temperature and of moisture movement from and into the cement mortar. The main object of curing is to keep the cement saturated or as near to saturation as possible. Prolonged moist curing delays the advent of shrinkage.

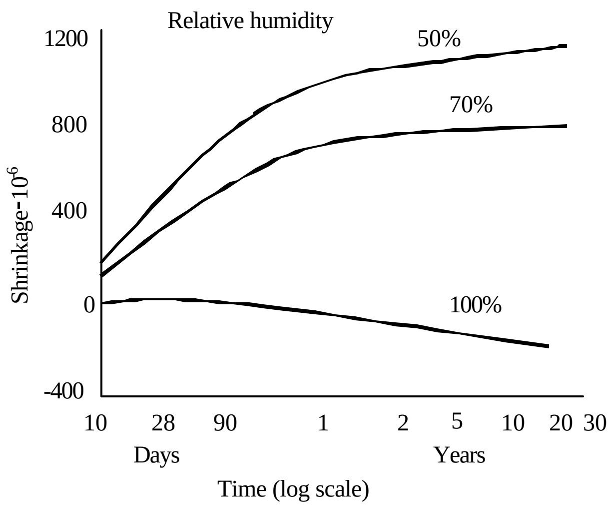

Fig. 3.3 Relationship between shrinkage and humidity (American Concrete Institute)

The ambient temperature has an important effect on the degree of shrinkage. Working with cement in hot weather, greater than 30^0C (Neville 1995), can cause problems. Because of the high evaporation rate there is a loss of workability and increased shrinkage. The increased shrinkage can cause high internal stresses that may lead to cracking. It is therefore advantageous to cast cement in cooler conditions, less than 20^0C, as the rate of water evaporation is less. This will reduce shrinkage rates as well as increasing strength.

The relative humidity of the surroundings also effects the degree of shrinkage. It can be seen in figure 3.3 that the drier the environment, the larger the degree of shrinkage. When the cement mortar is stored in 100% humidity (in water) it swells. Once removed from the water it will start to shrink. The above data is based on a mortar mix of 1:5, with a water cement ratio 0.59. The results are taken after 28 days of wet curing.

Aggregate

The size and grading of aggregate influence the magnitude of shrinkage. In general, coarser aggregate leads to lower rates of shrinkage because leaner mixes can be made. Ferrocement contains very fine aggregate in the form of sand so to make it workable relatively high water/cement ratios are required, typically in the range of 0.5 to 0.6. This makes ferrocement tanks very susceptible to shrinkage.

4.0 CRACKING

The development of cracks in any form of water retaining structure can have serious repercussions. This section looks at the how cracks develop in ferrocement and how their propagation can be reduced.

Cracks in ferrocement are mainly caused by:

- thermal and moisture movement incompatibilities between the phases of cement paste, sand and reinforcement,
- fatigue caused by repeated loading,
- induced stress caused by shrinkage.

This report will only deal with the later, stress cracks caused by shrinkage. Concerns regarding cracks in ferrocement, are expressed as follows:

- Aesthetic, from the aesthetic point of view a 0.3mm crack seen at a close distance is quite concerning, but viewed from a distance of 2 to 3 metres it is quite acceptable.
- Leakage, Nedwall and Swamy (1994) recommend an upper limit of 0.05mm for water-retaining structures.
- Durability, from the materials durability aspect, the stronger the construction material, the less likely it is to crack and the longer the tank life (assuming there is no mechanical damage).

In the case of the water tank one of the main concerns is leakage. This has two effects, loss of water and corrosion of the reinforcing material. Corrosion of the reinforcing mesh leads to spalling. Finely distributed reinforcement (wire mesh) combined with large mortar cover increases the resistance to corrosion. The permeability of the ferrocement depends greatly on the care taken in applying the mortar. The recommended minimum cover is only 2mm (Skinner 1995), assuming if the cement is applied well and cured in an appropriate manner. Because of variations of material and construction quality in less developed countries, Gould (1999) recommends a cover of 30mm, giving a wall thickness of 60mm. There are number of practical problems when it comes to applying very thin layers of cement mortar, the main one being the difficulties in ensuring an even cover over the wire mesh and that all the mesh is covered to the minimum thickness.

Development of cracks

Cracks with an applied tensile force in ferrocement develop in three stages. It can be seen in figure 4.0(a) that in the first stage of development both materials in the composite respond elastically, if the load is removed they will return to their unloaded state.

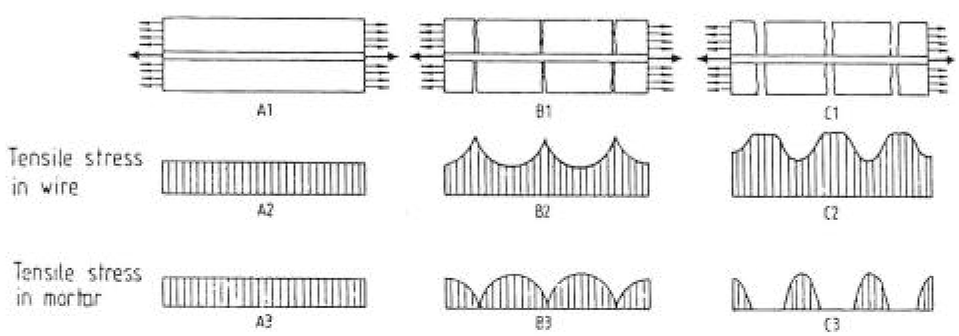

Fig 4.0(a) Stage one Fig. 4.0(b) Stage two Fig 4.0(c) Stage three

The ferrocement enters its second stage when micro cracks start to appear. During this stage, shown in figure 4.0(b), the number of cracks keeps increasing with the load though the width. Figure 4.0(c) show that the increase is only marginal. In the third stage, the number of cracks remain almost constant but their width increases with load. The mortar in the ferrocement no longer has any effect on its strength. Assuming that the steel reinforcement has not passed its yield point, if the load is removed the sample will contract leaving open cracks in the mortar.

The cracks develop in this way because the cement mortar is not as ductile as the steel reinforcement. It can seen that as the cracks develop, the load on the reinforcing increases and finally when the cracks are fully developed (stage three) the reinforcing carries all the load. The practical result of this is that, if quality of the mortar is not known and catastrophic failure is to be avoided, then the tank needs to be designed so that the reinforcing is capable of carrying the entire water load.

5.0 MATERIAL TESTING

This project looks into the practical effects of shrinkage on ferrocement water tanks. Shrinkage plays an important role in tank design as it induces forces that can cause tank failure. It is important to know the magnitude of these forces, and ways to reduce their detrimental effects need to be investigated. There is a limited amount of literature on the mechanical properties of ferrocement therefore three tests have been devised to help investigate these properties and their effect on shrinkage. They are:

- Tensile strength,
- Unrestricted shrinkage,
- Restricted shrinkage.

It is necessary to know the tensile strength of the material, as it is needed to produce realistic results in the spreadsheets. It is used in conjunction with the unrestricted shrinkage findings to calculate the theoretical crack propagation in the cement sample. The tensile strength is found by applying a direct tensile load, discussed further in section 6.2.

The unrestrained shrinkage test is needed to investigate the magnitude shrinkage. If the specimen's movement is not restricted, these results are used to help calculate the theoretical crack development of each sample. To measure the unrestrained shrinkage, blocks of each specimen are to be cast and then are allowed to set over a 28-day period, daily readings are taken and the shrinkage is calculated, discussed further in section 6.3.

The restrained shrinkage test is used to investigate the crack development in four different specimens. The test is aimed at mimicking the effect of cracking in the tank wall caused by the restriction in movement due to the base/wall junction (see figure 2.1). Two tests are used, the first looks at cracking in a reinforced specimen block and the second investigates cracking in a ring sample, both tests are discussed further in section 6.4.

There are numerous types of reinforcing materials used to enhance the mechanical properties of cement mortar. This project is aimed at tank construction in developing countries therefore only reinforcing that is available in these countries is to be used. Three types of reinforcing material that are commonly available are:

- Chicken wire (volume fraction 1%),
- Square mesh (volume fraction 2%),
- Polypropylene fibres (volume fraction 1.5%).

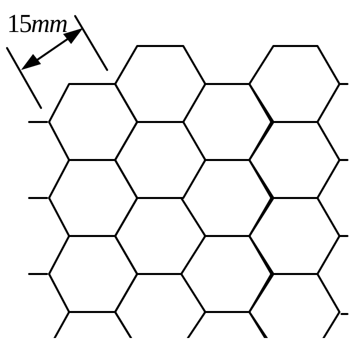
As little is known about the effects of reinforcing is the experimental volume fraction for each reinforcing material (shown above) are to be used.

To ensure uniformity of results, it is important to use an appropriate research methodology.

5.1 Procedure

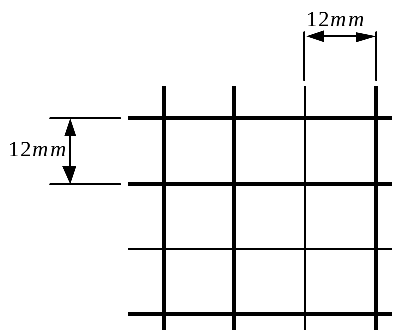
Materials

The chicken wire (figure 5.0(a)) and square mesh (figure 5.0(b)) are manufactured from galvanised mild steel. The polypropylene fibres are 'home-made' (figure 5.0(c)) and are approximately 10mm stands cut from a length of rope. The material's mechanical properties are given in Appendix I.



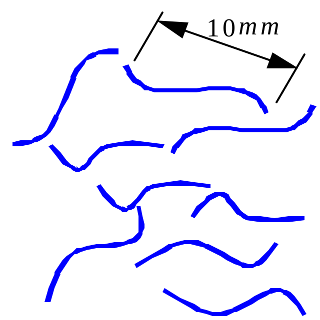
Mesh diameter = 0.5mm

Fig 5.0(a) Chicken wire



mesh diameter = 1.0mm

Fig 5.0(b) Square mesh



fibre diameter ≅ 0.5mm

Fig 5.0(c) Polypropylene fibres

The cement used in all the mixes is Ordinary Portland Cement (OPC). This is mixed with standard building sand to a ratio of three parts sand to one part cement by weight, with a water cement ratio 0.6.

Mixing and making

When cement based products are made in developing countries they are usually hand mixed. Due to the problems caused by the high ambient temperature, such as rapid setting due to water loss and in turn reduced workability there is a tendency to make a relatively wet mix. There is also sometimes a lack of knowledge about the correct consistency of cement. As stated previously, for the optimum strength of the cement, a water cement ratio of 0.4 is required. To add authenticity to the results all the samples are made using a relatively high water cement ratio of 0.6 and they are all mixed by hand. With increased mixing time, the strength of the cement paste slightly increases and variations in strength decrease therefore for the sake of uniformity all the dry materials are mixed for approximately three minutes and then wet mixed for a further three minutes.

Curing and storage

It is usual practice to cure samples of this size in a water pond for 7 days but to try to get a level of authenticity to the results, a curing regime is used that is more likely to be found in most developing countries. All of the samples are cured under wet/damp hessian for 7 days, the hessian is moistened on a daily basis. It is acknowledged that the weather patterns of a tropical country cannot be easily modelled in the workshop. Whilst the experiments were carried out the samples were stored at 25^{o}C, with a relative humidity of approximately 40%, this may be equivalent to an area such as Northern India in spring.

5.2 Tensile Strength

To help get a feel for the magnitude of tank wall thickness for various sizes of water tank. It is necessary to find out the tensile strength of the construction material. There is a great deal of documentation for the strength of concrete but little is known of the strength of ferrocement.

All the structural analysis is performed using thin shell theory. The assumption in this theory is that all the force is carried in tension through the centre of the material. There are three types of test for strength in tension: Flexural test, Splitting tension test, and Direct tension test. The first two tests are not suitable for the strength analysis used in the thin wall theory. In the Flexural test the reinforcing is at the outer edge of the sample.

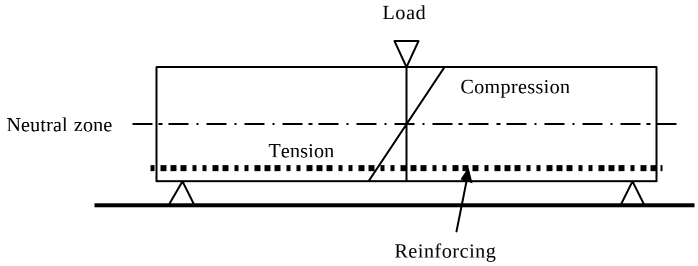


Fig 5.1 Modulus of rupture test

The indirect tensile test is used for testing the tensile strength of materials with a uniform constituency, such as concrete. This test is not suitable because the samples contain metal reinforcing.

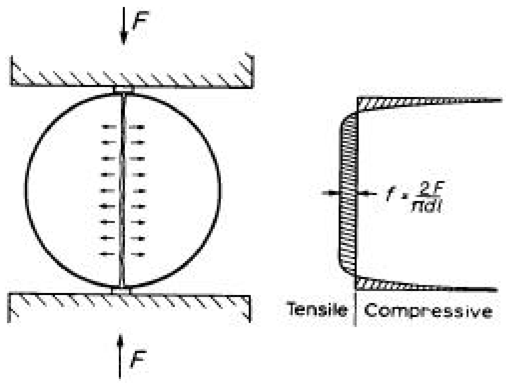

Fig. 5.2 Indirect tensile strength test (Kong and Evans 1985)

Therefore a more unconventional direct tension test has to be used to find the tensile strength. The direct tension test raises a number of problems, a direct application of a pure tension force, free from eccentricity, is very difficult. The test equipment used consisted of a square plate, into this a length of M10 threaded bar was screwed. On the other side of the plate four lengths of M6 threaded bar were attached.

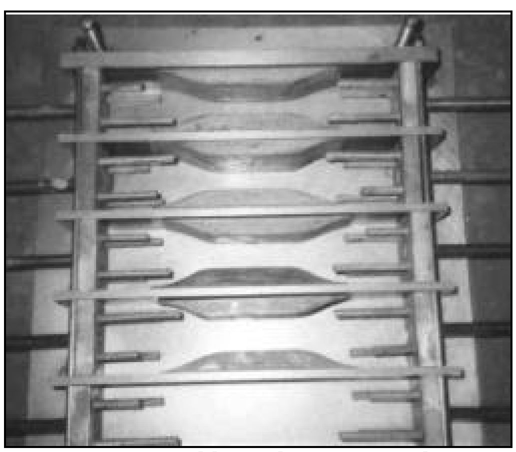

Fig. 5.3 moulds used to cast samples

The cement sample was cast onto the 6mm bar. The samples were manufactured in batches of five, in a mould (see figure 5.3). They were mechanically vibrated, this was carried out to aid compaction as there was difficulty manually compacting due to restricted access. To avoid creating a weak point at the end of the M6 retaining bars, the bar lengths were varied from 35 to 50*mm* long, see figures 5.4 and 5.5.

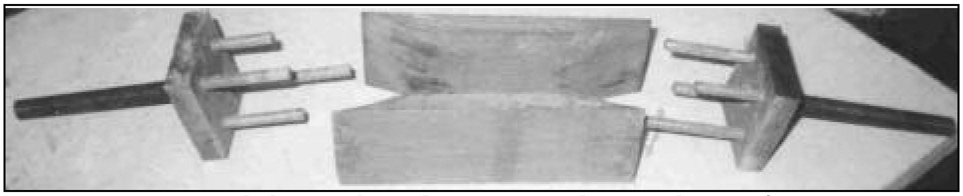

Fig 5.4 End plates and wooden inserts used in sample manufacture

The tensile load is applied through the 10mm bar by the tensile testing machine.

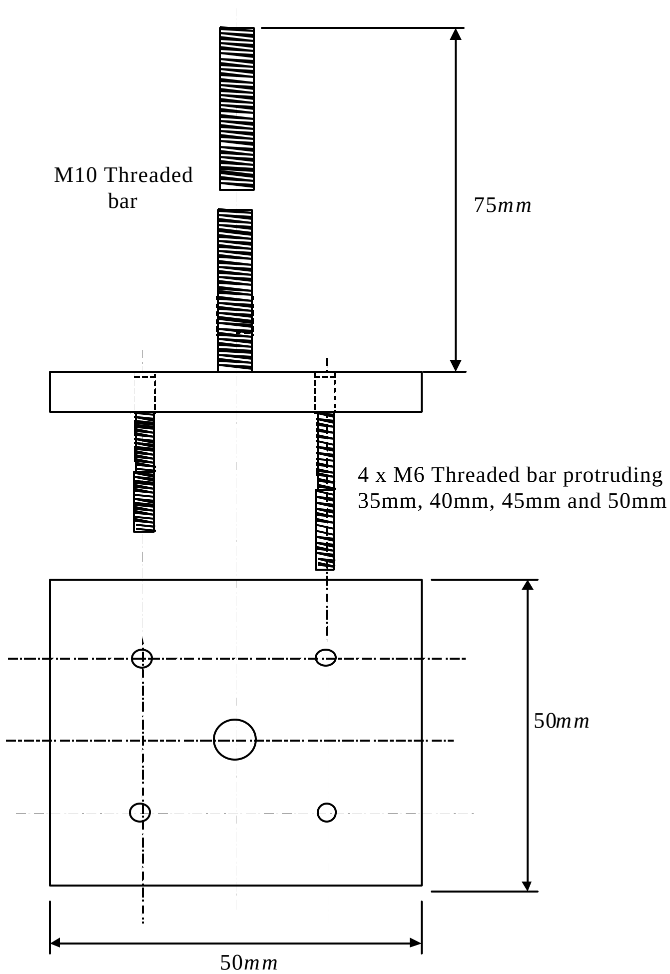

Fig. 5.5 Test plate assembly

The overall dimension of the specimen is shown in figure 5.6

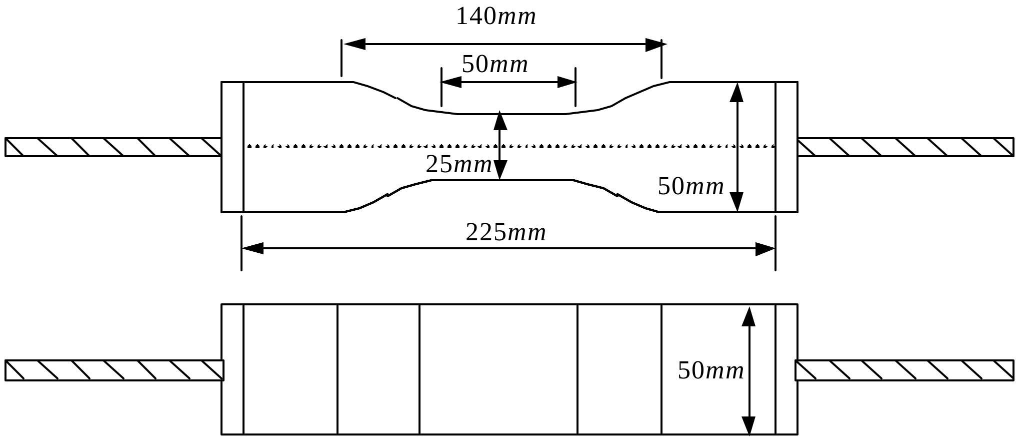

Fig 5.6 Specimen dimensions

To ensure the sample fails in the correct region the sample is necked using two wooden inserts, see figure 5.7.

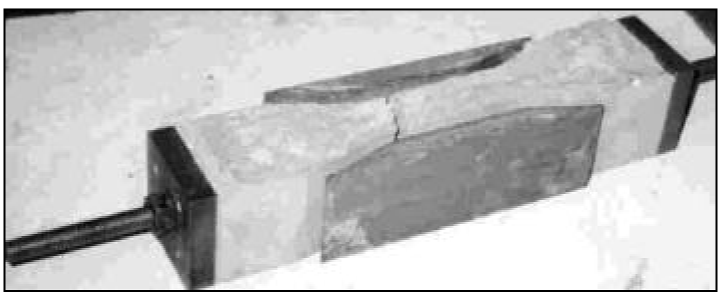

Fig 5.7 Wooden inserts used to neck samples

A full set of drawings of the test equipment can be seen in appendix II.

Results

The samples were tested using a Testometric 100kN tensile testing machine. The results only show breaking loads. During the test, loads were applied at a strain rate of 0.07*mm/min* until the cement failed, at this point the load was removed. In the case of the chicken wire reinforced samples the mortar and mesh failed at the same time. With the square mesh the mortar failed first. To increase the accuracy of the results five of each sample were made and the mean strength was found. A full set of results is given in Appendix III.

Results for samples reinforced with one sheet of 13mm 19 gauge (1mm diameter) galvanised mild steel square mesh (4 strands) and one layer chicken wire also galvanised.

Sample	Average Strength (MPa)	Standard Deviation	Coefficient of variance
Plain mortar	1.60	0.57	0.24
Reinforced with chicken wire	1.90	0.45	0.15
Reinforced with square mesh	2.40	0.41	0.13

Table 5 tensile test results

Discussion

The results show that the reinforced samples are stronger. It can also be seen that there is less variation in strength in the reinforced samples compared to the non-reinforced. The reinforcing mesh acts in two ways, it provides tensile strength, but more importantly it restricts crack growth. It can be seen in figure 5.8 that if there is a flaw in the sample it acts as a stress concentrator where cracks can start to grow. In the plain mortar samples there is nothing to stop the propagation of the crack. In the reinforced sample crack propagation is stopped or restricted when it meets the mesh. The effect the mesh has on the cement is analogous to rip-stop nylon.

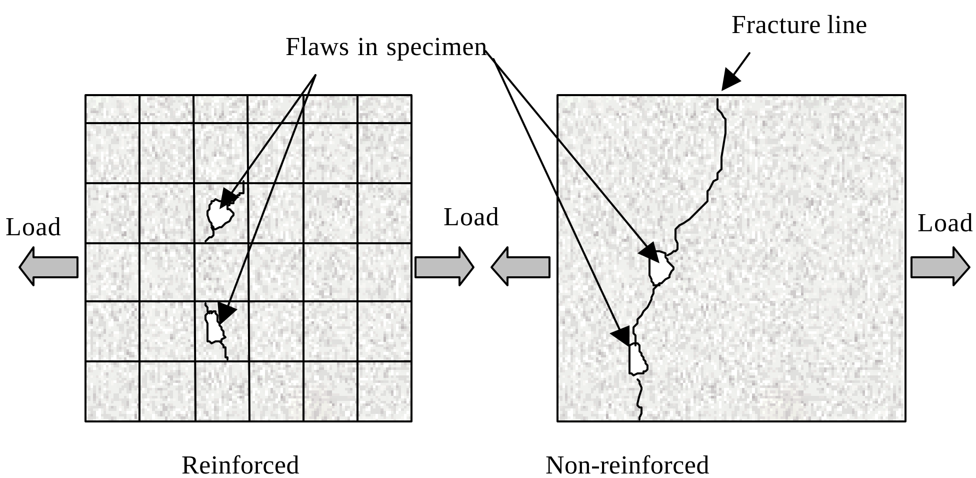

Fig. 5.8 Crack propagation in cement

Figure 5.8 shows one of the square mesh reinforced sample in the third stage of crack development (discussed in section 4.0). The sample was subjected to a tensile load, this load was increased until the cement mortar broke, then the load was removed. It can be seen that although the sample has failed it still retains its integrity, this implies that if the tank fails due to overloading, the failure will and will not be catastrophic but initially only lead to water leakage. If the cracks are small, e.g. less than 0.05mm, leakage will not occur. Cracks larger than 0.05*mm* will leak, this will cause water loss and corrosion on the reinforcement, which will also lead to spalling.

5.3 Unrestrained (free) shrinkage

The unrestrained shrinkage test is used to find the degree to which the specimen contracts if it is free from external clamping. These results are used to calculate the theoretical crack development of each sample. The unrestrained shrinkage tests were carried out on three samples, plain cement, chicken wire reinforced and square mesh reinforced. The reinforcement volume fraction and positioning was similar to that for the tensile testing (see figure 5.9). All of the samples are 225*mm* long and have a 50*mm* square cross section, see figure 5.9. The length of the sample over which the measurements were taken was 200*mm*. The unrestrained shrinkage test was not performed on any fibre reinforced samples as work in this area has already been carried out by Karagular & Shah (1990), see Appendix IV, and showed that the addition of fibres does not substantially alter the degree of free shrinkage.

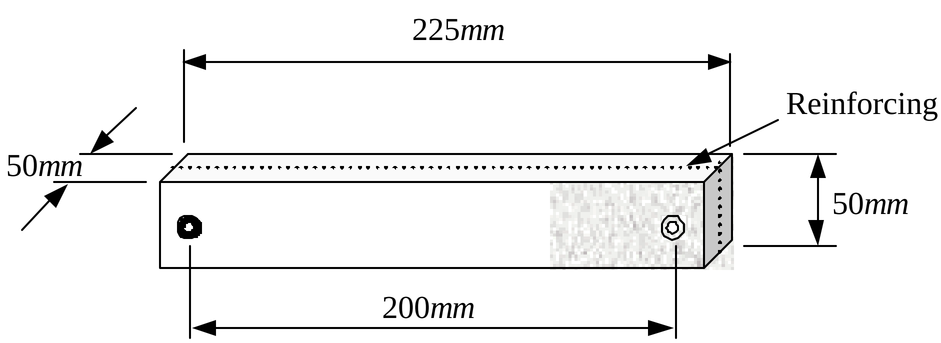

Fig. 5.9 Dimensions of unrestrained shrinkage sample

Daily readings were taken over a 28-day period using a demountable mechanical strain gauge (see Appendix II). To investigate any possible warping caused by differences in drying rates, measurements of shrinkage were taken two on sides of the sample, see figure 5.10.

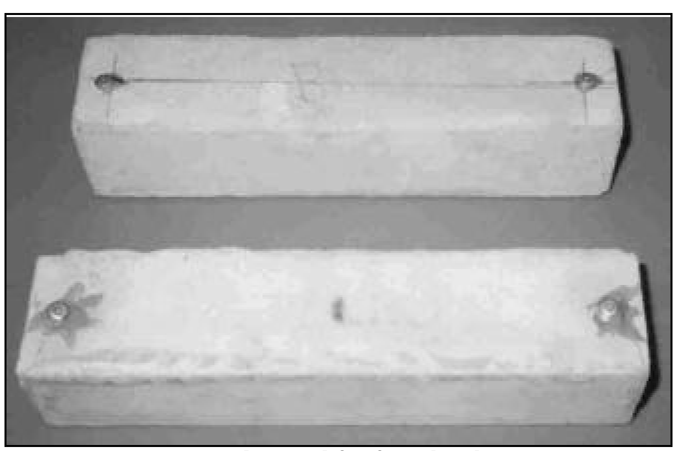

Fig 5.10 samples used for free shrinkage rests

Results

The results from this test compare favourably with the theory that was discussed in section 3.0 and Neville (1995). It can be seen in figure 5.11 that rates of shrinkage are relatively high, this is due to the high water/cement ratio (0.6), dry storage conditions (40% humidity), and an average temperature of 25^{0}C. The initial swelling is due to curing in a damp environment (under hessian), once this is removed the samples began to shrink. All data points are points are given in Appendix III.

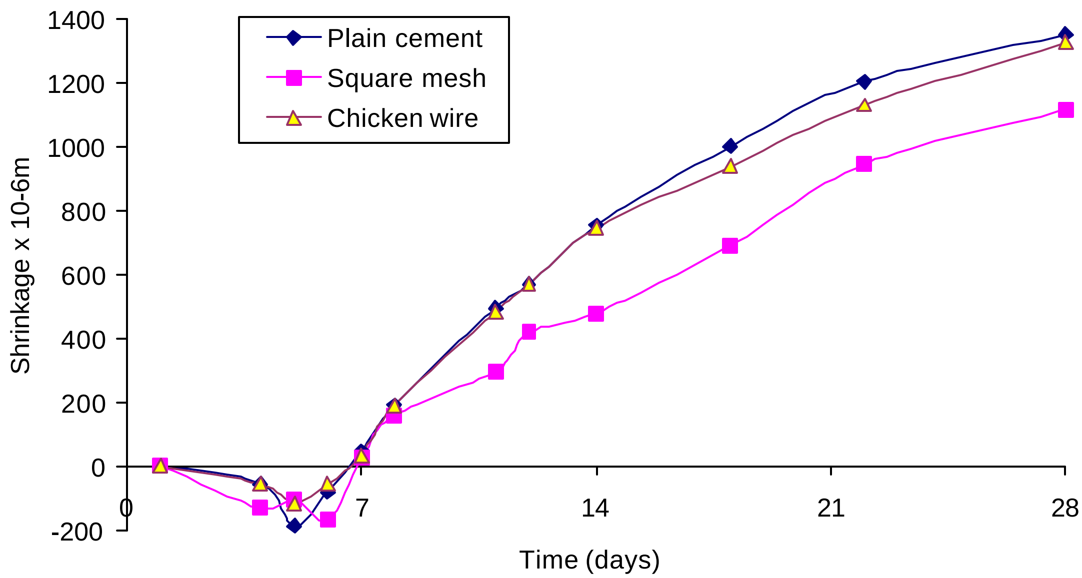

Fig. 5.11 Unrestrained Shrinkage results

Discussion

Cement swells when kept in moist conditions and shrinks in dry, the hotter and drier it is the faster the rate of shrinkage. As stated earlier, ferrocement tanks built in developing countries are very susceptible to rapid shrinkage because they have high wall area to volume, high water/cement ratios and they tend to be constructed in hot (and sometimes dry) climates. The results from the free shrinkage test show that there is initial swelling of the cement and as it dries it shrinks.

If the shrinkage is free to develop without any restriction, and it does not generate any extra stresses it should have little effect on the tanks performance. It can be seen that the use of chicken wire has little effect on the degree of shrinkage when compared to the plain sample. The ferrocement sample that contains square mesh has the greatest effect on the degree of shrinkage, this will induce additional internal stresses in the material.

The chicken wire does not perform as well as the square mesh when it comes to restricting shrinkage because it has a tendency to collapse under load, whereas the square mesh carries the load in same plane, see figure 5.1(a). There are two other reasons why the chicken wire may not perform as well:

- they are the wire is a smaller gauge,
- there is a lower volume fraction.

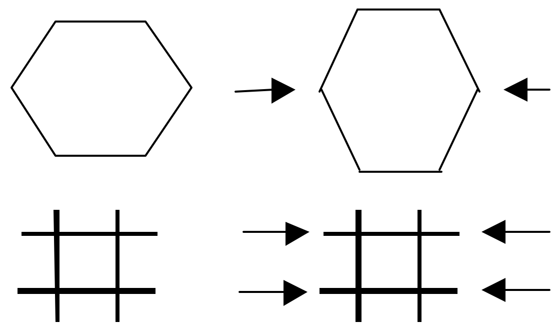

Fig. 5.11(a) Effects of compressive load on wire mesh

If the samples were restrained so that the strain caused by the shrinkage was not free to relieve itself, then the cracks would start to develop when the stress caused by the shrinkage exceeds the tensile strength of the material. Using the values for Youngs modulus in appendix I, i.e. 3.0GPa for cement and 210GPa steel, and knowing the volume fraction it is possible to calculate the overall Youngs modulus for each specimen. Using the results from the tensile testing (table 5), the theoretical time after which cracking will start to occur can be calculated, these are shown in table 5.1.

Sample	Tensile strength (s) MPa	E (GPa)	$e=\frac{s}{E}$ (me)	No. of days before cracking starts (see figure 6.7)
Plain	1.6	3.50	373	9.5
Chicken wire	1.9	3.67	518	10.5
Square mesh	2.4	3.85	623	17

Table 5.1 Breaking strains

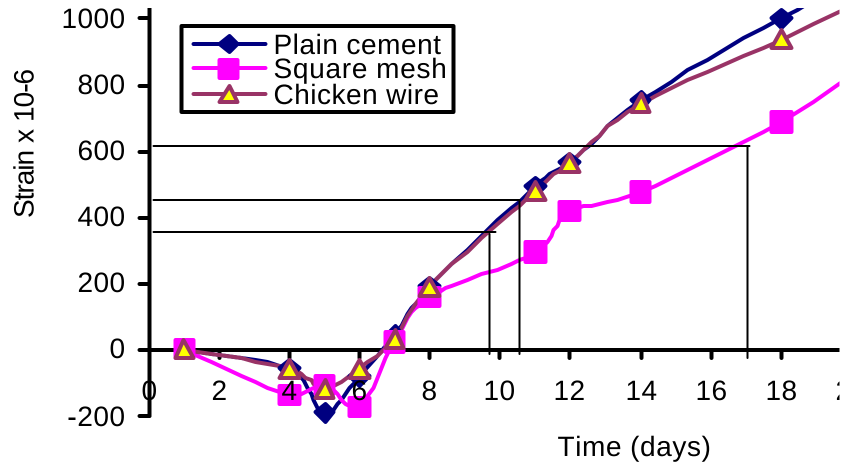

Fig 5.12 Breaking strain

It can be seen from figure 5.12 that the higher the tensile strength, the longer it will be before cracks start to develop. The practical implications are that to stop the tank cracking one or more of the following must be done:

- the amount of reinforcement needs to be increased, Skinner (1995) recommends a volume fraction of at least 5.1 to 6.3%,
- the tank needs to be kept in moist conditions so shrinkage is minimised (see section 3, figure 3.3),
- or the wall thickness needs to be increased so that the tensile strength is higher.

5.4 Restrained Shrinkage

The restrained shrinkage test is used to investigate how the cracks develop in a cement specimen. The test is aimed at mimicking the effect of cracking in the tank wall caused by the restriction in movement due to the base/wall junction (see figure 2.1). There is no British Standard test to assess cracking caused due to restrained shrinkage so a test had to be devised. The first test investigated cracking a reinforced specimen block, this test proves to be unsuccessful so a second test was used. The second test investigated cracking in a ring sample. The main failure in the first test was the effectiveness of the retaining pins, using a ring specimen this problem was overcome.

Test Method 1

An initial test was devised to examine when and where the specimen would crack if the shrinkage were restrained. To ensure that the test gave reliable results it was important to ensure that the two ends of the cement specimen were not free to move. A test rig was set up using a section of steel 'U' channel and two of the end plates from the tensile testing experiment, see figure 5.13. The 'U' channel had two purposes, it was a mould for the sample to be cast in to and it also ensured that the end plates did not move.

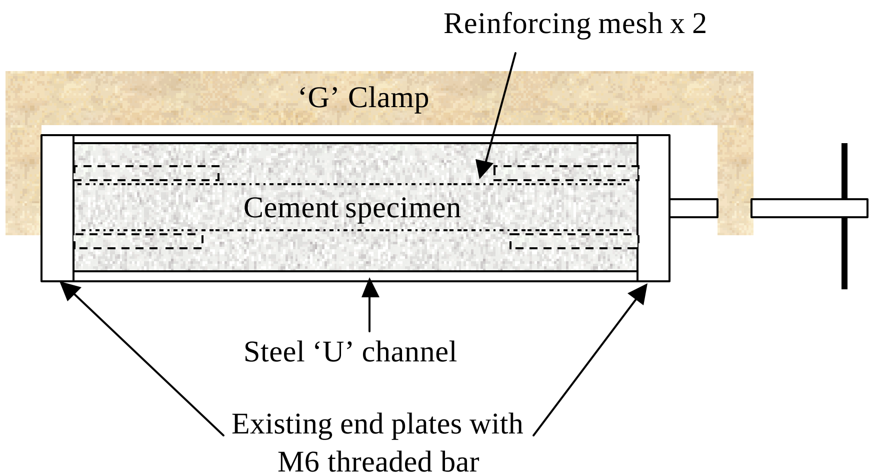

Fig. 5.13 Initial crack test

Results

This test gave inconclusive results, there was initial cracking, but these did not develop beyond micro cracks (less than 0.1*mm*), see figure 5.14.

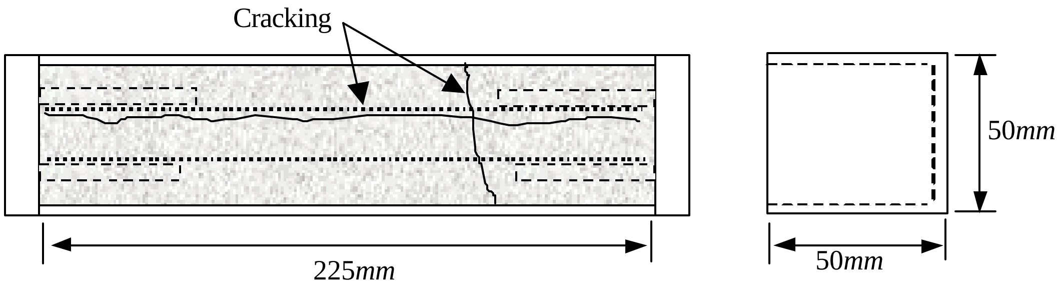

Fig. 5.14 Cracking caused by shrinkage

It can be seen from the specimen in figure 5.15 that even after 28-days the cracks were difficult to see without very close examination.

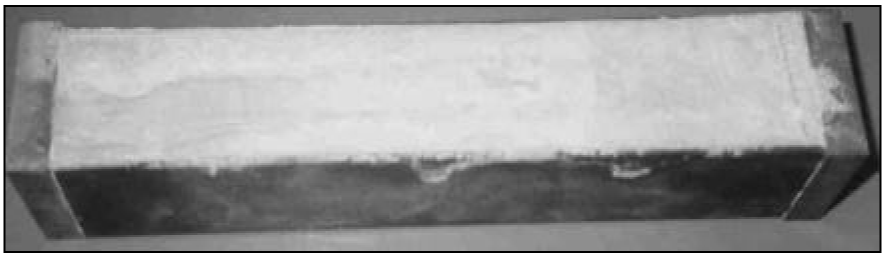

Figure 5.15 Micro crack development in restrained sample

The results from the unrestrained shrinkage tests showed that the amounts of shrinkage should have been much greater. These inconclusive results could have been due to a number of reasons such as that the specimen was cast in a steel ‘U’ channel therefore the cracks could only be viewed from surface also the moisture could only escape through one face. Another factor affecting the poor results was that the cement mortar might have pulled off the threaded retaining pins therefore leaving the mortar free to contract. All these factors lead to the test being discarded and a more reliable test being developed.

Test Method 2

Test method two overcomes the problem of holding the sample. A ring mould is used (see figure 5.16) and the cement is then rendered onto the outside of it. This test is likely to give more reliable results compared to the first test as it more resembles a ‘real life’ tank. In similar way to an actual tank, the ring mould gives greater surface area where moisture can escape therefore modelling real life conditions.

Due to time restrictions and uncertainties in the testing technique only one of each sample was made, one of each of the following:

- Reinforced with one layer of square mesh (see figure 5.17),

– Reinforced with one layer of chicken wire (see figure 5.17),

– Reinforced with 'home-made' polypropylene fibres,

– Plain mortar.

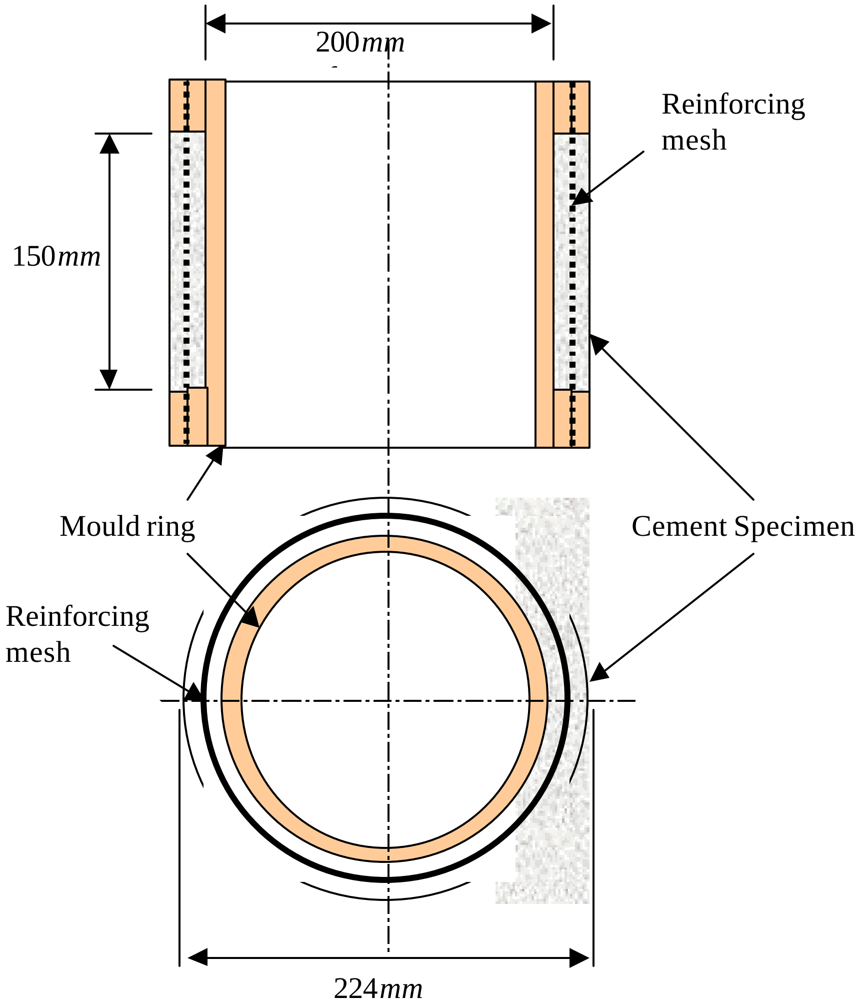

Fig. 5.16 Ring test used to investigate cracking

As with all the other samples, these were manufactured using the procedure described in 6.1, i.e. cured under wet/damp hessian for 7 days. Whilst the experiments were carried out the samples were stored at 25°C, with a relative humidity of approximately 40%. The cement used is OPC, which is mixed with standard building sand to a ratio of three parts sand to one part cement by weight, with a water/cement ratio of 0.6.

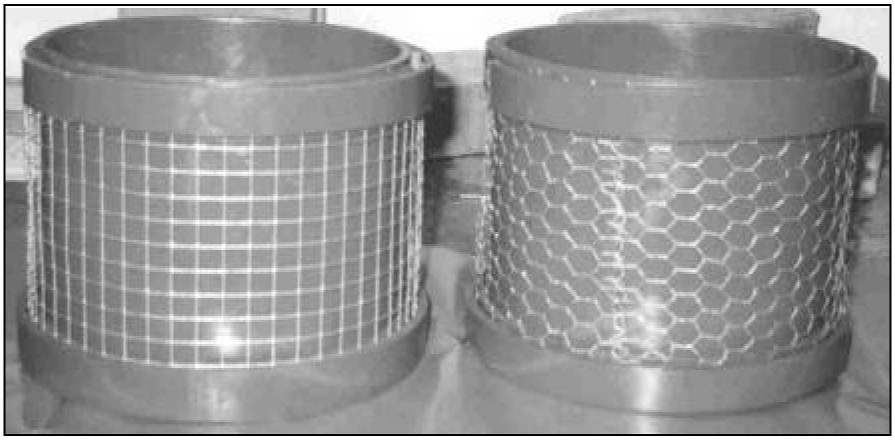

Fig 5.17 Reinforcing on test rings before mortar is rendered on.

As with both the tensile and unrestrained shrinkage, the restrained shrinkage tests were also carried out over a 28-day period.

Results

Plain mortar

The plain mortar specimen (figure 5.18) showed signs of cracking after five days. A single crack developed at a relatively linear rate, approximately 0.09mm/day. After 28 days the crack width was approximately 1.75mm.

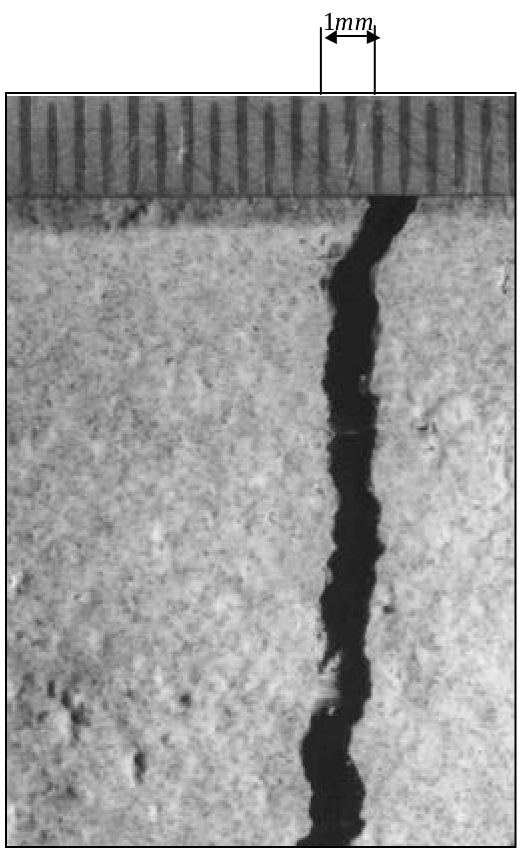

Fig. 5.18 Crack in plain mortar sample

Fibre reinforced

In this case two vertical cracks developed over the complete length of the specimen, they were approximately 180^{o} apart. After 28 days the larger crack was slightly less than 0.5mm (figure 6.19(b)) and the smaller one approximately 0.1mm (figure 5.19(a)). The cracks started to develop after 6 days and developed at a relatively linear rate, the larger crack at approximately 0.02mm/day and the smaller at 0.005mm/day.

Fig. 5.19(a) Small crack in fibre reinforced sample

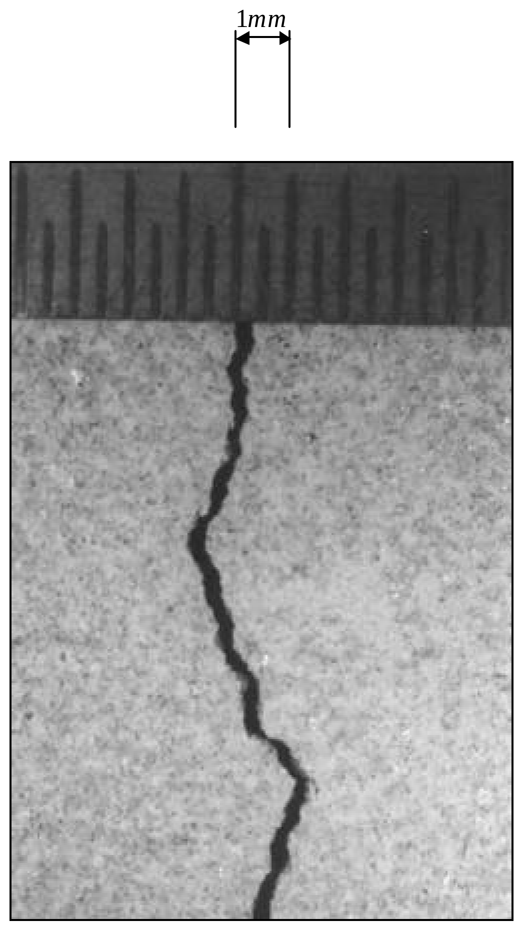

Fig. 5.19(b) Large crack in fibre reinforced specimen

It cannot be clearly seen in the photographs but the fibre strands in the mix bridged the gaps between the cracks helping hold the sample together and therefore reducing shrinkage. This is illustrated in figure 5.20. The fibre also added to the tensile strength of the specimen, this also helped to reduce the shrinkage.

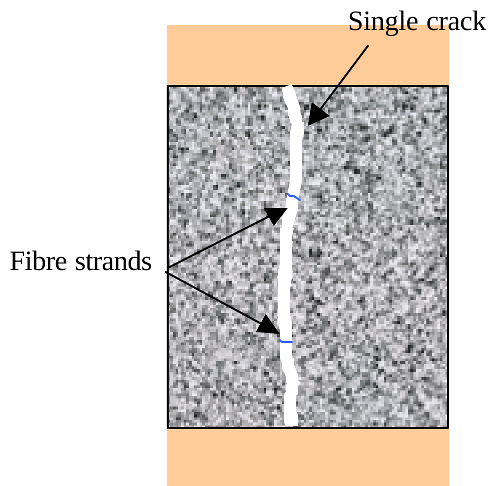

Fig. 5.20 Fibre reinforcing

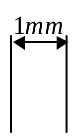
Chicken wire reinforced

In the specimen containing chicken wire reinforcing the crack size was greatly reduced compared with the two previous samples. It can be seen from figure 5.21(a) that chicken wire reinforcing increased the number of cracks but reduced the size of individual cracks. Figure 5.21(b) shows a single larger crack with a width of approximately 0.2mm, due to the effects of the reinforcing. Towards the top of the specimen, the crack divides into two smaller cracks. Again in this case the cracks run vertically and are approximately 180^{o} apart, the cracks started to develop after 7 days.



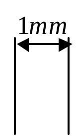


Fig. 5.21(a) Development of small cracks in chicken wire reinforced specimen

Fig. 5.21(b) Large cracks in chicken wire reinforced specimen

Square mesh reinforced

The specimen containing square mesh reinforcing showed the least amount of cracking. There were a number of minor hairline cracks propagating from the edge (figure 5.23). The specimen only had one major crack, see figure 5.22(a). Of all the minor cracks the greatest can be seen in figure 5.22(b). The cracks started to develop after 8 days, the rate of growth was relatively slow compared to the previous three and the rate decreased over time.

Fig. 5.22(a) Single cracks in square mesh reinforced specimen

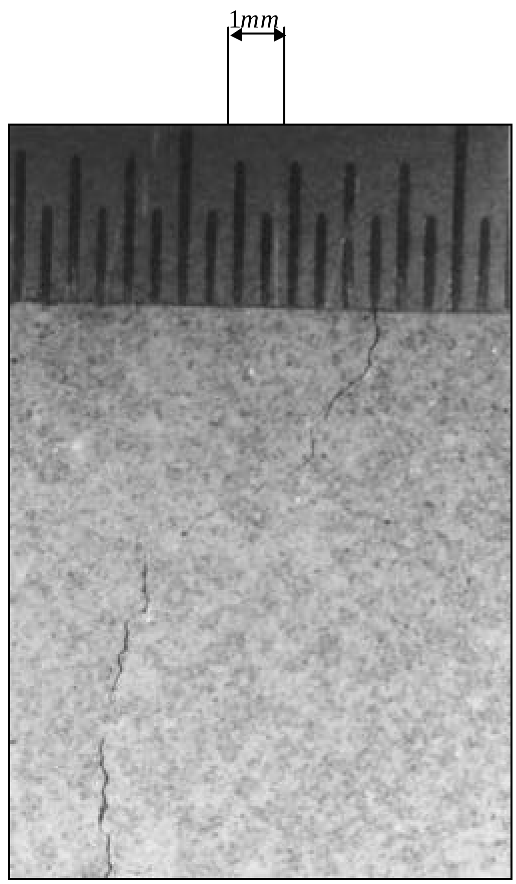

Fig. 5.22(b) Distributed cracks in square mesh reinforced specimen

Discussion

In all cases, the cracks started to develop at the edge of the specimens and propagated vertically towards the centre. In all the cases apart from the square mesh reinforced sample, the cracks were approximately 180^0 apart. The cracks started at the edge due to stress raisers caused by the rough surface finish of the cement mortar. This can be seen in figure 5.23. If the surface between the ring mould and the sample had a zero friction factor then only one crack would develop, if the friction factor is greater than the force needed to start a crack, a new crack will develop. This is what happened in this case.

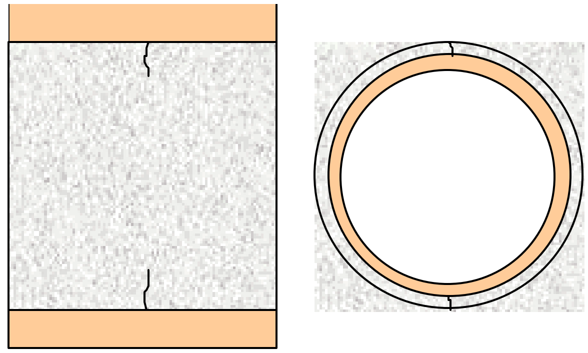

Figure 5.23 Crack development

One of the factors that affects the rate of shrinkage is the environment. In the early stages where rates of shrinkage are high, this has a very important role. The experimental results show that ferrocement cured and stored in a dry environment (40% relative humidity) is very susceptible to cracking (all samples started to crack after 5 to 7 days).

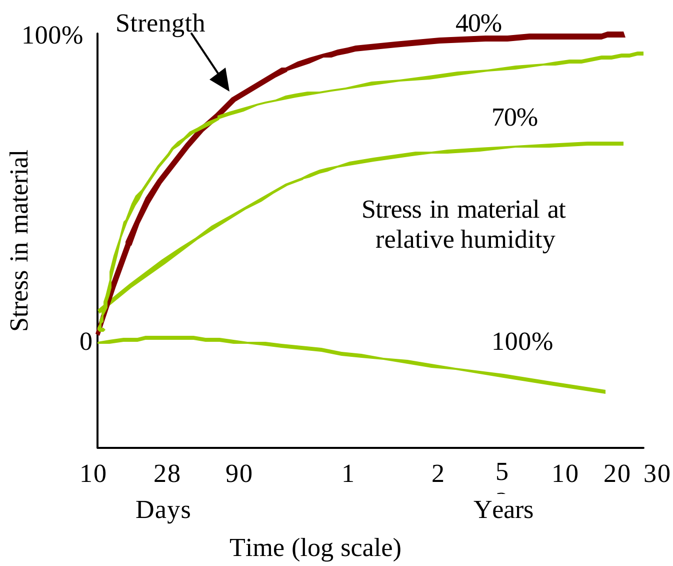

Fig. 5.24 Stress in material caused by shrinkage

To take full advantage of the composite strength it is important not to allow the cement to crack. This can be achieved by making the walls thicker as this slows down moisture loss and also increases overall strength. Another way of achieving this is to keep the cement in such an environment that shrinkage will not occur preferably in moist conditions.

Figure 5.24 shows the theoretical development of stress caused by restrained shrinkage against the development of stress in the cement as discussed in section 3.0. It can be seen that at a relative humidity of 40% the stress developed is greater than the strength of the material, causing the material to crack or fail. If the cement is in an environment with a higher humidity the cracking will not occur. From the figure 5.24 it is seen that after about 40 days the composite has gained enough strength to withstand the internal stresses caused by shrinkage. These results have a practical application, if the water tank is constructed in humid conditions it will be less likely to crack due to shrinkage.

Fig 5.25(a) Polypropylene fibre reinforced

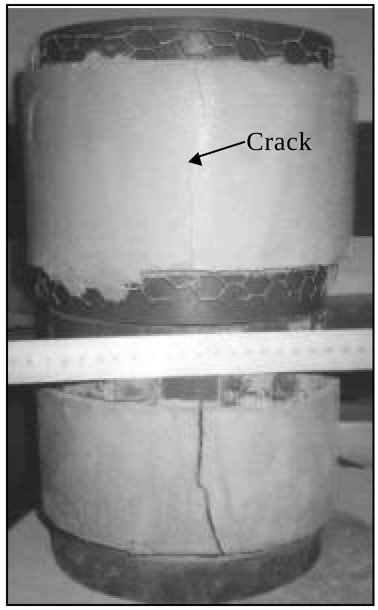

Fig 5.25(b) Chicken wire reinforced

Fig 5.25(c) Square mesh reinforced

Figures 6.25(a-c) show the relative crack size when the plain cement specimen (on the bottom) is compared to the three reinforced specimens. Compared to the crack development in the plain specimen, the specimen containing square mesh restricts the shrinkage cracking by approximately 95%, the specimen containing chicken wire by 80% and the fibre reinforced specimen by 52%. The mesh reinforcing disperses the cracks into a series of micro-cracks. In the specimen containing square mesh the majority of these micro-cracks are less than 0.05mm, according to Nedwall and Swany (1994) cracks of this size should not leak.

One of the reasons the fibre reinforcement does not restrict crack size when compared to the other two is because it has a lower tensile strength 29-38MPa compared to 215 MPa for steel mesh as well as having a higher ductility. Another reason is that there may be a tendency for the reinforcing to pull out of the mortar matrix.

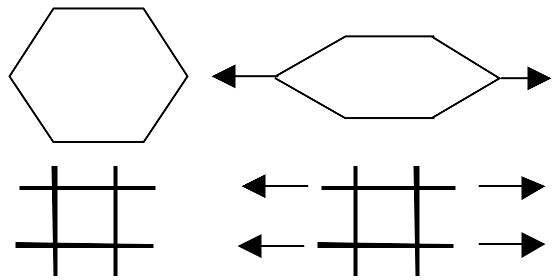

Fig. 5.26 Effects of tensile loads on wire mesh

The main reason why the specimen containing the square mesh restricted the cracking to a greater degree compared to the chicken wire can be seen in figure 5.26. When chicken wire is loaded there is a tendency for the mesh to ‘flatten’ out and expand in the plane of the load. In the case of the square mesh, the load is carried in the same plane therefore the only expansion is due to the wire mesh stretching. There are also a number of other factors which effect the degree to which a specimen shrinks such as volume fraction and the wire gauge. Generally, the larger the volume of steel reinforcing and the larger its gauge the lower the shrinkage will be.

6.0 DISCUSSION

Spreadsheet

In the current spreadsheets the designer is free to enter any safety factor they wish. It would be useful if the designer had some feel for what size of safety factor is required. For example, if the designer knows that the tank is going to be constructed by skilled masons, with high quality materials in a cool wet environment, a safety factor of 2 to 3 could be used. If a designer is not sure of the quality of the raw materials or skills of the masons but knows it will be constructed in a cool wet environment a safety factor of 4 to 5 could be used. If the designer has little knowledge of the environment or the quality of the materials a higher safety factor of 6 to 8 may be used.

Materials

For a typical ferrocement tank constructed in Kenya costs vary from 26$US\$/m^3$ for a 46m^3 tank to 50$US\$/m^3$ for a 11m^3 tank (Gould 1999). Approximately 80% of the cost is materials. If the tanks are going to be financed by the individual householder or community this cost will normally be out of their range. Any saving in the cost of raw materials can be of great benefit, for example, the cost of cement in Uganda is equal to its cost in the UK, but the average income in Uganda is approximately 1/30th to that in the UK. Therefore the real cost of cement is equivalent to 30 times the cost in the UK, (£100-£150 per 50kg). One of the best ways of lowering these costs is to reduce the amount of expensive raw materials. This can achieved be through in a number, this report investigates tank design and improved construction methods.

The spreadsheet allows for experimentation with tank design. Results from the mechanical testing show that reinforcing square mesh inhibits shrinkage better than chicken wire. Reinforcing is used not only for strength but also to add uniformity to the structure. It also gives a base for the cement to be rendered onto. The reinforced samples have greater strength uniformity, this gives the designer greater confidence in predicting the strength of the materials thus allowing for reduced safety factors and therefore thinner walls which in turn reduce material inputs.

Construction techniques

One of the main problem areas in tank design is the wall/base interface. It was shown using the spreadsheet that the interface causes additional stresses, but more importantly the interface restricts the free shrinkage of the tank walls therefore generating additional forces at the tank base of the walls. There are two ways to overcome this problem, either strengthen the base/wall interface or construct the tank so the wall is not connected to the base and it is free to move. The first method increases material costs and second method adds to construction complexity. The final decision on what option to take is up to designer/builder, factors such as cost of additional materials and levels of available construction skills have to be taken into account.

7.0 GUIDE TO THE DESIGNER AND MANUFACTURER

The project has looked into many aspects of tank design and construction. This section summarises the findings into a set of useful guide rules that will help the designer and/or manufacturer. Some of these rules are already in use in the construction industry. Using theory and experimental results these rules have been made specific to overcome problems that are particular to constructing ferrocement water tanks in hot, dry climates.

One of the main problem areas is differential shrinkage; this can be reduced in a number of ways,

- The wall thickness should be kept to a minimum and where possible constant throughout the tank, this will reduce the build up of internal stress. For example, a wall thickness of 75*mm* internal stresses caused by shrinkage can vary by 20%.

- The tank should not be constructed so it is half shaded, this will cause internal stress to be built up. Ideally, the tank should be constructed in a shaded area, this will reduce rapid water loss.

- If possible the application of cement mortar should be continuous. Rendering wet mortar onto dry should be avoided, as stresses will build up between the layers. The maximum recommended time between layers is 4 hours.

Hot dry weather has an adverse effect on tank strength.

- Where possible tanks should be made in the wet season or in the coolest part of the day, ideally in the morning so the construction materials have had the opportunity to cool down overnight.

It is important to incorporate good building practices and have an understanding of the properties of the construction materials.

- The water/cement ratio should be kept as low as possible as a low water/cement ratio will maximise strength and minimise shrinkage. Cement mortar having a water/cement ratio of 0.6 is 40% weaker than that with a water/cement ratio of 0.4.

- There is less variation in strength in reinforced cement compared to non-reinforced. In the tensile strength experiment, compared to plain mortar, variations were reduced by 40% and 45% for chicken wire and square mesh respectively. The lower the variation the lower safety factors that can be used.

- Increasing the amount of reinforcement can reduce cracking. Skinner (1995) recommends a volume fraction of at least 5 to 6%.

- Ensure that not only fine gauge mesh (chicken wire) is used, from experimental observations it was seen that when failure did occurred it was catastrophic.
- The finer the mesh size, the slower and more disperse the crack propagation. Using experimental results, compared to plain mortar the chicken wire reduced cracking by 80% and the square mesh by 95%.
- A good curing regime is required, i.e. the use of wet hessian and plastic covers. The tensile strength of a tank cured in water is approximately 300% greater than that cured in dry air. Appropriate early curing is very important as cement acquires 75% of its final strength within 14 days of casting.
- Shrinkage and cracking can be reduced if the tank is partly filled with water. This needs to be carried out as soon after construction as possible, the depth is not critical as long as the important wall/base junction is covered, e.g. 75 to $100mm$.
- Use of safety factors, for example, 2-3 for a tank constructed by skilled labour, with high quality materials in a cool wet environment, 4-5 if the materials are of dubious quality but there are skilled labour, and 6-8 if there is little knowledge of environment, quality of the materials and labour.

For tanks of similar storage volume the material input for tanks with doubly curved walls are lower than that for tanks with singly curved walls. For example, a Thai jar uses approximately 30% less construction materials than a conventional cylindrical tank of similar volume.

8.0 FUTURE WORK

Spreadsheet

The spreadsheet that is used to calculate the force in doubly curved tanks needs to be made more user friendly. The effects of edge loads also need to be incorporated. The spreadsheets do not take into account the effect of shrinkage and cracking. At the moment their effects are covered by the use of safety factors. Ideally, it should possible to enter a numerical correction factor, which has a similar effect as the safety factor, this may vary depending on construction materials and environmental conditions.

The current spreadsheets do not cater for tanks with non-uniform wall thickness, further work needs to be carried so that this facility is possible. Once this facility has been added it will be posted on the DTU's rainwater harvesting web site and available to the general public.

Construction materials

Future RWH work may concentrate on developing lower cost construction materials. Ideally these should be locally sourced. Work needs to carried out on a replacement for OPC using rice ash husks, rice straw ash and peanut shell ash and future study needs to be carried out on how they reduce shrinkage and therefore cracking. The cost elements need to also be examined. Tank construction materials that could be investigated include bamboo-mud composites, especially in remote rural areas where access to conventional materials such as cement and steel reinforcing bar may be limited. In tropical areas one option is latex, this could be used in conjunction with jute or coir (coconut shell) sacking, as a waterproofing material. Flexible tanks could be made from this composite.

Construction techniques

The merits of shotcreting or the spraying of cement could be studied. Shotcreting is the spraying of concrete at high velocity, conventionally it is projected through a hose usually to a thickness of 50mm. The advantage of spraying concrete/cement is that the mix can be much drier (water/cement ratio 0.30 to 0.50), which in turn will reduce shrinkage and cracking. Spraying cement will give thin uniform cover over reinforcing mesh, as well as reducing application time.

9.0 CONCLUSIONS

Thin wall ferrocement tanks have many advantages and their use should be promoted. One of the main factors that reduce their widespread use is the cost of construction materials, in developing countries it is approximately 80% of the overall cost. The project has looked at the problems that can occur when material inputs are reduced, these are mainly the problems caused by shrinkage induced cracking.

Due to the restricted sample size the accuracy of the results from the material testing may be limited. The purpose of testing was to get a ball park figure for tensile strength and investigate the mechanics of shrinkage of ferrocement. Three reinforcing regimes have been examined and their effects of tensile strength and shrinkage have been reported.

To help optimise material inputs two spreadsheets have been produced. These spreadsheets give the designer an opportunity to experiment with many shapes of tank, as well as material properties. The spreadsheets also have the added advantage of speed, allowing the designer to make changes to the tank specification and immediately seeing the consequences of their actions. This allows iterations to be made quickly and easily. For example comparing a Thai jar (figure 2.7(b)) style water tank to standard cylindrical tank (figure 2.7(a)) of a similar volume material inputs can be reduced by approximately 30% (assuming the material is homogeneous).

One of the main problems that can arise when material inputs are reduced is cracking that is caused by shrinkage. Various ways of reducing this and cracking has been investigated. They include,

- Reducing the effects of potentially damaging differential shrinkage,
- Incorporating good curing regimes,
- Studying the role reinforcing plays in reducing shrinkage and cracking.

The project has also sought to improve construction practices that will help with the manufacture of thin walled ferrocement tanks. A guide for the designer/manufacturer has been produced, this gives a list of some simple, practical and easy to follow rules that can be used in the ‘field’ to help overcome the problems that can occur when material inputs are reduced.

APPENDIX IV

Unrestrained shrinkage

Unrestrained Shrinkage

Base on free shrinkage test carried out by Karagular and Shah (1990) on concrete samples, cured in water for four hours and then after demoulding dried at 40% humidity.

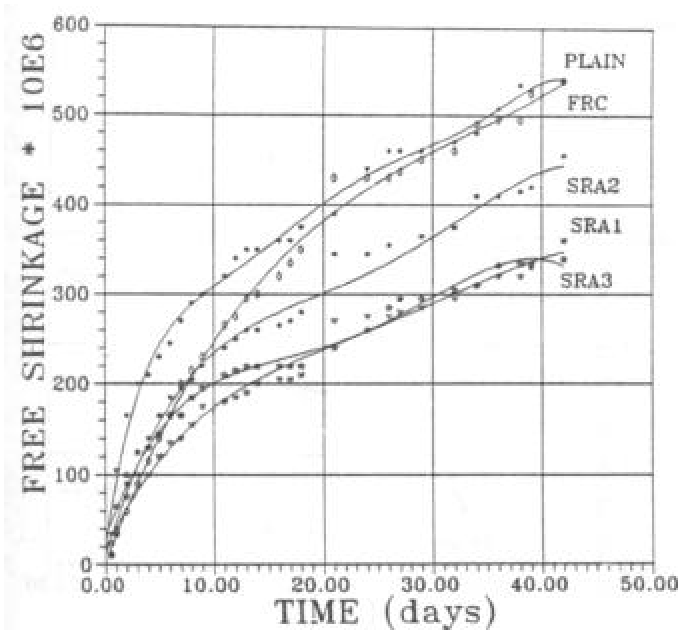

Fig A 4 free shrinkage test results (Karagular and Shah 1990)

Where;

- FRC is fibre reinforced
- SRA is shrinkage reducing agent

The plain concrete was reinforced with steel fibres, the amount being 0.5. Work was also carried out on the effects of shrinkage reducing agents, these agents were a commercially available material containing alkoxylated alcohol. The results for these agents can also be seen above.

Summary

This working paper carries out an investigation into cracking in cementitous renders used to waterproof cheap hand-built water tanks in the developing world. A study of the theory behind cracking in mortar is followed by a review of readily available admixtures that affect the properties of mortar. Extensive experimentation has been carried out on these different mixes of mortar, with the result that the investigation suggests the use of a superplasticiser will reduce the cracking and hence the leakage in a mortar rendered tank. A further recommendation is to add silica fume to the mortar to increase its strength and help reduce cracking. Further investigation into the subject is also recommended.

Contents

Chapter 1: Introduction

1.1 Overview

In the developing world, many communities don't have access to a reliable water source, and as such have to travel long distances to find water. The Developing Technology Unit (DTU) in the University of Warwick is working on providing a source of water to such communities. This project is involved with the production of low cost water tanks to provide people with water.

Uganda is an example of where the tanks will be used, because it has high rainfall during some parts of the year and periods of drought at other times. This sort of climate is ideal to implement rainwater harvesting (RWH). Runoff water from rooftops can be collected and stored in a large tank next to the house. The tank itself can be either above-ground or below-ground and is constructed from local materials such as rammed earth. The defining factor in the production of these tanks is that they have to be cheap and therefore made from readily available materials from local sources. However, such materials are permeable and hence not suitable for storing water.

Waterproof renders consisting of a thin layer (10mm) of mortar, are applied to the walls of the tanks to allow them to store water. These cementitous renders are prone to shrinkage induced cracking, which causes leakage reducing the effectiveness of the tanks. This project is concerned with investigating and developing methods of reducing any cracking, and hence allowing more reliable water tanks to be constructed.

1.2 Project Aims

As stated above, the purpose of this project is to conduct a study of cementitious renders used to waterproof tanks used for RWH. This study will centre on investigating the amount of, and seriousness of cracks in various types of mortar based renders. The experimental side of the study will report on various measures of crack reduction available, and combined with an investigation into the theory behind crack development in cementitious materials, lead to conclusions on which mix of mortar is most suitable for the use described above.

Steve Turner, a graduate of engineering from the University of Warwick in 2000, had begun a similar study into leakage from waterproof renders in the summer before the commencement of this project. He had cast some mortar samples to experiment on, but was unable to carry on, and these samples were inherited and experimented on as an extension to this investigation. These samples provided an introductory look into cracking in cementitous renders, and Steve's notes are provided in the appendix, followed by results taken from the samples he prepared. These results are later used in the analysis and to draw conclusions. Chapter 9 illustrates problems with the procedure and highlights any alterations made to the design of test equipment.

Chapter 2: RWH Tanks

2.1 Description of tanks

Much research has been carried out by the DTU on the forms of water tanks to be used for RWH, so only a brief summary of the types of tanks is given in this report to familiarise the reader. There are 3 types of water tank that can be used for RWH:

- Above ground
- Below ground
- Overhead (roof of building)

The cheapest being below ground tanks as the surrounding ground provides support for the walls and therefore less emphasis must go into designing the tanks for strength. This project was undertaken with below ground tanks in mind although the principles developed can be applied to all types of tank.

The soil walls of the below ground tank are normally reinforced with rammed earth which can then be rendered. In readiness for the waterproofing mortar the tanks walls are scored to provide a good gripping surface on which to plaster. The mortar must be of a suitable consistency to allow plastering, not too thick, and not too runny. A capacity of 10,000 litres is average size for one of these tanks. Figures 2A below, taken from the DTU web site, show the excavation and completion of a partially below ground tank, PBG, combining the benefits of both designs.

Fig 2A

2.2 Pros and Cons

The pros and cons of the 3 types of tank.

	Pros	**Cons**
Above Ground	Helps prevent contamination from water run off. Easy to identify and repair cracks and leaks. Water can be extracted using a simple tap. Can be used in any environment regardless of soil types.	Expensive. Needs lots of free space. Weaker than below ground tanks. Must be designed to be strong enough to hold enough water. Easily damaged.
Below Ground	Cheap. Economical on space. Earth provides sidewalls so are very strong. Not easily damaged.	Hard to spot any cracks or leakage. Pump needed to extract water. Contaminated water could drain into tank. Dangerous to children and animals (should they fall in). Need stable soil conditions to prevent failure of sidewalls
Overhead	Increased water pressure due to head created from elevation. Economical on space. Easy to identify and repair cracks and leaks. Can be used in any environment.	Weaker than below ground tanks. Expensive. Must be designed to be strong enough to hold enough water. Failure of tank can potentially cause serious injury.

Chapter 3: Cement Theory

3.1 How Does Cement Harden?

Water is the key ingredient that causes cement to harden. The process by which cement powder combines with water to harden is called hydration. This process is when the major compounds in the cement react with the water to form hydrates. The water used is vital in determining the strength and end properties of the mortar. Cement is vulnerable to imperfections in additives and impure water can cause weak mortar. The water cement ratio is also important when mixing mortar. Too much water will result in weak mortar whereas too little will make it unworkable and not appropriate to use for many of the tasks in which it is employed. This will be discussed further in sections that follow.

3.2 Hydration

Hydration only occurs when the cement has access to moisture. Moist cement will hydrate and cure, but this process stops once the sample has dried out. This means that the strongest mortars are left to cure for a long period of time. This process can last months and even years. Amounts of water added to mortar, and the length of time it is wet for before drying out, are vital factors when considering the strength and usefulness of mortar. Portland cement has five major constituents. These are listed in the table below.

Cement Compound	% weight	Chemical formula	Alternative chemical formula
Tricalcium silicate	50	Ca_3SiO_5	$3CaO{\cdot}SiO_2$
Dicalcium silicate	25	Ca_2SiO_4	$2CaO{\cdot}SiO_2$
Tricalcium aluminate	10	$Ca_3Al_2O_6$	$3CaO\ {\cdot}Al_2O_3$
Tetracalcium aluminoferrite	10	$Ca_4Al_2Fe_2O_{10}$	$4CaO{\cdot}Al_2O_3{\cdot}Fe_2O_3$
Gypsum	5	$CaSO_4{\cdot}2H_2O$	N/A

All of these compounds undergo hydration when exposed to water, but only the calcium silicates contribute to the overall strength of the mortar. Tricalcium silicate reacts more quickly than dicalcium silicate, and so is responsible for most of the strength of the mortar after the first 7days of hydration. The manner in which each of the calcium silicates affects strength of mortar will be discussed individually.

3.2.1 Tricalcium silicate

Tricalcium silicate reacts rapidly with water to release calcium ions and hydroxide ions. The reaction is exothermic and therefore a lot of heat is produced. The chemical equation is given below.

Tricalcium silicate + water ⟶ Calcium silicate hydrate + Calcium hydroxide + Heat

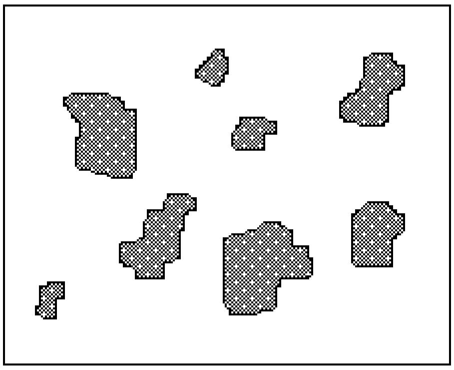
$$2\,Ca_3SiO_5 + 7\,H_2O \longrightarrow 3\,CaO{\cdot}2SiO_2{\cdot}4H_2O + 3\,Ca(OH)_2 + 173.6kJ$$

The Ph rises to over 12 due to the presence of alkaline hydroxide ions. The reaction continues over time, gradually producing more calcium and hydroxide ions until the effect is a saturation of these ions. Crystallisation of the calcium hydroxide now begins to occur, while at the same time calcium silicate hydrate crystals forms. The evolution of heat from the reaction increases due to *Le Chatlier's principle.* This is where ions precipitate out of solution, accelerating the reaction of tricalcium silicate to calcium and hydroxide ions.

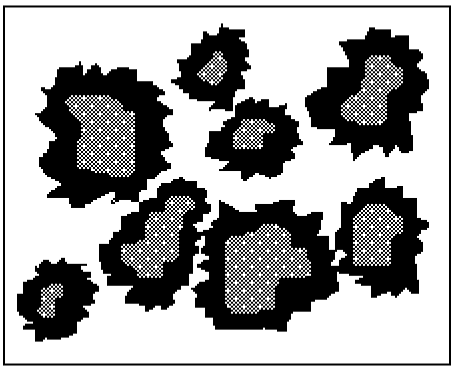
The formation of calcium hydroxide and calcium silicate hydrate crystals increases. The crystals act as a starting point for more calcium silicate hydrate to grow upon, and so they get bigger as further hydration takes place. This makes it harder for water to reach the unhydrated tricalcium silicate, and hence the reaction slows down. As further crystal growth continues the speed of the hydration reaction is constrained by the rate at which water can penetrate through to the unhydrated tricalcium silicate, so over time the production of calcium silicate hydrate becomes slower and slower. The diagram below (figure 3A) illustrates the process.

Figure 3A

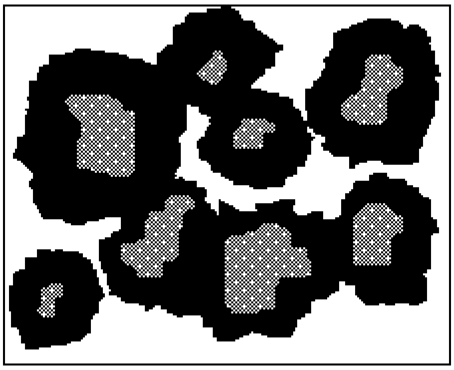
Hydration not yet occurred. Pores filled with water.



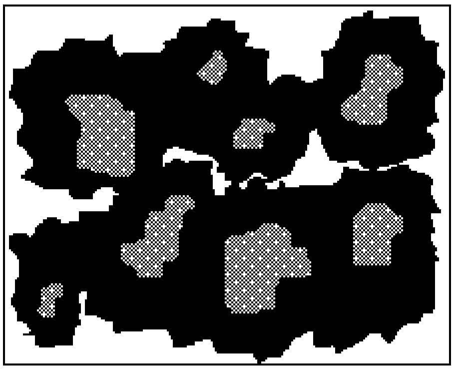
Beginning of hydration. Calcium silicate hydrate builds up.



Hydration continues. Spaces filled with water and calcium hydroxide



Nearly hardened concrete. Most space filled with calcium silicate hydrate. Remaining gaps mainly calcium hydroxide solution



3.2.2 Dicalcium silicate

Dicalcium silicate affects the strength of mortar much more slower than tricalcium silicate. It reacts with water in a similar way but is much less reactive and so less heat is evolved. The products of the hydration of dicalcium silicate are the same as those for tricalcium silicate, and are shown below.

Dicalcium silicate + water ⟶ Calcium silicate hydrate + Calcium hydroxide + Heat

$$\mathbf{2\ Ca_2SiO_4 + 5\ H_2O \longrightarrow 3\ CaO{\cdot}2SiO_2{\cdot}4H_2O + Ca(OH)_2 + 58.6\ kJ}$$

The production of calcium silicate hydrate and calcium hydrate occurs in a similar way as shown in the above diagram, but over a longer period of time.

3.2.3 Tricalcium Aluminate

The amount of tricalcium aluminate is relatively small but can have a significant affect on the properties of the hardening cement paste. The hydration of tricalcium aluminate can occur extremely fast which can lead to a phenomenon known as flash setting. This can occur because the reaction between tricalcium aluminate is very violent and can result in advanced hydration over a very small period of time (a few seconds). This is undesirable as it would cause premature setting of the cement mixture and makes it very difficult to work with. When the clinker first forms in the kiln there is nothing to stop flash setting of the material should it come into mortar with a small amount of water. Because of this gypsum is added as it suppresses flash setting. Gypsum is added to the clinker before the whole mixture is ground down to make cement paste.

3.2.4 Gypsum

When gypsum is added to the clinker, it reacts with the tricalcium aluminate to form calcium sulphoaluminate.

Tricalcium aluminate + gypsum $\longrightarrow$ Calcium sulphoaluminate

$$3CaO \cdot Al_2O_3 + CaSO_4 \cdot 2H_2O \longrightarrow 3CaO \cdot Al_2O_3 . 3CaSO_4 \cdot 31H_2O$$

A lot of heat is produced in the hydration of tricalcium aluminate and a rapid rise in the temperature of cement paste within five minutes of water being added hints that not all of the tricalcium aluminate becomes calcium sulphoaluminate, resulting in limited rapid hydration which explains the rapid rise in heat.

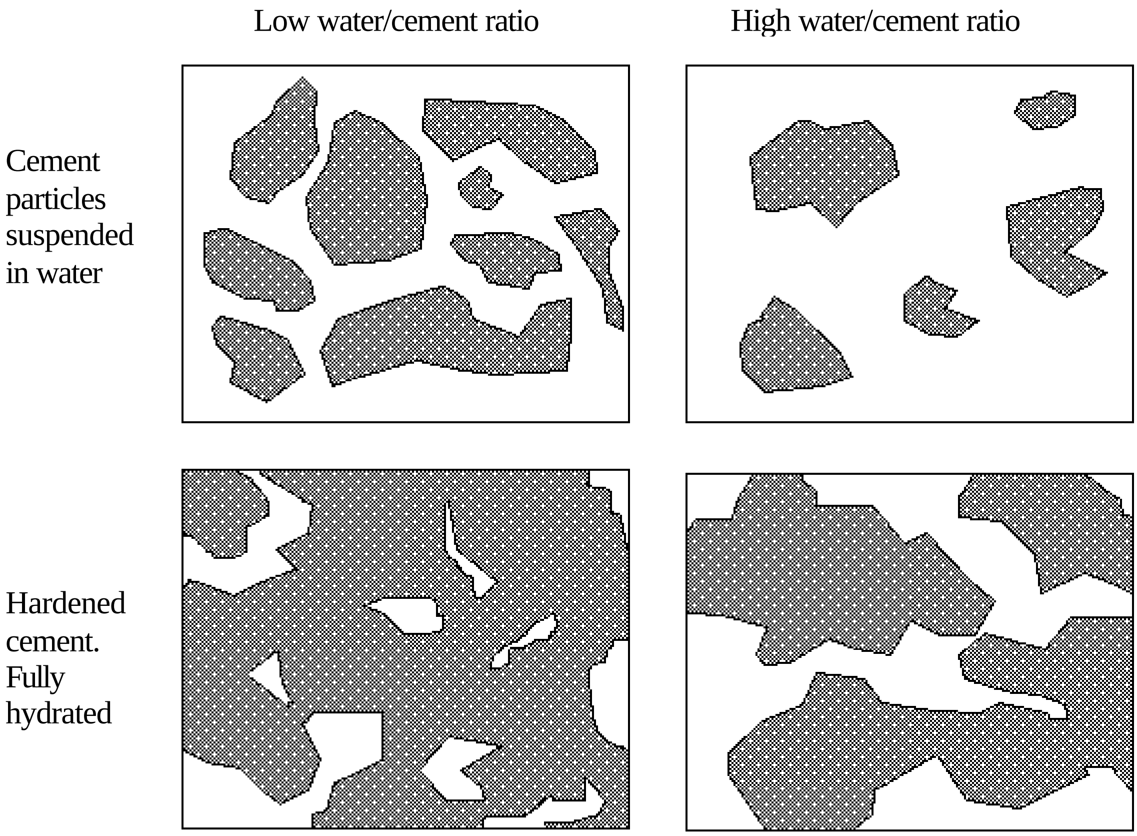
Chapter 4: Strength of Mortar

The strength of mortar is determined by 2 main factors.

1. The amount of water used (water / cement ratio).
2. The length of time for which the mortar is left to cure.

Total hydration requires an exact amount of water, much less than what is used in practice to add to cement. An excess of water is provided to increase the workability of the mixture and allow it to be worked into the desired position. Any excess of water not used up by hydration will simply remain in the mixture and reside in pores in the microstructure. Once the mortar dries, the water will evaporate out of the mixture leaving the pores empty. The more excess water used, the more will be left over after hydration has occurred and therefore the larger the pore volume will be. It can therefore be seen that the strength of mortar reduces as more water is used. If the amount of water used is much greater than that needed by hydration, the space taken up by pores in the microstructure will be relatively large and the porosity of the mortar will increase. This can be illustrated in the diagrams below (figure 4A).

Figure 4A

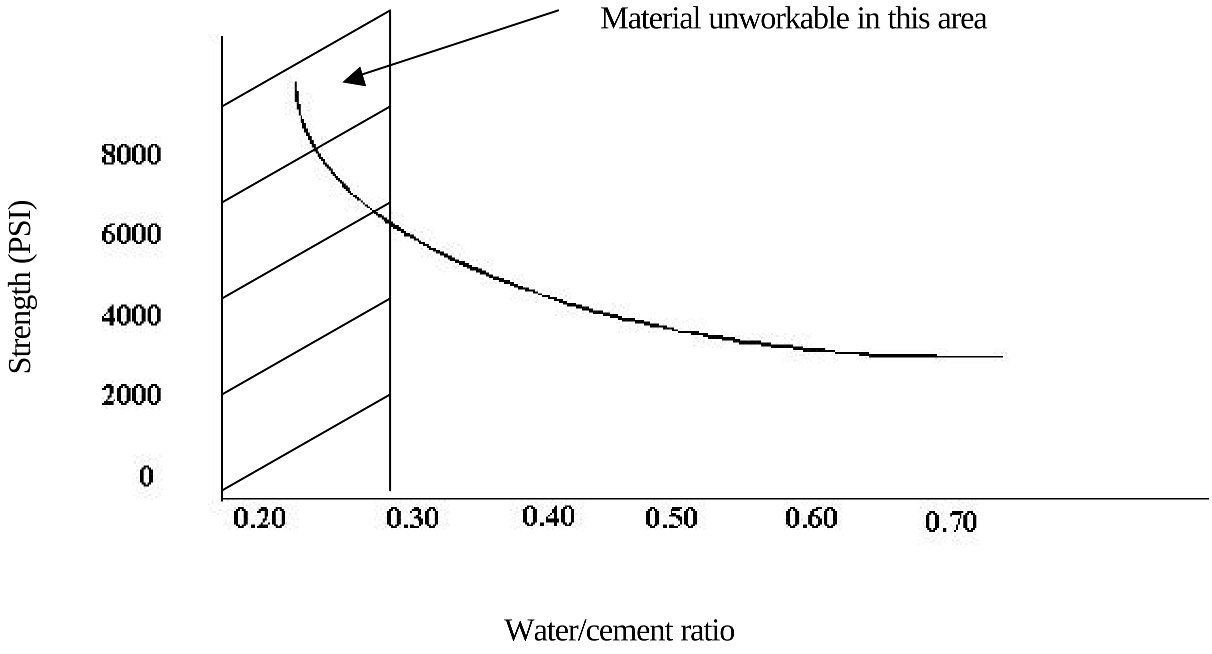


It can be seen from the diagrams above that the mixture with the lower water cement ratio has fewer pores than the high ratio mixture. Porosity of the cement/mortar is directly linked to its strength and the lower the porosity the higher the strength.

Achieving the theoretical maximum strength by using the exact amount of water for complete hydration is not achievable in reality as there will always be some pores present, even if the cement has been highly compacted. The trade off between strength of mortar and the workability desired to use the material depends on what task the mortar needs to perform. For casting in moulds it must be very liquid to allow pouring, but while this does increase workability it will result in weak mortar. For applications such as plastering, less water is used and the paste is much more viscous and will be stronger and less porous once set.

The graph below (figure 4B) shows how the water cement ratio affects the strength of the mortar produced. The graph highlights the limit of workability of concretes and mortars, below which it would be impossible to use the mix for any practical purpose.

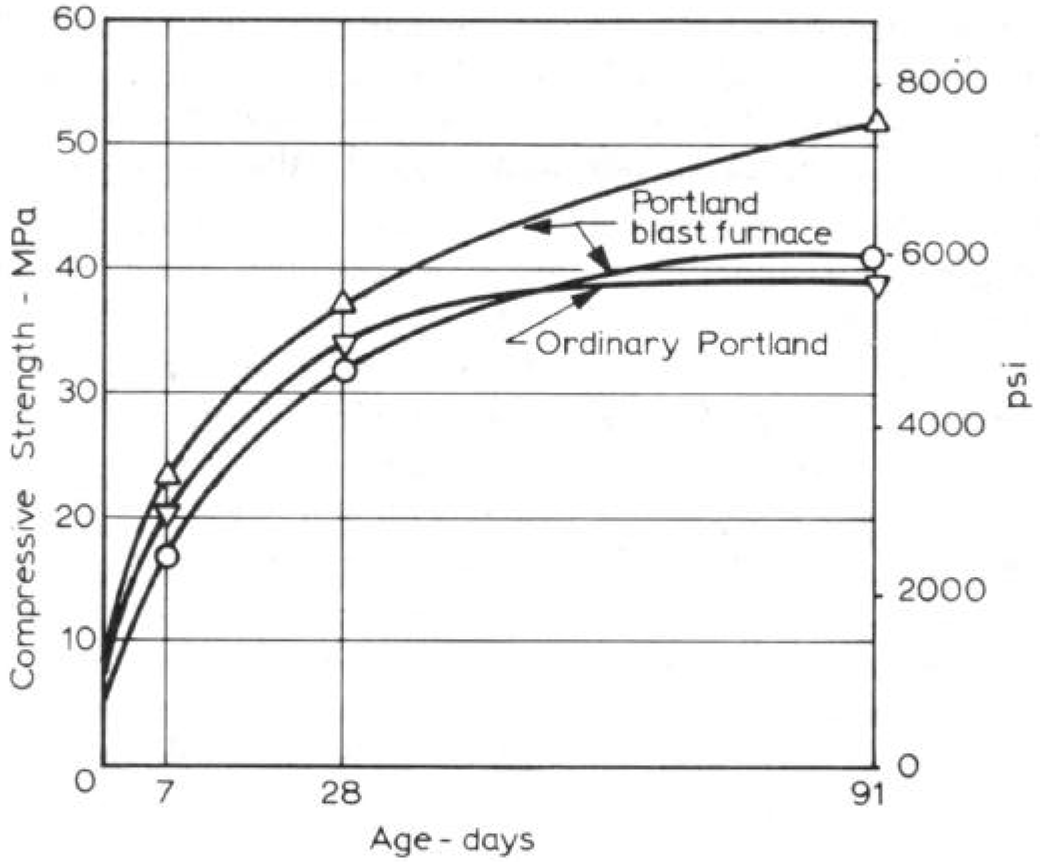
Figure 4B



The other factor that decides the strength of mortar is the length of time it is allowed to cure. Curing is the continuing process of hydration. It can take years for all of the calcium silicates to become hydrates and so the longer the mortar is left to cure the stronger it will be once dry. The graph on the following page (figure 4C) taken from “Properties of Concrete” by A.M.Neville, illustrates the manner in which different types of cement harden over time. The 7 and 28 day points have been plotted because they are commonly used indications of the strength of concretes and mortars. It can seen from the graph that even after 90 days the different types of cement are still increasing in strength, and many will do so for months afterwards, although at a very slow rate.

Figure 4C

0.6 water/cement ratio concrete



Chapter 5: Cracking in Mortar

5.1 Why does Mortar crack?

It has already been shown that mortar is a very complex material and many reactions take place within the cement to allow it to harden. A very common problem with the material is that over time cracks appear on the surface. Internal cracks are also common and in structures it is possible that cracks propagate unseen through the material for a long distance before finally breaching the surface. As the mortar is being used as a waterproofing agent in this investigation it is important to keep cracking to a minimum.

When cement powder is mixed with sand and water to form mortar it can be of various viscosities, but there is always a volume of water present which will be lost at some stage during the curing and drying processes. This loss of water changes the volume of the mortar and therefore the material shrinks. If the mortar is unconstrained then this change in volume is not a problem because the material will simply shrink with no damage to its properties. If the mortar is constrained during curing and drying, then it cannot change its volume as easily. Tension builds internally, and if this force exceeds the materials yield stress then it will crack. Mortar has a very low strength in tension compared to its strength in compression and so cracking occurs very easily in a constrained sample.

Theoretically, the strength of cement paste is much higher than those values actually achieved. The theoretical strength has been estimated to be up to 10.5Gpa, but this theory is based on perfect surface texture and internal structure. In reality, the material is not homogenous and there are many stress concentrations that are set up in the material. These concentrations allow very high local stresses to accumulate resulting in micro-cracking. Thousands of micro cracks are present in every meter squared of mortar but these do not cause any significant structural problems. Larger cracks of the order of 1mm or more, while not as common, represent a more significant reduction in the yield strength. These cracks can initiate from places such as the suspended aggregate, and any small imperfections in the material.

Cracking is caused by restraints acting against the shrinkage of the mortar, the tank wall in this case. Another form of restraint is non-uniform shrinkage within the mortar itself. When the paste dries, moisture is lost first from the surface and only later do the internal sections dry. This sets up a moisture gradient, which is part of what is called differential shrinkage. If a specimen dries in a symmetrical way this is not much of a problem, but in extreme cases warping can occur if the specimen dries in a non-symmetrical way. Because of the fact that the surface dries much quicker than the interior, size and shape of a specimen are extremely important factors in how much the mortar shrinks and to what extent it cracks.

Differential shrinkage should not be a factor considering the thickness of mortar used in this project. In theory the layer of mortar should be as thin as possible to counteract differential shrinkage, but considering the project is looking at renders with a thickness of the order of 10mm, the amount of shrinkage caused in this way will be negligible. The main consideration for this will be when the tank walls are left to dry. They should be left covered, with even heat distribution throughout so as not to allow one area of the tank to dry before the rest, which could cause cracking at the boundary between the two differently dried areas. Also, the walls should not be exposed to sunlight while drying, as this is likely to cause uneven heat distribution resulting in uneven rates of drying, and in turn a moisture gradient which could lead to cracking.

Chapter 6: Mathematical Model

Cracking in cementitious materials is progressive and as such can occur over long periods of time, although the majority of cracks initiate and propagate to nearly full length in the first month after drying begins. The effect a crack has on the material properties depends on its length, depth and width. When considering a cement based material for strength, it is found that the wider the crack the greater the resultant reduction in strength. This section will attempt to model how crack width affects the permeability of mortar. When considering a crack in concrete it is useful to make assumptions to make analysis easier. Two methods of analysis are shown in this section for different assumptions about how a crack can be modelled. They are shown below.

6.1 First Method

From fluid theory, flow through a crack can be approximated to flow through a tube (see figure 6A). Assume the pressure gradient, G, is parallel to the axis of the tube. For such an arrangement the forces can be derived as follows.

$$\text{Axial force} = \text{Gäë . 2ðr är} \qquad \textbf{1.}$$

$$\text{Viscous Shear force} = \text{2ðr äë . í .}\left(\frac{\text{dõ}}{\text{dr}}\right) \qquad \textbf{2.}$$

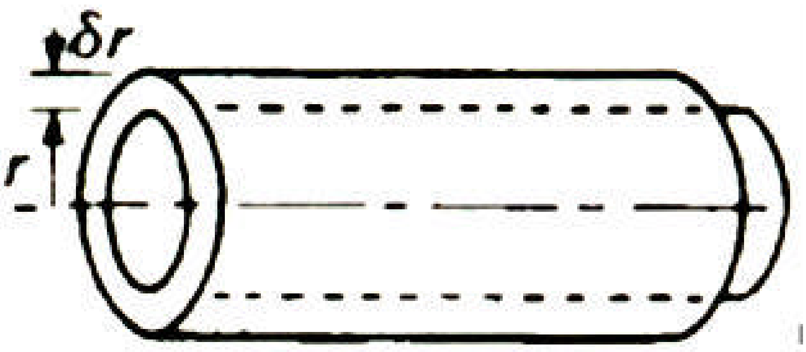
Equating 1 and 2 above produces the following expression for Gär:

$$\text{Gär} = \text{í}\left(\frac{\text{dõ}}{\text{dr}}\cdot \text{är}\right) \qquad \textbf{3.}$$

Substituting 3 for Gär into the equation for the viscous shear force yields the following:

$$\text{Viscous Shear Force} = \text{2ðr äë . í}\ \frac{\text{dõ}}{\text{dr}}\left(\text{är} + \frac{\text{d}^2\text{õ}}{\text{dr}^2}\text{är}\right) \qquad \textbf{4.}$$

Fig 6A



The laminar flow stresses $ô_{inner}$ and $ô_{outer}$ can be derived as follows and substituted into the force expressions in 1 and 2 on the previous page:

$$ô_{inner} = í\ \frac{dõ}{dr} \qquad \textbf{5A.}$$

$$\therefore\ F = äë \cdot 2ð r \cdot ô_{inner} \qquad \textbf{5B}$$

$$ô_{outer} = í\left(\frac{dõ}{dr} + \frac{d^2õ}{dr^2}\,dr\right) \qquad \textbf{6A}$$

$$\therefore\ F = äë \cdot 2ð(r + är)ô_{outer} \qquad \textbf{6B}$$

From 5B and 6B above the net force can be derived:

$$\text{Net Force} = 2ð d ë \cdot í + \frac{dõ}{dr} \cdot är + r\frac{d^2õ}{dr^2} \cdot är \qquad \textbf{7.}$$

To solve this differential equation set F to zero and reduce as shown below:

$$r\frac{G}{í} - \frac{dõ}{dr} - r\frac{d^2õ}{dr_2} = 0 \qquad \textbf{8.}$$

Solving this second order differential equation for the velocity distribution across the top of the tube of radius R yields the following:

Knowing that: $\frac{dõ}{dr} = 0$ at r = 0

õ = 0 at r = R

$$õ = \frac{K}{8}\left(R^2 - Rr^2\right) \qquad \textbf{9.} \qquad \text{Where } K = \frac{G}{í}$$

The mean velocity, $\bar{õ}$, can be found from 9 above by substituting the expression for õ in the equation shown below:

$$\bar{õ} = \frac{\int_0^R 2ð\, r\, õ\, dr}{ðr^2} \qquad \textbf{10.}$$

The result is shown below:

$$\boxed{\bar{õ} = \frac{K}{16}R^2} \qquad \textbf{11.}$$

The variable R, which represents the size of the crack, is of interest and equation 11 above shows that if the crack size R, has a square relationship with flow rate. An example is if a crack were twice the size, the flow would increase by 4.

6.2 Second Method

An alternative assumption of the form of a crack can be used to verify the above result. A laminar crack between two plates of width t, length b and thickness L. In this example the pressure gradient G = pressure drop/L.

$$\therefore \text{pressure force on layer } (F) = Gbdy \cdot äë \qquad \textbf{1.}$$

Shear force on bottom of layer = $\text{bäë} \cdot \text{í}\ \frac{\text{dõ}}{\text{dy}}$ **2.**

Shear force on top of layer = $\text{bäë} \cdot \text{í} \left(\frac{\text{dõ}}{\text{dy}} + \frac{\text{d}^2\text{õ}}{\text{dy}^2} \right) \cdot \text{dy}$ **3.**

Equating 2 and 3 above yields the following differential equation.

$$\frac{\text{d}^2\text{õ}}{\text{d}^2\text{y}} = -\text{G} \qquad \textbf{4.}$$

This can be solved in the same way as equation 8 in section 5.1 above. Using õ=0 at y=t/2 gives:

$$\text{õ} = \frac{\text{G}}{2}\left(\frac{\text{t}^2}{4} - \text{y}^2 \right) \qquad \textbf{5.}$$

The mean velocity, $\bar{\text{õ}}$, can be found from 5 above by the following integral.

$$\bar{\text{õ}} = \frac{\text{G}}{2} \int_0^{\frac{t}{2}} \left(\frac{\text{t}^2}{4} - \text{y}^2 \right) \text{dy} \qquad \textbf{6.}$$

Therefore:

$$\boxed{\bar{\text{õ}} = \frac{\text{G}}{2} \frac{\text{t}^2}{4} \left(\frac{2}{3} \right)} \qquad \textbf{7.}$$

6.3 Summary

Both the model for a tubular crack and the model for a laminar crack come to the same conclusion.

Mean velocity (flow per unit area of crack) $\propto t^2$

In the context of this investigation the result of the analysis is that: -

$$\textbf{Flow} \propto \quad \textbf{(crack length x crack width}^2\textbf{)}$$

IF the length of the crack is much bigger than the width (as should be the case)

The consequence of this result is that mortars should be designed to spread any shrinkage between many small cracks rather than few wide ones. The width is of great importance due to the fact it affects flow rate by a power law. Any small increase in crack width would increase flow rates dramatically.

Chapter 7: Admixtures

7.1 Overview

There are many different admixtures available on the market able to change many different properties of mortar, yet the most popular two types improve the material properties in the following areas:

1. Strength
2. Watertightness

These two factors are of interest to this project as they both can affect the mortars suitability as a render under the conditions set out in section 2. As highlighted, cracking is the major cause of leakage and cracking only occurs if the internal stresses in the mortar exceed its yield strength. Increasing this strength will reduce the amount of cracking for a given internal stress, thereby reducing the leakage. The usefulness of the second point is rather more apparent, although the manner in which admixtures that claim to improve watertightness do so is likely to be closely related to the strength of the material.

7.2 Tested Admixtures

The admixtures used in this investigation were inherited from previous research carried out by the DTU, and all satisfy the above criteria of being cheap and readily available in the developing world. The four admixtures are listed below.

1. Silica Fume
2. Superplasticiser (complast 211)
3. Harilal Leak seal
4. Festegral

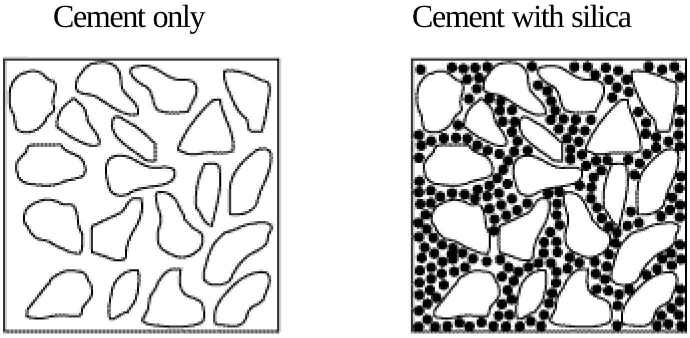
Another product was available for testing, which was a slurry-based layer that was to be sandwiched between two layers of plain mortar. This product, ferrofest, claimed to reduce shrinkage when used in this way, and hence reduces cracking and improves the water tightness of the mortar. Where available, an analysis of the theory behind each of the admixture's claims is given below.

7.2.1 Silica Fume

Silica Fume is created by heating quartz, coal, iron and wood at 1800^{o}c and collecting tiny particles from the emissions. These spherical particles have a diameter of approximately 0.1 microns (of the order of 100 times smaller than cement particles). Silica Fume increases the strength of concrete mixes and is used worldwide in all types of application, and hence is very readily available.

The silica particles, being so small, are able to fill spaces between cement grains and so displace excess water and act as nucleation sites for hydration to begin. This is known as the microfiller effect, and results in reduced porosity of concrete (or mortar as in this case) and hence it is stronger. Figure 7A below illustrates this effect.

Fig 7A



Another effect of silica fume that adds to the mortar strength is the pozzolanic effect. The amorphous silica particles have a very large surface area due to their small diameter and react with the calcium hydroxide in the cement to form calcium silica hydrates, which are the hydrate products found in hardened cement. This increase in the amount of hydrates adds to the strength of the material.

7.2.2 Superplasticiser

Plasticisers are used in concrete to reduce the amount of water needed to reach a required workability. In a normal concrete mix, cement particles tend to agglomerate, trapping mix water that would otherwise be used for lubrication. When superplasticiser is added to the mix, it is absorbed onto the cement particles causing electrostatic repulsion and dispersing the cement particles evenly throughout the concrete mix. The result of this is that water is not wasted because it is being more effectively used for hydration, and hence lower water:cement ratios can be used to achieve the same workability of mix as when the superplasticiser is not used. The reduction in water in turn increases the strength of the cement.

7.2.3 Harilal Leak seal

There is no indication on the packaging of this Indian admixture as too how it affects the permeability of cement.

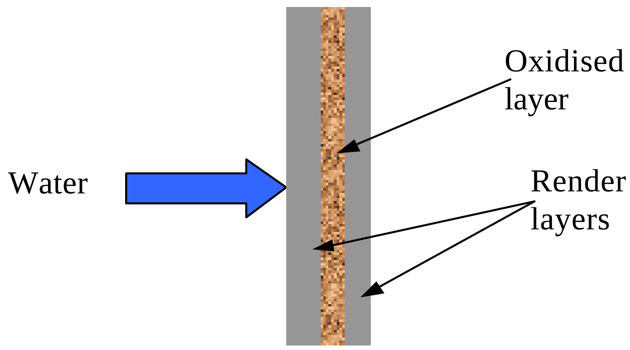
7.2.4 Festegral

There is no indication on the packaging of this Mexican admixture as too how it affects the permeability of cement.

7.2.5 Ferrofest

Ferrofest is not an admixture, and instead of being mixed in with the rest of the mortar ingredients, is sandwiched between two layers of plain mortar. It is iron based and claims to reduce the effects of shrinkage in concrete by expanding to counteract the shrinkage. During wet curing of the mortar, the iron within Ferrofest oxidises causing the layer to expand. These oxidised particles will clog up the pores in the plain layers and the associated expansion will help close any cracks formed in either layer of plain mortar, and therefore should reduce permeability. Figure 6B below illustrates the application of Ferrofest.

Fig 7B



The proportions of each admixture were provided by the manufacturers and are shown in figure 6C below.

Figure 7C

Sample	Admixture % (cement weight)
Harilal Leak Seal	2
Festegral	4
Silica fume	10
Superplasticiser (Complast211)	0.8
Ferrofest	100

Chapter 8: Variables

Three variables have been identified as appropriate for investigation in respect to waterproofing an underground water storage tank with mortar. Section 5 showed how upon curing and drying, mortar is prone to cracking. Because this is the root cause of any leakage from the tank, the variables chosen for investigation are all related to how much the mortar will crack and the resultant effects. They are as follows.

1. Shrinkage
2. Cracking
3. Leakage

Shrinkage – As the mortar dries, the associated water loss causes a change in volume that will be measured experimentally to determine the amount of shrinkage in each specimen of mortar.

Cracking – Cracking occurs in samples that undergo constrained shrinkage, and hence internal stresses build up causing crack initiation and propagation if the mortar's yield strength is surpassed.

Leakage – The purpose of the leakage experiment will be to determine what effects crack size has on water loss. Ultimately this will lead to conclusions stating whether it is better to have shrinkage accounted for by few large cracks or many small cracks.

Chapter 9: Experimental Procedure

The mortar must be of a suitable plastering viscosity, so a water cement ratio of 0.6 was used as a standard. All tests mentioned below use this ratio with the exception of the superplasticiser, which uses a ratio of 0.5 for reasons explained earlier.

9.1. Shrinkage

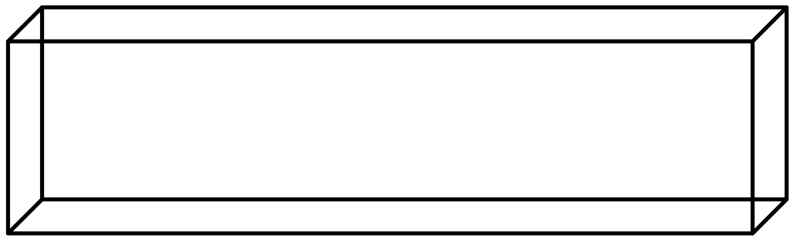
This variable proved very difficult to measure accurately as there are two possible means of shrinkage that occur at different stages. The manner in which the experiments were undertaken will be shown and then the associated problems discussed.

9.1.1. Procedure

Many methods of experimentation on concrete have been done in the past resulting in standard tests that the industry recognises and that are established as the way in which experiments with concrete are undertaken. British Standards (BS) 1881: part 5 (1970) and BS 2028 (1968), are two such standards relating to shrinkage measurement in concrete. However due to equipment and time factors, these standards could not be applied to this set of experiments, although they are of a very similar nature.

Firstly mortar was cast into blocks of dimensions 50 x 50 x 225mm and left to cure for a measured period of time. Once hardened (24 hours) small areas of the surface were dried using acetone and two metal tabs bonded to the surface of two opposing faces. These tabs were at a distance apart, which decreased as the blocks underwent shrinkage. The strain is then measured between the tabs using a dial gauge with an accuracy of 0.2 micro strain. The blocks were left to dry end-up so as to expose the greatest surface area to the air, to get even drying, thus helping to prevent warping. Two opposing sides were measured to monitor any possible warping that may occur during drying (see fig 9A).

Figure 9A



The amount of time the blocks were left to wet cure (no drying) was a variable investigated in the first round of experiments. In the first round three identical plain mortar samples were cast and left to cure in wet conditions for different lengths of time (2 days, 4 days and 14 days) to see what effect, if any, this would have on the shrinkage observed upon drying. Subsequent tests involving the admixtures would use a period of 2 days wet curing and results taken during 28 days of drying.

Each admixture used would be tested for shrinkage, and these results compared to the results for the other variables under investigation, cracking and leakage, to see if there was any correlation. See section 10.1 for breakdown of exact experiments that will take place.

9.1.2. Limitations

The main problem with doing experiments on the shrinkage of mortar is that at the time of casting the material is viscous and will flow, and only hardens to a point where it can removed from the mould after 24 hours. Any reduction in volume during this period is extremely difficult to measure and was not attempted in this investigation due to the said problem. Because of this, the results obtained for the shrinkage of the mortar are only for the period subsequent to the metal tabs being bonded to the samples, about 24 hours. Any shrinkage during the setting and early curing processes is unknown.

It would clearly be preferable to have values for the exact shrinkage or associated volume change from casting through to dryness, but this is not possible in this investigation. However, observation of the samples prepared by Steve Turner back up the opinion noted from literature on the subject, that shrinkage during wet curing accounts for only a tiny fraction of overall shrinkage when compared to the drying process. The samples were cured for three months underwater before the onset of this investigation, and upon initial inspection had no signs of any cracking on the surface. Once the samples were left to dry, extensive cracking was noted after 1-2 weeks.

Due to the observations made on the samples it is assumed that the shrinkage during the period of curing is negligible.

9.2. Cracking

9.2.1. Procedure

The purpose of investigating cracking in samples of mortar is fundamental to the overall aims of the project. It ties in with the other two variables because it is the shrinkage that causes cracking, and the cracking that causes leakage. Cracking will occur in a sample of shrinking concrete/mortar if the sample is constrained and not allowed to shrink unhindered (see section 5).

Steel rings are to be used as the constraint in this experiment. Mortar is to be applied to the rings in a layer 10mm thick between two retaining clips at the top and bottom of the cylinder (see fig9B). The rings have the following dimensions:

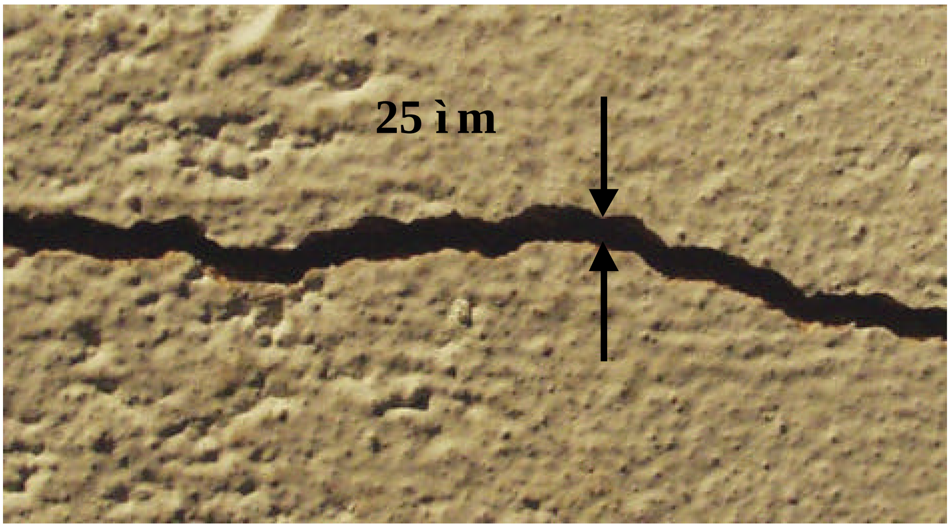
- Diameter = 170mm
- Height = 140mm
- Wall thickness = 5mm

Fig 9B

On application the mortar will adhere to the surface of the ring and harden around it. As the mortar layer dries, it will shrink and this movement will be constrained by the ring, resulting in internal stresses in the layer of mortar and eventual cracking. Cracks should begin to initiate towards the end of the first week and will have propagated significantly by weeks 1-2. The specimens will be left to dry and crack for 28 days, the same testing length as the shrinkage experiments.

Regular checks are made on the mortar covered rings to watch for signs of cracking or propagation of existing cracks. The width of any crack is vital as to determining the effect it has on the overall structure and flow rate of leakage water, so this is measured using a microscope with a lens calibrated with divisions every 50ìm allowing measurements to made in 25ìm increments. Fig 9C below illustrates a crack seen on the surface of a specimen prepared by Steve Turner prior to the commencement of this project.

Fig 9C



9.2.2. Limitations

This experiment only registers cracks that have broken the surface of the mortar and would not account for any cracking beneath the surface. However, any leakage that may take place would require a surface breaking crack to allow the water to escape. For this reason sub-surface cracking is not an important factor in this investigation as it is to do with leakage, but such cracks must be considered because over time they will eventually propagate to the surface and allow leakage.

When considering the use of mortar as a render for water underground water storage tanks, it is desirable to have the tank permanently filled or at least have some moisture present to keep up the relative humidity in the tanks, as the more time it is left empty to dry, the greater the likelihood of cracks emerging. It has been noted the specimens investigated, cracks generally appeared after 1-2 weeks so if the tank was left dry longer than this period, then extensive cracking is likely.

Another factor to consider is the rate at which the mortar dries, and therefore the rate at which it shrinks and what relationship this has to cracking. The quicker mortar dries, the greater the likelihood of cracks initiating. The reason for this is that creep plays a part in relieving the internal stresses that build up inside the material due to constrained shrinkage. If the samples dry slowly then the material will creep and result in reduced cracking compared to a sample that was dried very quickly. It is for this reason that the relative humidity of a near empty water tank must be kept high by covering it with polythene (for example), because if humidity were low, the moisture would be able to leave the surface of the render with greater ease.

9.3 Leakage

9.3.1 Procedure

The leakage experiments have been designed to run in conjunction with the cracking experiments. The steel rings as shown in fig 9B in section 9.2.1 were modified with a spiral groove run from top to bottom. This groove was `V` section and, due to warping in the rings, had a varying depth of between 2-3mm. The depth was set at a minimum of 2mm to ensure it could not be blocked with mortar, as it had to act as a channel for water to flow through. The pitch of the spiral was set to 48mm. The reason for this is that the channel is designed to be in contact with every crack in the mortar to feed each with water and allow leakage through them. The minimum crack length noted from samples prepared by Steve Turner was 50mm after one month and as these samples were to be left for the same amount of time and would generally be weaker because of the reduced curing, it was thought that no crack in any of the samples would be beneath the 48mm in length that the lathe was capable of machining.

Once any mortar was applied to the rings, there was no way of telling whether the channel was blocked and so it was decided to test various measures to stop it getting blocked.

Two methods were devised and tested prior to any of the experiments taking place. The first involved placing a length of string in the channel. This would act to stop the channel getting blocked and also acted as a wick to help draw the water down along. The second was to place thick wire in the channel which after consideration was to be crimped so as to stop it from sealing the channel and stopping the water feeding any cracks. Fig 9D below illustrates how the metal may seal the channel and prevent the water feeding the cracks.

Fig 9D

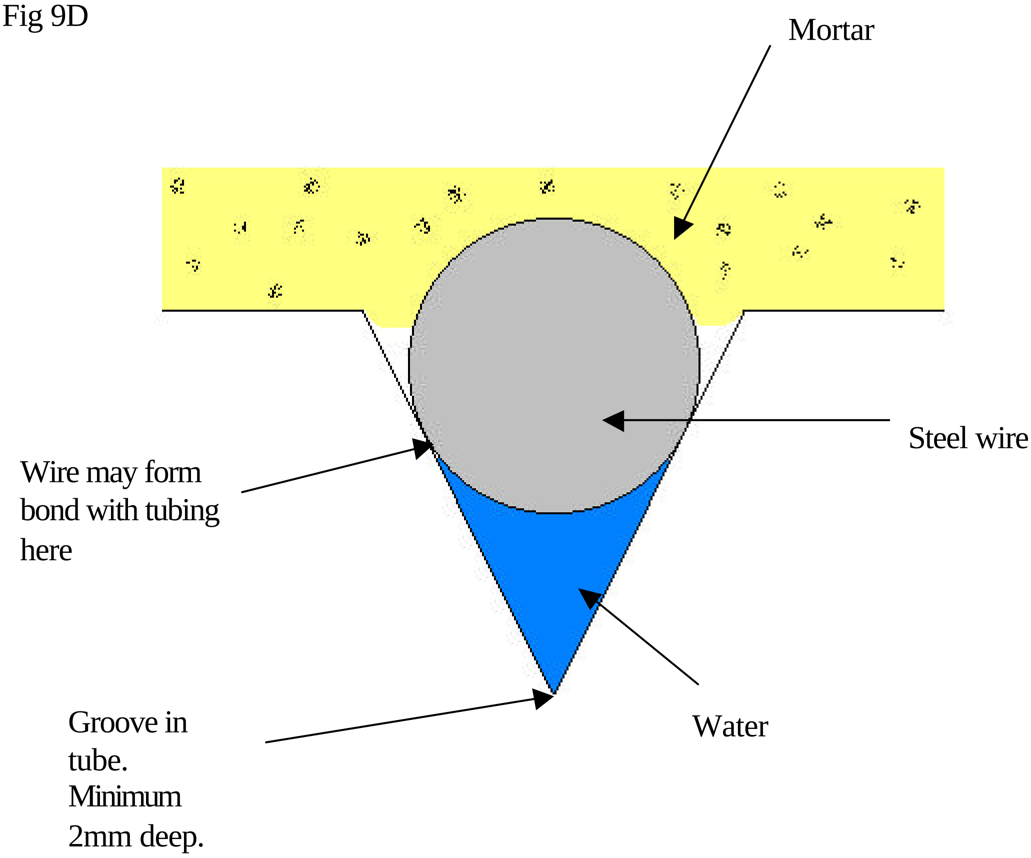


Figure 9D illustrates the way in which the two materials would prevent the channel getting blocked. Crimping the metal would prevent it sealing the channel and the string is porous and doesn't have a smooth surface finish so wouldn't seal the channel as the metal could.

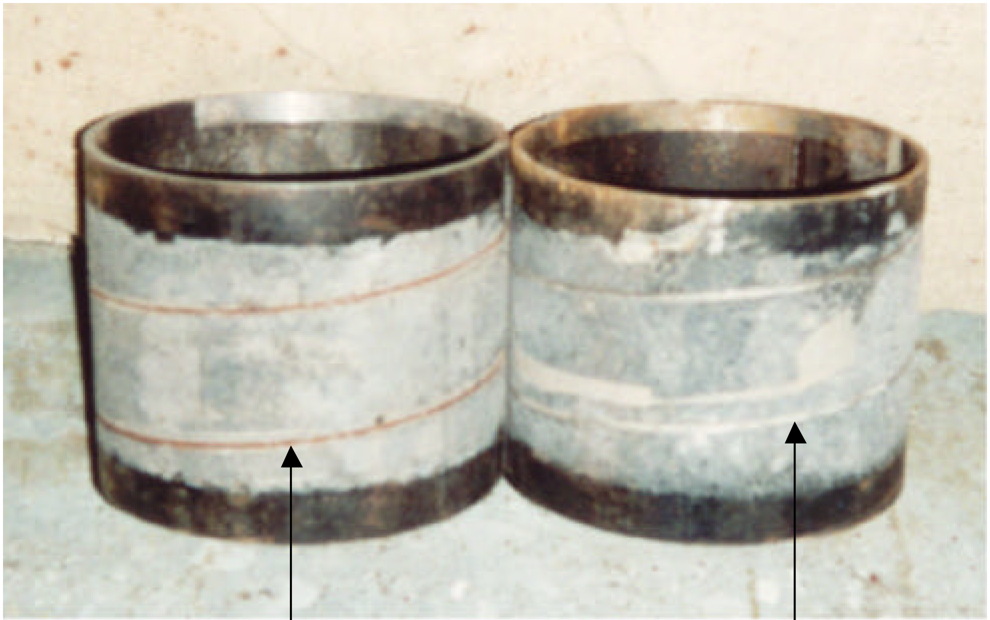
Both of these methods were tested and any problems with their implementation noted. The string was exceptionally easy to lay in the crack and was simply taped at either end and posed no problem when plastering the steel in mortar. Because the steel wire was quite thick, it was very difficult to bend into shape and keep in the channel. It was carefully taped in place until the two ends could be fixed, but on removal of these tapes small sections of the channel were open. The results of two tests on each method were that the string kept the channel open and in both cases water flowed through the length of it. The wire method allowed the channel to get blocked on one occasion and so it was decided to use the string.

Once the mortar was removed and the lengths of string and wire removed, the channel was checked to see what state it was in. Both channels in which the string was used had a layer of rust along their lengths, showing that water did reach all areas of the channel, see fig 9E. The blockage in one of the wire samples was found to be caused by the wire coming out of the channel and it being blocked with mortar.

fig 9E

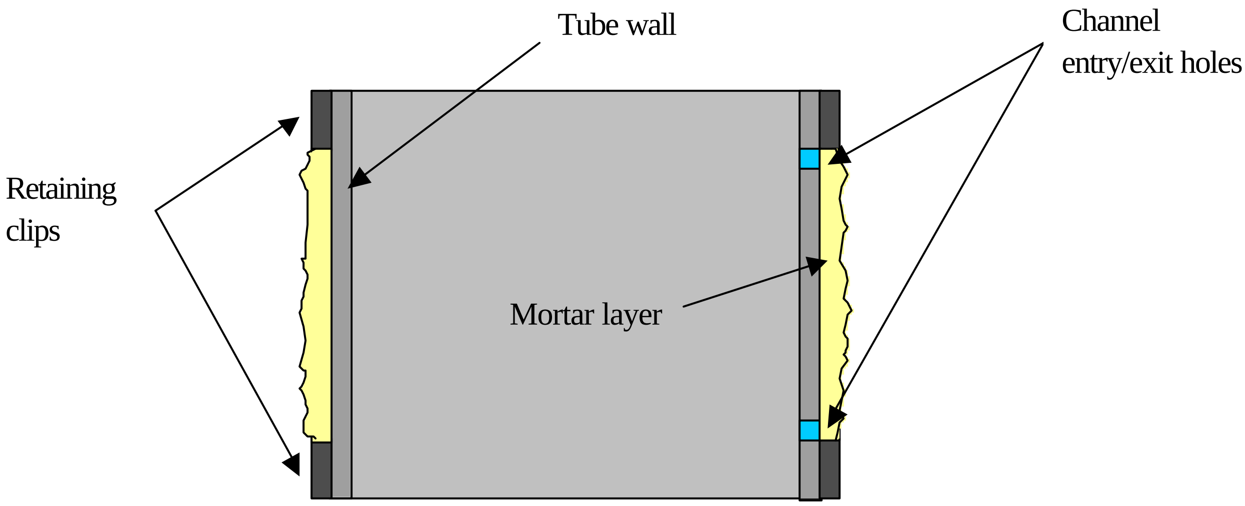


String sample
Rusted areas

Wire sample
No rust

2.5mm diameter holes were drilled 25mm from the edges of the rings in the groove to provide a means of feeding the channel water. The channel was then sealed upstream of these holes to stop water leaking out through the top of the rings. Hollow tubing was bonded over the holes on the inside of the rings to allow rubber tubing to be fixed on and connected to a supply of water which comprised of a glass tube calibrated at 1ml intervals. Once this was full and attached to the groove, the samples were observed to see how much leakage, if any, occurred. Fig 9F below shows a cross section of plastered the steel tube, with retaining clips top and bottom, and feed points to the channel.

Fig 9F



The glass tube used to supply the groove was positioned with the water level 1.5m above the sample to provide a "head" of water to help drive water through the cracks. As each sample leaked the level of water in the tube dropped and so too did the head, which would result in less water pressure on the cracks, so after every measuring interval, the water was topped up to the zero point 1.5m above the base of each sample. The amount of water lost in each time interval was approximately equivalent to only 4cm or 2.7% of the total head.

In all of the experiments on this variable, the aim was to find the steady flow rate of water through any cracks. Expected results would show that there would be an initial period of instability where the flow rate changes from an initially very high level. This can be accounted for by the time needed for the groove to be filled with water, the string to become fully saturated and for the cracks to fill with water.

The full flow rates for each sample are included in the results to illustrate this point, but it is the steady flow rates that are of most interest. From the first leakage sample it can be seen that the flow takes approximately 7 minutes to settle to a steady level. To take into account any differences in the samples, readings were initially taken every minute for the first 10 minutes while flow rates are high, and then every 5 minutes for a further 45 minutes. Flow rates are calculated by recording how much water has leaked out of the samples over the test period (1 or 5 minutes) and using this value to find the total volume of water that would leak out over an hour period.

9.3.2. Limitations

The experiments using the steel rings worked well for studying crack propagation, but problems were encountered when the leakage experiment was set up. There was inadequate sealing between the layer of mortar and the retaining clips, and due to the close proximity of the channel entrances to the boundary between the clips and the layer of mortar, water quickly leaked out. The manner in which this happened can be seen in figure 9F below, which is a photograph of the equipment and clearly shows water leaking from the top of the retaining clips.

Fig 9F

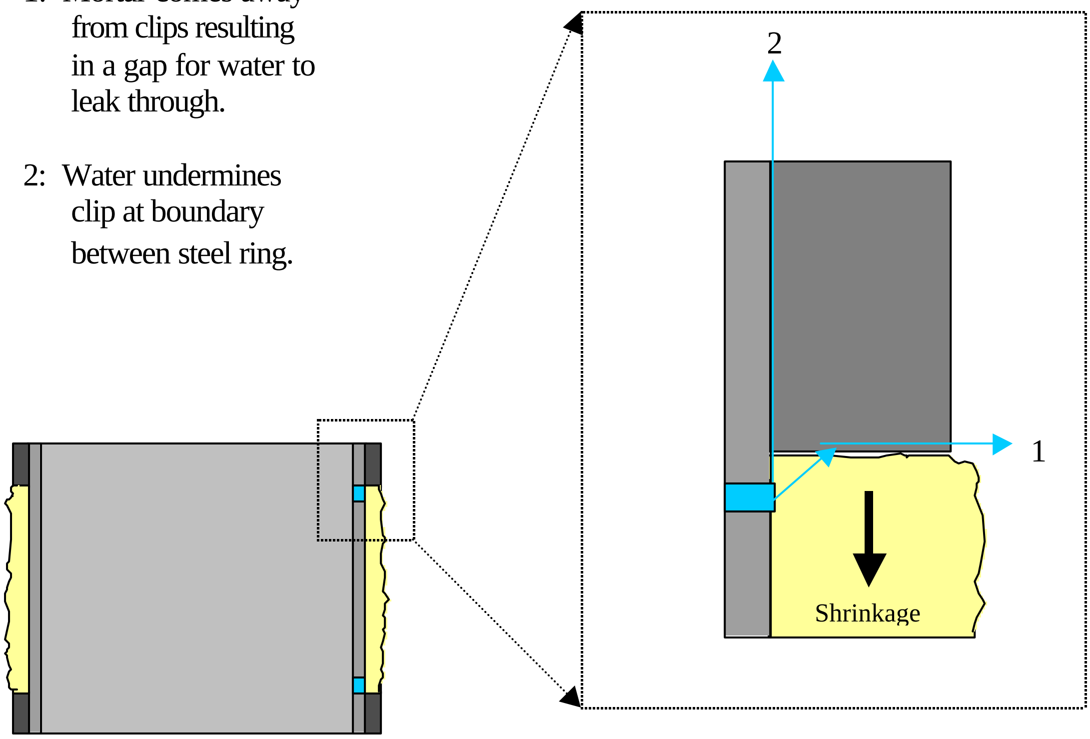
Upon manufacture of the samples, care was taken to ensure the boundary between the clips and the mortar was filled, but due to shrinkage along the axis of the cylinder, the mortar came away from the clips making it easy for water to drain out of the channel. Figure 9G on the following page shows diagrammatically how the experiment failed.

The net result of this leaking was that the samples had to be recast taking into account the means of failure of their predecessors. It was decided that to prevent the clips coming away from the mortar at the boundary between the two, that the clips would be enclosed in mortar themselves. The clips were also raised 5mm to increase the distance from the water feed holes. Once the samples dried and it was time to test for leakage, the added measure of sealing all exposed boundaries with silicone sealant was implemented. The boundary between the clips and the tubing was sealed to prevent any water undermining the clips and, the boundary between the mortar and clips was also sealed. Now any shrinkage of the mortar will result in it pulling into the clips rather than away from them, making the experiment less vulnerable to leaking.

Fig 9G

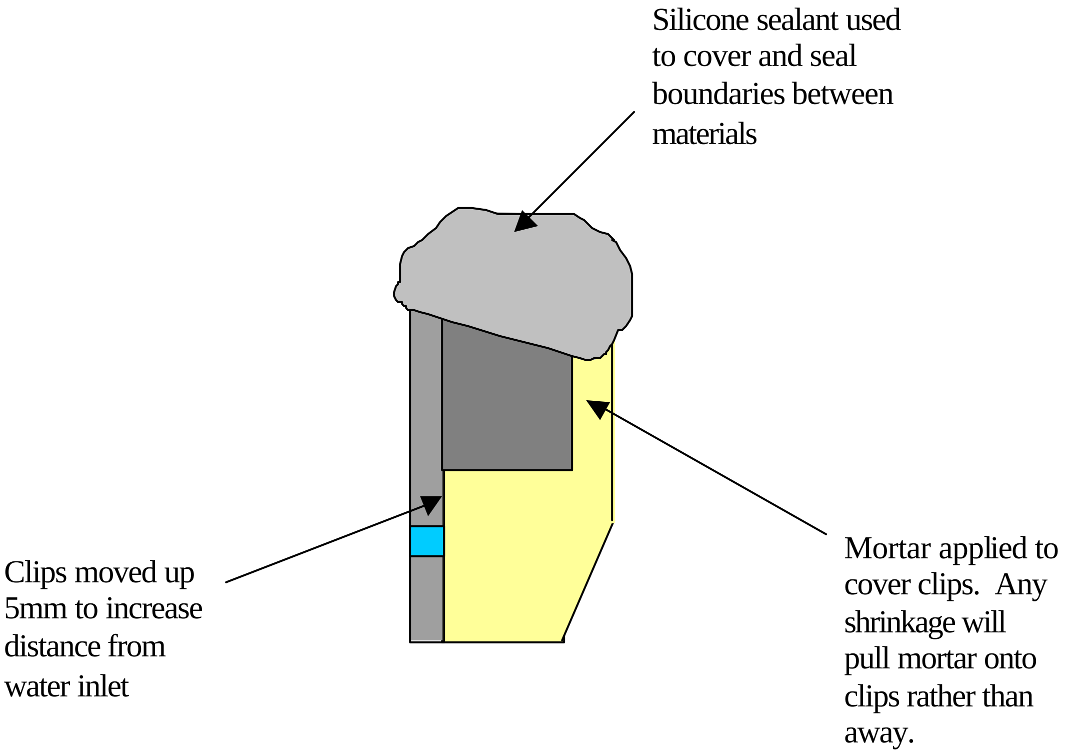
1: Mortar comes away from clips resulting in a gap for water to leak through.

2: Water undermines clip at boundary between steel ring.



The diagram at the top of the following page, figure 9H, illustrates the changes in the design of the experiment.

Fig 9H



Due to the fact that the first round of samples had to be recast, a month of experimental time was lost, and the time constraints on this investigation made it not possible to conduct a second round of experiments. This means that the only 4 samples investigated for cracking and shrinkage were plain mortar, silica fume, Harilal Leak Seal and Superplasticiser Complast 211. Had there been time for a second round of experiments, another 4 samples could have been cast consisting of a ferrofest sample, a sample with a layer of pure cement paste sandwiched between 2 layers of plain mortar, and a further 2, possibly investigating the uses of multiple admixtures in each sample.

Chapter 10: Summary of experiments

10.1 Shrinkage

1st round – 4 blocks cast. 3 plain mortar (no admixtures), 1 pure cement paste (no sand). 3 plain blocks left for various lengths of time to wet cure, 2 days, 4 days, and 14 days respectively. Pure cement left for 2 days wet curing.

2nd round – 3 blocks cast, 1 using silica fume admixture, 1 using superplasticiser admixture, 1 using Harilal leak seal admixture. All left for 2 days wet curing.

Each block had its shrinkage monitored regularly for 28 days after drying began.

10.2 Cracking

1st round – 4 rings cast. 1 plain mortar, 1 with superplasticiser admixture, 1 with silica fume admixture, 1 with Harilal leak seal admixture.

Each sample was left to cure for 2 days before drying began. Samples left to dry for 28 dries and cracks monitored.

10.3 Leakage

1st round – 4 rings cast. 1 plain mortar, 1 with superplasticiser admixture, 1 with silica fume admixture, 1 with Harilal leak seal admixture.

Each sample began testing after having been dried for 28 days

Chapter 11: Previous Investigations

As mentioned in the introduction, Steve Turner began experimentation into cracking in waterproof renders before this project began - his notes can be found in the appendix as can results taken from the samples he prepared. The samples talked about in the included documents were of similar design to the rings cast in the main investigation experiments into cracking and leakage. The main difference was that the plain, ferrofest, and nil coat samples, were cast on larger sized steel tubing, a practice dropped for the reports own experiments to keep the procedure constant.

The leakage experiment was never carried out on these samples because it was decided that the chance of all of the cracks lining up with the holes in the tube were small. It was thought necessary to be sure that all cracks were fed with water to ensure correct leakage rates were measured, which is why it was decided that the rings be modified with a spiral groove, of a pitch that was no less than the length of the smallest crack in the specimens studied prior to commencing the investigation.

Results on the cracking of these samples are included for comparative purposes, although changes in the experimental design restrict their use somewhat for this purpose. The manner in which the render shrinks makes it vital that, for experimental purposes, there is no room for an element of unconstrained shrinkage. The gauze was thought to reduce the steel ring's suitability as a constraint and may allow for some unconstrained shrinkage to be present.

To summarise, results from the samples prepared by Steve Turner, are included in the appendix and are referred to and considered in the analysis, although changes in the design of these experiments restrict exact comparisons being made.

Chapter 12: Shrinkage Results and Analysis

12.1 Shrinkage Results

The results for the set of shrinkage experiments are displayed over the coming pages, including graphical analysis. All numerical references to strain are as read from the equipment (x10^{-2} ì strain) from this point forward.

Table 12A and Graph 12A – Results for plain mortar with 2 days wet curing
Table 12B and Graph 12B – Results for plain mortar with 4 days wet curing

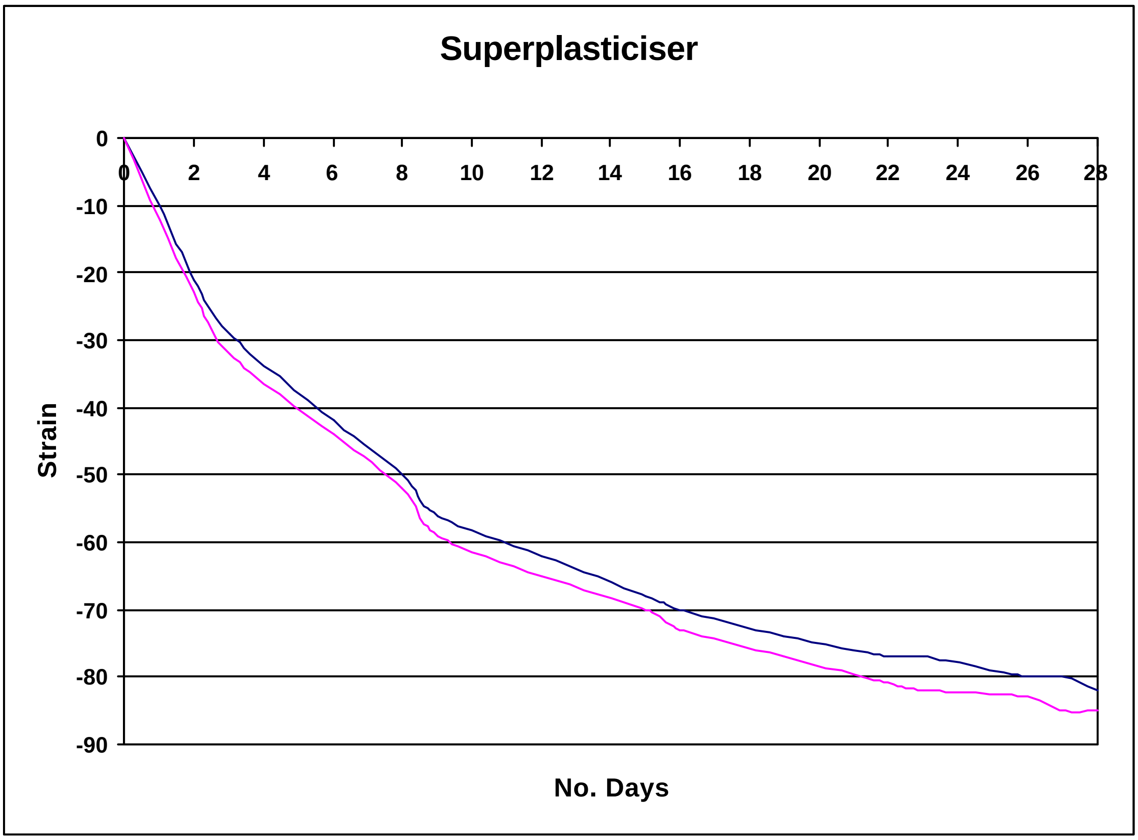
Graph 12G



12.2 Shrinkage Analysis

The first round of shrinkage experiments consisted of 4 samples, 3 plain mortar and 1 pure cement paste. Graphs 12A-12G plot shrinkage against time and show well how each sample shrinks quickly at first before slowing, resulting in a relatively smooth curve of decreasing gradient. The two lines on each graph represent the two sides of each sample and it can be seen that generally warping has not been significant with any samples, including the second round of admixtures, because the lines remain close together throughout the plots. Any difference in the position of the lines would indicate a difference in the shrinkage of one side relative to the other. The sample with the most amount of warping was the plain mortar block wet cured for 2 days, with a 4.5% difference in strain between each of the two sides, but this figure remains small enough to not affect the validity of the result.

The next observation to be made is what affects the period of wet curing had on the shrinkage characteristics of each sample. Firstly, research shown earlier in this report predicted that the majority of shrinkage would take place after drying has begun. This indeed was the case and due to the fact that during wet curing the samples were at 100% humidity, no shrinkage was recorded. Instead the opposite occurred and all of the first round samples underwent an increase in volume. This increase in volume was seen in the sample wet cured for 14 days, to level off at approximately +10 micro strain. This result wasn't entirely unexpected as research showed that this it is not uncommon for cementitous materials to increase in size in 100% humidity conditions. Even after drying this affect can be seen, although was not investigated in this project.

The period of wet curing had a marked affect on the amount of shrinkage seen in each of the 3 identical plain mortar samples. The sample cured for 14 days shrank 25% less than the one cured for only 2 days. The sample that experienced 4 days wet curing had a 10% reduction in shrinkage compared to the 2 day sample. It was expected that the increased curing would increase the material's strength, but it was unexpected that it would affect the shrinkage in such a significant manner. 25% is a major reduction in shrinkage and even though the period of curing was of secondary interest in this report, the result shows that it is a field worthy of further investigation.

In the context of using the mortar as a render in a water tank it is undesirable to have a long period of wet curing, but it should be considered if it could reduce the overall shrinkage seen in the render. Even an extra two days has been seen to reduce the shrinkage by up to 10%.

A possible explanation for the reduction in the levels of shrinkage recorded can be linked to the material strength, as follows: It has been shown that cementitous materials shrink when water is lost through evaporation. As the material dries pores are left, basically cavities where excess water has been stored, which makes the material porous after drying and reduces the strength of the material. The longer the mortar cures, the stronger it will become and it would be able to resist the shrinkage forces associated with drying and water loss. It may therefore shrink less and instead have greater internal forces built up within the material when compared to a less cured and hence weaker mortar.

When looking at the results from the samples containing admixtures, it can be seen that they too have had a big effect on the shrinkage of the mortars. As mentioned in section 6, an admixture will generally make a mortar less permeable by one of the two following methods:

1. Reduce shrinkage
2. Increase strength

Silica fume is an admixture that is used to make cementitous materials stronger. This will in theory reduce permeability because the material would crack less for any given reduction in volume. This theory is backed up by this result because the addition of silica into the mortar has had a negligible effect on the shrinkage. It underwent a reduction in length of 125 micro strain compared to 128 for the average of both sides of the similarly cured plain mortar with no admixtures, less than a 3% change.

The superplasticiser had the biggest effect on the shrinkage characteristics of mortar. At 83 micro strain reduction, it experienced a 35% reduction in shrinkage compared to the plain sample. This was expected because the plasticiser allowed a reduction in the amount of water used, although the magnitude of the reduction is surprising seeing as only 17% less water was used to create the 35% reduction in volume.

It was not known at the beginning of the investigation how the Harilal Leak Seal would affect the permeability of mortar, but it can be seen that it is less like the silica fume than the plasticiser because it has resulted in a reduction in the recorded shrinkage of 24% compared to the plain sample. The next experiment on cracking will determine whether it also has an effect on the strength of the mortar.

All of the admixture samples were prepared and tested over the same period, and a small anomaly can be noted on the day 8-9 period on all of the graphs for these samples. The anomaly in question is a small kink in the graph indicating an increase in shrinkage over the one day period. It is interesting that it is present on all of the samples and is a good indication of the validity of the results because it shows all samples were tested under the same conditions. The increase in shrinkage can be explained by there being a temporary increase in the temperature of the samples over that period which would result in more moisture being evaporated and hence a greater reduction in volume.

Chapter 13: Crack Results and Analysis

13.1 Crack Results

The results for both rounds of the crack experiment are provided over the next 2 pages.

13.2 Crack Analysis

The first fact that can be noted from looking at the tables on the crack sizes is that there is a great range of lengths and widths of cracks across the samples, as well as the number of cracks per sample. The first round of results show that the silica fume sample was most extensively cracked in terms of quantity, but the plain sample had the widest cracks of all samples.

Multiplying the length and width of each crack and adding all values for each of the cracks in any one sample can be a simple piece of analysis. It will provide a rough idea of the total crack surface area for each sample. See table 13.3A below.

Table 13.3A

SAMPLE	TOTAL CRACK SURFACE AREA: ROUND 1 (ìm^2)	TOTAL CRACK SURFACE AREA: ROUND 2 (ìm^2)
Plain	47.65	45.03
Silica Fume	33.19	38.16
Harilal Leak Seal	35.33	32.5
Superplasticiser	20.00	23.59

It is accepted that cracks vary in width along their length and that each crack may be of different depths so these figures may not correlate exactly with the leakage rates shown later, but the figures correlate well with those seen for shrinkage. The plain sample, which was seen to undergo the greatest amount of shrinkage, also has the highest crack surface area up to 30% more than the next highest of Harilal Leak Seal.

Comparing silica fume with Harilal, the total area of cracking is very similar, although with silica fume the area is spread out over a greater number of thinner cracks compared to the few wide cracks of Harilal. The mathematical analysis of flow through cracks in section 6 would suggest a greater leakage rate for the Harilal sample because of the extra width of the cracks. Whether this is the case or not can be seen in the next piece of analysis.

From the shrinkage results it was shown that mortar with silica fume present experienced a similar level of shrinkage compared to plain mortar, while the Harilal sample shrank considerably less, yet the resultant cracking is very similar. This is an important development because it confirms that the silica fume sample is likely to be much stronger than the Harilal mortar. The strength seems to have affected the distribution of the cracks also, because the silica fume sample has many more cracks than any of the other samples, a fact which is true for both rounds of experimentation.

Overall these results correlate well with those from the shrinkage experiments and the superplasticiser has performed the best in this area of investigation as well. The superplasticiser experienced up to a 43% reduction in cracking compared to the plain sample, from a 35% difference in shrinkage levels measured. Even though the superplasticiser has enjoyed a significant reduction in shrinkage induced cracking, the cracks are relatively wide when compared to examples from the silica fume sample. This is predicted to be undesirable due to the much bigger flow rates that wide cracks may be subject to. The final piece of analysis of the leakage results will show whether the superplasticiser's reduction in crack area will be of benefit if it results in wider cracks.

Chapter 14: Leakage Results and Analysis

14.1 Leakage Results

The results of the Leakage experiments carried out on the 2nd round of crack samples is provided over the coming four pages.

14.2 Leakage Analysis

The first thing to check when looking at the results for the leakage experiments is whether initial flow rates for each sample are of a similar magnitude. This is an important factor because if one sample has a much lower initial flow rate when compared to the others, this may restrict the amount of leakage seen due to the water not flowing through the groove quickly enough. This doesn't seem to be the case because all initial flow rates are of the same order of magnitude and the final flow rates seen are much lower than initial rates so shouldn't be restricted in any way. It should be reiterated that leakage results are only available for the samples from the second round of crack investigation.

As expected water levels in the test equipment drop significantly in the first few minutes of experimentation which can be apportioned to the groove filling with water and saturating the string. On all of the samples it has taken approximately 7-10 minutes for the flow rates to level off to a constant rate. The first few seconds of very high flow is, as mentioned above, due to the groove in the testing rigs filling with water. The flow drops off very quickly but remains higher than final values until around the 7 minute mark. Prior to this the medium flow rates can be attributed to the cracks filling with water. Over the first 7 minutes of the of the experiment it can be assumed there is little or no actual leakage from the mortar, rather than the flow can be explained on the water gradually filling every crack before being able to seep out onto the surface. Evidence of this is that no water was visible on the surface of the mortar for the first 5 minutes or so of each experiment. Subsequent to this moisture was visible originating from some of the cracks.

It has been stated that steady flow rates are of the most interest in this round of experiments, and it was predicted that it might take a few minutes for the flow to settle to this steady level. Comparing the steady flow rates shows some interesting correlations with previous results. The plain sample, which was the most cracked prior to the leakage test, experienced a significantly higher flow rate than any of the others with the equivalent of approximately 59ml per hour lost. The silica Fume sample which had a crack surface area 15% lower than the plain sample, had a steady flow rate of only 24ml per hour, 40% lower than the plain sample. This result could be of extreme importance because it would confirm the theory that for any given area of cracking, it is desirable to have it spread over a larger number of thin cracks rather than over a smaller number or wider cracks.

Subsequent results correlate with the total area of cracking. Harilal Leak Seal leaks at a rate of approximately 20ml per hour leakage, while 13ml per hour is the rate for the superplasticiser.

Comparing the silica fume sample to the Harilal is of interest because they both underwent similar levels of cracking, but had different numbers and widths of cracks. The Harilal sample came out on top as it leaked approximately 17% less. When this is compared to the 16% less cracking it experienced, the result becomes more important, because in this case it seems to go against the theory that crack width is the most important factor when considering leakage through cracks in mortar. All of the crack surface area of the Harilal sample was taken up by 2 long wide cracks with an average width of 125ìm, while the silica sample had 6 much thinner cracks with an average width of only 54ìm.

The superplasticiser leaked the least of all of the four samples, 76% less than the plain sample. It did also crack the least out of the 4 samples so this was not entirely unexpected, but again the cracks were of greater width than many cracks seen on other samples so initially this results seems to go against the theory that width is the key to how much water leaks from any one sample. The study on whether crack width affects leakage has proved inconclusive, a matter which is discussed in a following chapter.

Chapter 15: Summary of Analysis

The results from the experiments of the three variables have provided extremely relevant information on the suitability of each type of mortar for use as a waterproofing render on water tanks. The correlation between the shrinkage recorded from examples of each type of mortar and the amount of cracking has been high. The only exception to the pattern of high shrinkage causing high cracking was the relationship between the plain mortar, and the sample with silica fume added to it. The addition of silica had negligible effect on the shrinkage of the mortar, but this sample cracked significantly less than the plain mortar, a fact that has been attributed to the extra strength of mortar with silica fume added to it.

The remaining two admixtures, Harilal Leak Seal and the superplasticiser, both led to reduced shrinkage recorded in the mortar when compared to a plain sample. This reduction in shrinkage was confirmed by the experiments on cracking, where the two admixtures had far less cracking than the plain sample.

The silica fume sample experienced greater cracking than the other two admixtures but the extra strength of the mortar caused a spread of the shrinkage over a greater number of cracks, which according to section 6 would have a large effect on how much water leaked from it. Unfortunately the experiments proved inconclusive on this subject, because there is evidence that both supports and contradicts this theory. Comparing the leakage rates and the crack characteristics of the silica fume sample with the plain sample supports the theory, while comparing the silica fume with the Harilal Leak Seal seems to contradict it.

If the reader refers to the appendix and the results of cracking in previously carried out work (Steve Turner's), it can be seen the similarity between the types of cracking on the mortar enhanced with silica fume. These samples underwent different curing times (3 months wet curing in this case) and the cracking resulting from drying is seen to consist of many thin cracks rather than wider ones as seen on other samples. Again the plain sample experienced fewer, but wider cracking. The superplasticiser performed well as it did in this set of experiments with all of its cracks relatively short and thin. The main result of interest out of these results is the performance of the nil coat layer. This method of applying mortar involves casting an initial layer of thin mortar, allowing it to dry, and applying an even thinner layer of cement slurry (no sand), and protecting this with a final coat of mortar. The thinking behind this is that when the first layer dries and cracks the pure cement layer will help fill any cracks, and because it is denser than mortar, will be more impermeable as well. There was no opportunity to explore this possibility in this investigation due to the failure of a round of experiments and the time involved in retesting them.

The Ferrofest sample also did well, but again there was no scope to test it in this investigation. Further experimentation into the performance of these type of "sandwich" layers is recommended.

A further admixture, Festegral, was used in Steve's samples, but was unavailable for testing in this experiment as there was insufficient quantities left to experiment on but a glance at the results of the cracking experiment using this admixture suggest a lack of performance.

Chapter 16: Discussion

The leakage experiment has been the source of most of the problems in this investigation. It needed careful planning when designing the experiment to make sure all of the possible unknowns were removed to ensure reliable results were produced. In hindsight there is still a problem with the experimental method used. Observation of the surface of the samples throughout the course of the experiment showed that not all of the cracks in the mortar were leaking. From here it can be concluded that even though the mortar layer is thin at 10mm, it is not definite that all of the cracks propagated the whole depth of the layer of mortar. If this was the case then any relationship between the level of cracking and the flow rate of water through any cracks is invalid.

For a crack to affect the rate of leakage of a sample, it must be deep enough to reach the water supply at the surface of the steel ring. If a crack does not propagate this deep, then it will in no way play a part in the observed leakage. Below is a picture of a crack in one of the samples (fig 15A). If an imaginary section is taken along the dashed lines, there is no way of telling how deep the crack goes. Figure 15B on the following page shows a diagram of how this crack may have propagated in depth.

Fig 15A

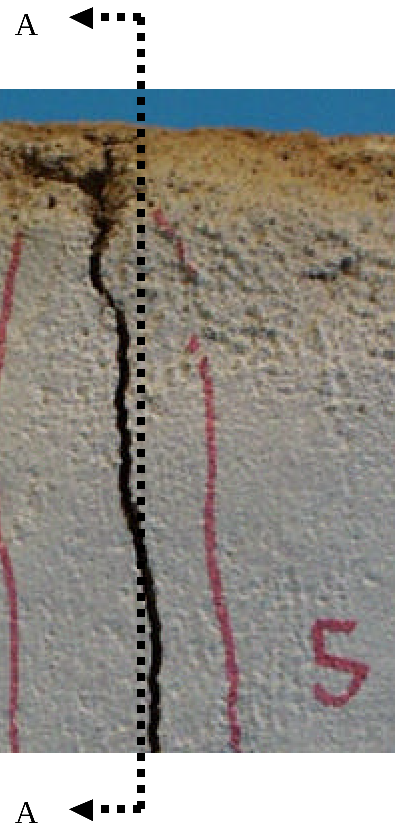

Figure 15B

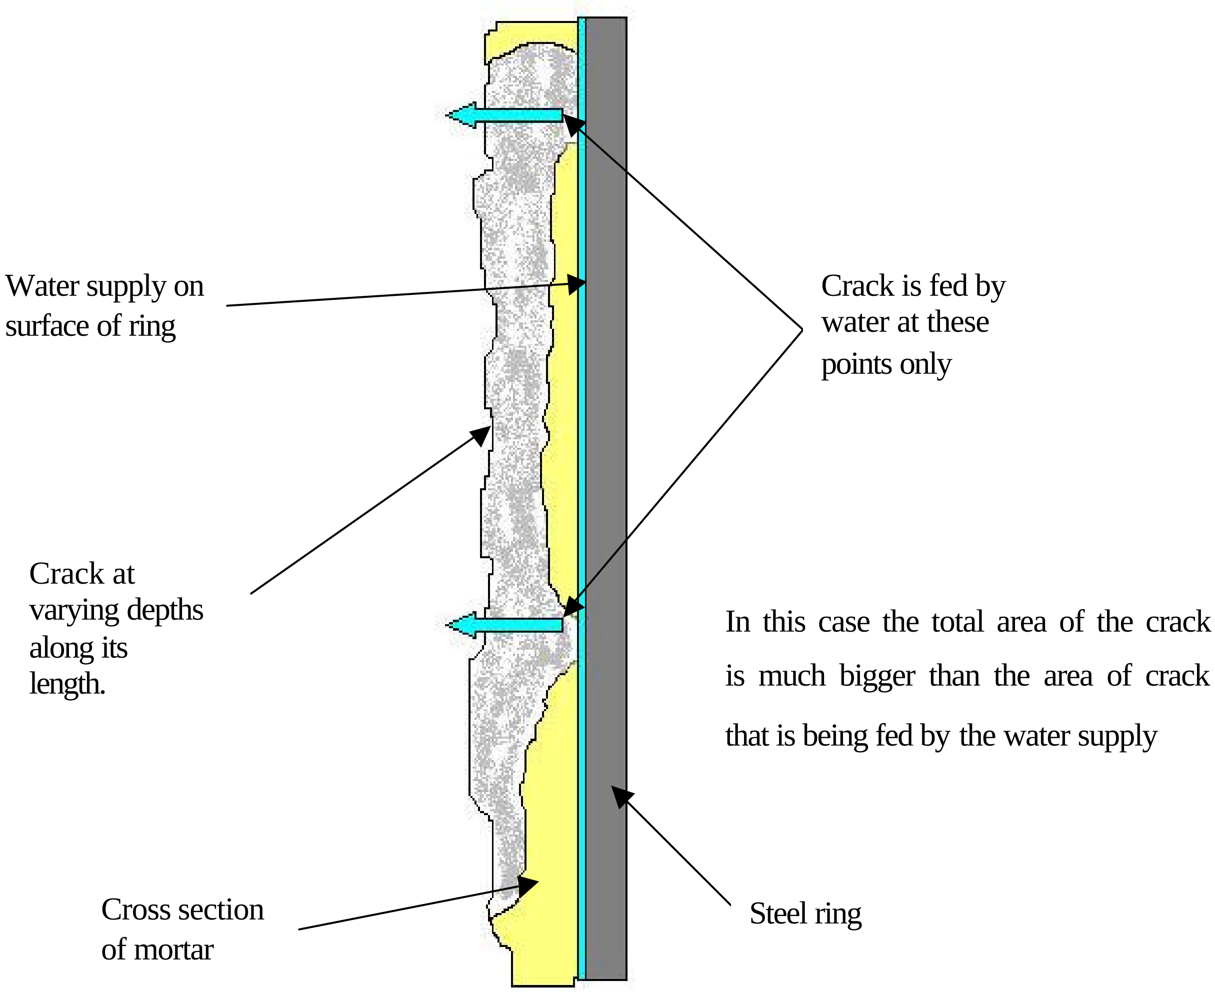

To allow valid comparisons between crack area and leakage flow rates, the area of crack in contact with the water supply must be known. It was impossible to find this area in the bounds of this investigation. A possible way of doing it would be to cut down the length of each crack after the leakage results have been taken, but this was not possible using conventional methods because the disruption of the mortar would cause further crack propagation and be generally too intrusive to give accurate results.

Even though the comparisons between crack area and leakage may not be valid, the leakage results are still important. If a crack does not propagate the whole depth of the mortar layer, then it will not cause leakage and hence some tension has been released at no cost. It would be extremely desirable to have a mortar that relived the shrinkage-induced tension with purely superficial surface cracks, as it would then not leak at all. This hasn't been the case with any samples tested but anomalies that occur when comparing the leakage and the cracking of some samples can be explained by the possibility that not all of the cracks penetrate the full depth of the mortar. This helps to explain why the Harilal Leak Seal sample leaked slower than expected when compared to the silica fume sample.

There are many other factors to consider when looking at the experimental procedure for the leakage variable. Both shrinkage and crack measurements are relatively easy to perform reliably and accurately, but the leakage of water from a sealed vessel is notoriously unreliable, especially when the vessel is sealed with a material as coarse as mortar. The groove in the steel ring is basically a small water tank with the top and sides sealed with mortar. It must be well sealed to make any results for leakage useable. There are many places other than a crack in the mortar that water could leak from, as seen in the first round of leakage experiments where the water was lost at the boundary between the mortar and the retaining clip. The subsequent change in design of the experiment appeared to have cured this problem but the equipment can still not be guaranteed watertight. Had the first round of experiments not leaked, then two sets of results for leakage would be available for analysis, and this would show whether the results were repeatable, and hence increase their validity.

In chapter 6, it was suggested that the flow rate of water through a crack was related to the crack width by the relationship ÓLb^2 where L is the crack length and b is the width. This cannot be proved or disproved, as there is evidence both for and against it.

The only way to be entirely sure that any results from the leakage experiments are useful when considering water tanks, is to construct a tank as would be used in places like Uganda, render it with mortar and carry out a study of how much it leaks. In reality it would be impractical to do this for every type of mix, so the experiments used in this investigation are useful to determine which mixes of mortar are likely to be best suited to carrying out the desired task. However, the results provided should not be regarded as a guarantee of the suitability of a mix of mortar for the task it has been set to do.

Chapter 17: Conclusions

Analysis of the results from the three experimental methods has provided information from which conclusions can be made. The first conclusion is that admixtures have a definite impact on the properties of a mortar mix to which they are added, in some cases a dramatic impact. Of the three admixtures studied in this report, the superplasticiser has the largest favourable effect on the shrinkage properties of drying mortar, causing a 35% reduction in shrinkage. The silica fume had the least effect on shrinkage at only a 3.5% reduction when compared to plain mortar, although this is unsurprising because it is used as a strengthening admixture rather than one that reduces shrinkage. Prior to the results from the shrinkage experiment, it was unknown how the Harilal Leak Seal admixture would reduce leakage from a mortar rendered water tank. It can be concluded that it reduces the shrinkage experienced by a sample of mortar, rather than increasing the strength, although whether it affects the strength is unknown as no experiment was done on this variable.

The analysis of the cracking experiment shows correlation between shrinkage and cracking. The superplasticiser experienced the least cracking, which was expected after it was discovered how much it reduced shrinkage. It can also be concluded that increasing the strength of mortar will help distribute shrinkage over a greater number of thinner cracks. The superplasticiser underwent the least shrinkage but its cracks were wide when compared with those on the silica fume sample. Referring back to section 6, it was shown that increasing the width of a crack by a factor of 2 will increase the leakage by a factor of 4, so the type of cracking on the superplasticiser is undesirable when compared to the silica fume.

From the leakage experiment it can be seen that all of the three admixtures tested are favourable when compared to plain mortar. The plain mortar sample experienced most cracking by area, had the widest cracks, and had significantly greater flow rates through the cracks. Consistently throughout the investigation, the plain samples have preformed poorly when compared to the samples where admixtures have been used. Again the superplasticiser and the Harilal leak seal performed best in the leakage experiments. It was proposed in the discussion that any comparison between cracking and leakage would not be well founded due to the unknown surface area of crack being fed by the water supply. For this reason the result of the mathematical model in section 6 cannot be verified, although there is evidence both for and against it. The plain sample had by far the most significant cracking and had the highest flow rates by over a factor of 2 which supports the analysis in section 6, although the comparison between crack widths and leakage rates in the Harilal and silica fume samples go against the theory. This report recommends that an investigation into flow through channels of controlled widths be carried out to decide whether crack width has such a significant effect on flow rate.

The possibilities of mixing different admixtures in a sample of mortar was not looked into in this investigation due to the amount of time each round of experiments took, and the need to re-cast a round as explained previously in the report. From the results it is suggested that a mortar sample that has both silica fume and a superplasticiser added to the mix be investigated. The two factors highlighted in section 7 that affect the leakage through a mortar (strength and shrinkage), can be improved individually with these admixtures. It appears that no one admixture can improve both of these properties but combining the two that most significantly improve each one may combine the benefits of each.

Another possibility for further investigation would be to experiment on the ferrofest layer as described in section 7, and a similar layering technique using a sandwich of two plain coats and a thin layer of pure cement paste in the middle to act as a “filler” to block any cracks that form in the first layer. Many combinations of admixtures are available and many products are on the market that haven’t been tested in this investigation due to time constraints. An exhaustive study of these would show which combinations of admixtures would be most suitable.

However, the conclusion of this report using the results recorded is that if using a single admixture, the superplasticiser is most suitable for use in a mortar to render a water tank. The report also recommends that a combination of the superplasticiser and silica fume in a sample of mortar is likely to combine the benefits of each, and further study into this possibility is recommended.

Engineering Undergraduate Project

Development and Selection of Low Cost Handpumps for Domestic Rainwater Water Tanks in E. Africa

Vince Whitehead

University of Warwick

May 2001

Summary

This report gives details of the development and selection of a handpump suitable for use with domestic rainwater harvesting tanks in East Africa. The objective of the project was to develop a small low cost handpump, which can be manufactured, maintained and repaired with a minimum of tools and skill and that the materials can be found in most local hardware outlets and markets.

Four designs were proposed which were selected from a range of pump technologies for low head and low flow rates. From these, two were selected for their ease of manufacture, low skill level and expected reliability. The two handpumps ('Harold' and the 'Enhanced inertia') were subjected to a series of performance and durability tests. From these tests, both handpumps were found capable of lifting at least 15 litres per minute at 70 cycles per minute with acceptable hydraulic efficiencies. The actual lifting rate was significantly greater than the value given in the specification.

The durability tests showed very little evidence of wear in either handpump after 145 hours continuous running other than some potential splitting in the valve surfaces. An extended endurance test on the recommended handpump, the Enhanced inertia, resulted in it lifting around 300,000 litres and having an equivalent life of 8 years.

The handpumps were produced in Uganda for less than $10 for a 3.5m length, which was one of the main criteria in the specification. The pumps were successfully manufactured by a number of technicians in Uganda after a two-day training workshop and this illustrates that the design and technology is appropriate.

Contents

Acknowledgements

I would like to express my thanks to the following people:

All the staff at Kyera farm, Mbarara, Uganda who assisted in the first stage of this project and for their hospitality and encouragement whilst working there.

Everyone at the Development Technology Unit, University of Warwick for the experience and opportunity of working in Uganda.

To Andre and Bob Leliveld for the photographs and for their company during my stay in E. Africa.

Erich Baumann and the Handpump Technology Network (HTN) for their valuable assistance, knowledge and feedback throughout this project.

Also to Jonathan Keighley for his time in proof reading the report.

1. Introduction

The aim of this project was to develop a suitable small low-cost handpump, which could be used for abstracting water from Domestic Roofwater Harvesting (DRWH) systems in East Africa. A low-cost DRWH system is shown in Figure 1, and consists of a roof to intercept the rain, a series of gutters and downpipes, and a purpose built tank into which the handpump is installed.

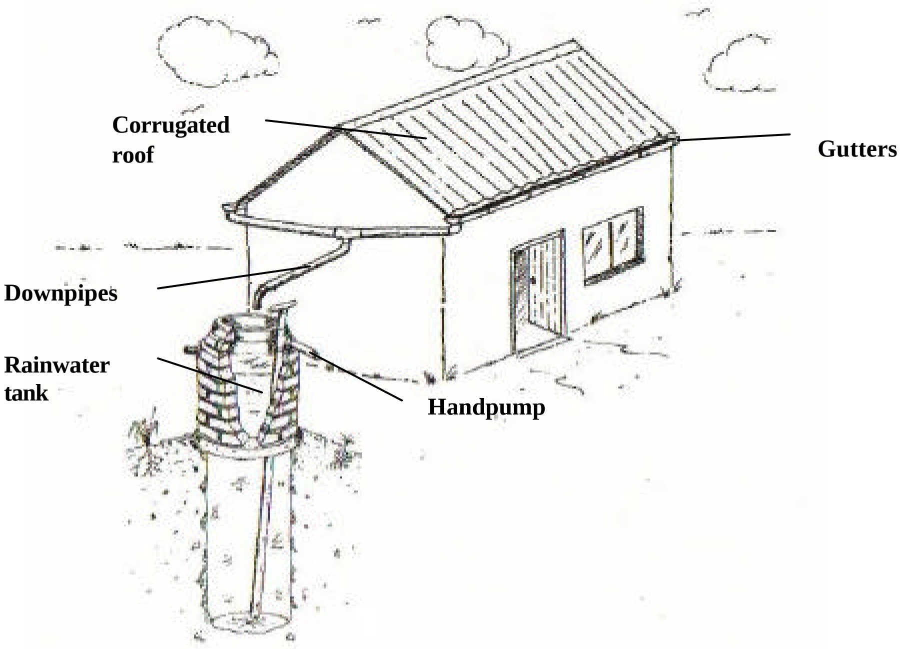

Figure 1 A domestic Rainwater harvesting system

This project was divided into two phases. Firstly an introductory phase, carried out in Uganda (chosen to represent African conditions), was used to identify constraints within the environment and expose four handpump designs to users. Secondly, the main phase of the project was to identify two candidate designs, refine them and carry out performance and endurance tests at the University of Warwick.

One of the main priorities in developing the handpumps was to ensure that the manufacture and materials could be made and/or sourced from within the local area.

The first phase was carried out by the author in Mbarara, (the fourth largest town in Uganda), during July/August 2000 and at Kyera farm, Mbarara. This involved assessing the manufacturing capabilities within the locality, material supplies and the availability of tools in local markets. Some prototype handpumps were manufactured and installed in DRWH systems in Uganda.

Many existing pumps may be regarded as over designed and too expensive to incorporate in to a DRWH system. They can also be difficult to maintain because of the high cost of spares, and the spares may be stocked some distance from the pump location.

The second and main phase was carried out at the University of Warwick. This involved choosing two of the four proposed designs and carrying out a series of performance tests, refining them and then subjecting each handpump to an endurance test.

To achieve the aims and objectives of this project, a plan was set out so the project could follow a logical sequence of tasks over the allocated period and finish completed on time. A software package was used to plan the projects tasks, this was then used to monitor the progress of the project and make adjustments should any arise. A hard copy of the project plan is shown in Appendix 1.

2. Analysis of need and development of specification

Many areas of East Africa have a very varied rainfall pattern and in particular regions, for example in Rwanda, this can result in a six-month dry season. Many rural families do not have access to an adequate and safe water supply. This can mean long treks to some distant water source, which may be of low quality and consume valuable hours from their daily duties.

Fetching water may often involve many hours a day in walking several miles to and from the source by either children or women. The time spent collecting water is a double burden, as it means less time is available for the productive activities on which subsistence economies depend[1].

Definitions given by WHO (1996[2]) are as follows:

- Access to water: In urban areas, a distance of not more than 200 metres from a home to a public standpost may be considered reasonable access. In rural areas, reasonable access implies that a person does not have to spend a disproportionate part of the day fetching water for the families needs.
- Adequate amount of water: 20 litres of safe water per person per day.

[1] Water Supply and Sanitation programmes, DFID

[2] WHO, catalogue of Health Indicators. Geneva.

- Safe water: Water that does not contain biological or chemical agents directly detrimental to health.

46% of the rural population of Uganda for example does not have access to safe water (UNICEF).

To ease the burden of the above points, a DRWH system, which incorporates a handpump as shown in Figure 1, can be used to supplement a household's daily need during this dry season.

2.1 Specifications

The following specification has been drawn up to represent the particular conditions under which a handpump will be used:

- The handpump must be of low cost (i.e. affordable by low-income households in Uganda, with a maximum cost of UGS 18,000 ≈ $US10).
- It must be possible to manufacture and maintain the handpump within E. Africa at village level with a set of basic hand tools.
- The handpump should be capable of raising at least 10 litres per minute from a depth of 3 metre.
- Reach water within 200mm of the bottom of a tank.
- It should have good durability i.e. capable of lifting a minimum of 100,000 litre before requiring replacement (based on a family of five people with a 20 lpcd for three years).
- Only require basic maintenance - say every 10,000litre before requiring maintenance.
- The footvalve must not leak faster than 0.1 litre per minute.

In addition, it is desirable, but not essential, that handpumps have the following characteristics:

- Be reasonably secure against children pushing stones or pouring liquids into the outlet.
- No part should be easily stolen or removed.
- The outlet must be at such a height that most collection vessels, especially jerricans, can be easily filled.
- It must be ergonomically suitable for a child of about 6 years old to use comfortably.
- Be capable of fitting various types of tank covers, including ferro-cement covers (dome), and through a parapet wall.
- Permit the rising main and footvalve to be withdrawn for maintenance purposes.
- Suitable for production by artisans as an income generating activity.

3. Review of water lifting techniques and selection of candidate pumps

There are four different mechanical principles of transferring water from one location to another and these are shown in Table 1. These can range from simple devices such as scoops to more complex centrifugal pumps.

For the first three methods given in Table 1 these can be further subdivided in to rotary and reciprocating categories, for a taxonomy of pumps see Appendix 2.

Table 1 Summary of four mechanical means of lifting water

Direct lift:	By using a container to physically lift the water
Displacement	Water can be regarded as incompressible and can therefore be displaced
Creating a velocity head	Flow or pressure can be created by propelling water at high speed
Using the buoyancy of a gas	Passing air bubbles through water will raise the level of the surface

(Fraenkel, 1997, p29)

Rather than go in to any detail here an outline of techniques for lifting water in the low head, low flow rate range are summarised below. For a more detailed account, these are well documented by Fraenkel (1997).

To briefly discuss the most common types of low head, low flow capacity lifting devices the following descriptions are given:

3.1. Direct lift

Many of the direct lift methods of lifting water require open access to the water surface, i.e. buckets or containers on ropes or a lever for mechanical advantage supported on a frame. Persian type wheels rotate scoops or buckets in to the water, which transfer the water on the down side of the rotation. These can be employed in small-scale irrigation and to fill cattle troughs. The construction of these is simple and basic requiring a very low skill level.

3.2. Displacement pumps

Lift and suction pumps fall in to the category of displacement pumps. These rely on a piston, which is close fitting within a cylinder containing water. Lift pumps physically lift the water that is above the piston up the pipe to the outlet. Suction pumps have the piston above the surface of the water. By lifting the piston a vacuum is created which displaces the water up the pipe. A one way footvalve is needed to stop the water in the pipe from flowing back in to the well/tank. Figure 2 shows the basic principles of lift, suction and displacement pumps.

3.3. *Suction pumps*

Suction pumps rely on a piston seal within the cylinder. On the upstroke a pressure difference occurs between the air at the water level and the air in the cylinder chamber. This forces water in to the cylinder, which gradually rises on each successive stroke. The annulus or gap between the piston and the cylinder will affect the performance of the pump. The annulus needs to be at a minimum or even have some interference, and may be lubricated in some

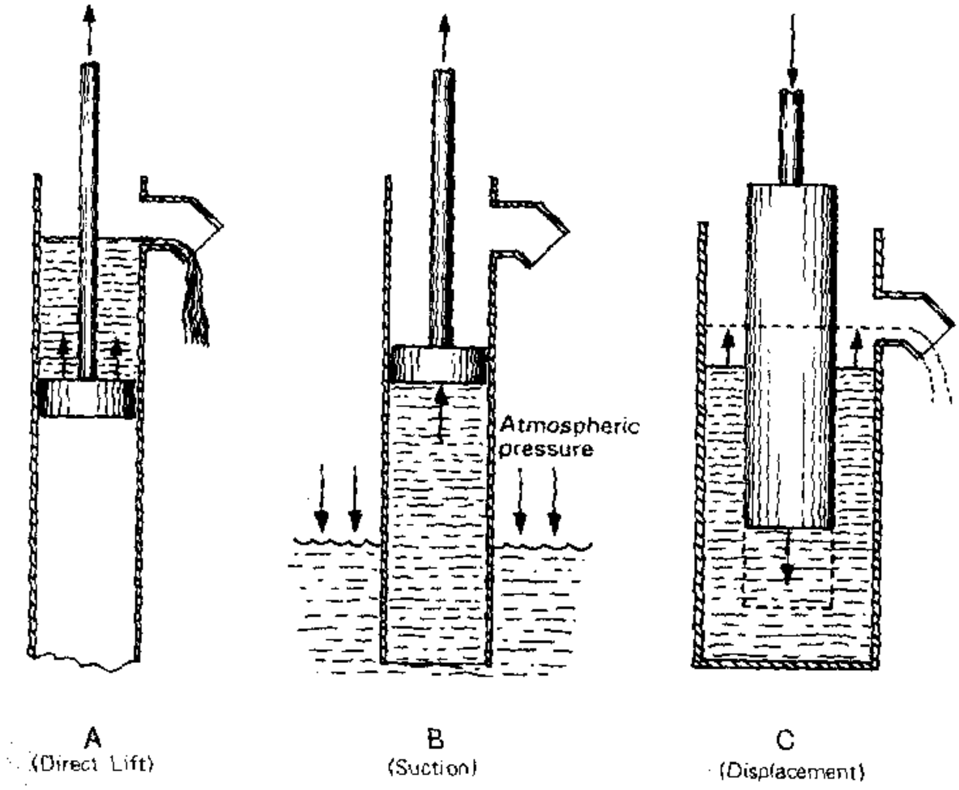

Figure 2 Basic principles of positive displacement pumps

cases to reduce friction. Priming may be required to get a pump to work, because water is more viscous than air it helps to improve the seal during the first few strokes. Priming can be achieved by physically pouring water in to the piston chamber or by retaining water in the chamber during non-operation of the pump. The latter requires a footvalve that does not leak or leaks at such a slow rate that the chamber is not emptied before the pump is used again.

There are limits to how high the suction lift can be. In theory, this is 10.4m at sea level, and in practice, 6.5m is a more practical limit. This will be further reduced by increased temperature of the water and higher elevations. For example, an increase in temperature from 20° to 30° will reduce the suction head by 7%, and for an elevation of 1500m the maximum suction will be around 5m [Fraenkel 1997, p14]. As a general rule for every thousand metres of elevation a loss of 1m suction head will apply.

3.4. Lift pumps

Lift pumps have some similarities with suction pumps in their components but differ in the position of the piston. For lift pumps the piston is below the surface level of the water, and by raising a handle, connected to the piston via a pull rod, water can be drawn up the rising main.
For lift pumps, it is preferable that there is a good fit between the piston and the cylinder but it not as critical as it is with suction pumps.

As Fraenkel relates there is a basic relationship between the discharge rate (Q), the piston diameter (d), the stroke length (s), the number of strokes per minute (n), and the volumetric efficiency (η_{vol}). The volumetric, or hydraulic, efficiency is an indicator of the actual discharge over the swept volume per stroke.

If the swept area of piston is A	$= (\pi d^2)/4$
Swept volume per stroke, V	$= As$
Discharge rate q	$= \eta_{vol} V$
Pumping rate per min Q	$= nq$
Then Q	$= 60n\eta_{vol} s\pi d^2/4$

The term slippage is sometimes used and refers to the difference between the swept volume and the actual discharge per stroke:
Slippage $X = V - q$
Slippage arises partly because the valves take time to close, they are often still open when the piston starts its upward travel, and because of back leakage past the piston or valve seats. Slippage is therefore normally less than unity, typically 0.1 or 0.2; it tends to be worse with shorter strokes and higher heads (Fraenkel, 1997, p38-39).
In some pumps the volumetric efficiency can be greater than 1. This arises in particular pumps that use the inertia of the water to raise an amount of water. As the column of water is accelerated upwards, it has inertia that keeps the column rising for a short time while the pump is being pushed downwards while the valve remains open. Therefore, the volume of water discharged is greater than the actual swept volume of the piston.

4. Manufacturing environment, competition and materials choice

4.1 Review of handpumps in Mbarara

Figure 3 Semi-rotary handpump

A search of hardware shops in Mbarara, Uganda was carried out to find what types of handpumps were available. The only one found was a semi-rotary type, as shown in Figure 3, and was made in Czechoslovakia. This consisted of a heavy cast iron chamber with a series of internal brass valves. The pump operates through rotating the handle repeatedly through approximately 120°. The pumps are generally very stiff to operate, and pumping is very exhausting work beyond ten minutes. The handpumps cost UGS600,000 (GBP250), no performance data was available with the pumps. This handpump is deemed too expensive and regarded as too difficult to operate, certainly by a child.

4.2 Manufacturing capabilities and materials available in Uganda

A reasonably thorough search of Mbarara, and to a lesser degree other towns, was carried out to find what trade outlets and manufacturing facilities were available which may be drawn on for the purpose of developing handpumps.

Like many Ugandan towns there are a large number of hardware shops dealing in a wide range of hand tools and plumbing fittings of reasonable to good quality products. There were also many steel stockholders and builders merchants in most towns visited. The steel stockholders did not have any stainless steel or brass sections in stock but some were willing to secure an order from Kampala.

Only one engineering workshop capable of any precision engineering was found in Mbarara. This consisted of a centre lathe, drill press, an off-hand grinder and one machinist.

There are many carpentry/joiners located in most towns, and mainly produced beds and cabinets, some of the larger establishment had wood lathes, and were capable of very high quality of craftsmanship. Also, there are plenty of roadside welding facilities available, usually fabricating burglar bars. For a list of common materials, tools and accessories found within a typical market in Uganda see Appendix 3.

4.3 Suitable materials for the rising main and cylinder

A durable, light weight and corrosion resistive material would be ideally suitable as a means of conveying water from the tank. The material must also be capable of being processed with simple and basic tools. This would rule out steel pipes as they are difficult to process without expensive equipment. One material that is widely available, non corrosive and lightweight is PVC.

4.4 The use of PVC as a suitable material for handpumps

There are several valid reasons for using PVC for handpumps, though there are some drawbacks as well. Table 2 gives some advantages and disadvantages of PVC. There is a range of PVC pipes available in E. Africa. These are thin walled low quality with no manufacturing marks for identification.The use of PVC has widely been accepted as a suitable and safe material for use with drinking water As Michael Dudden of the Consumers' Association Research & Testing Centre (CARTL) quotes:

> "The UK Drinking Water Inspectorate, the Swedish Environmental Protection Agency, the Swedish Water and Waste Waterworks Association, the World Health Organisation and the Organisation for Economic Co-operation and Development have confirmed the safety of PVC pipe. All these organisations have approved the use of PVC pipes to carry potable (drinking) water"

Table 2 Advantages and disadvantages of PVC for handpumps

Advantages	Disadvantages
Non-corrosive (esp. in aggressive water conditions)	UV degradation (causes embrittlement)
Light weight	Low impact strength
Low cost	Above ground parts may be subject to high forces: from animals using the pump as a scratching post, pipes being used as a resting post or being accidentally hit with full jerricans and possibility of malicious damage.
Flexibility (i.e. heat manipulation,)	
Ease of transportation (easily carried by bicycle)	
World wide availability	
Secondary uses (recyclable)	
Low cost joining ability (solvent welding)	
Non toxic (through usage) or taste tainting	

5. Calculations of power and efficiency

5.1. Power required from specifications

Determining the power required to operate a handpump is important for both its efficiency and to match the prime mover. The power capabilities of humans at various ages and durations are shown in Table 1 (Fraenkel, 1997, p118). As we are only interested in lifting 20 to 40 litres at a time, the first column is of most relevance.

Table 3 Power capabilities of human beings

Age	**Human power by duration of effort (Watts)**					
Years	5 min.	10 min.	15 min	30 min	60min	180 min
20	220	210	200	180	160	90
35	210	200	180	160	135	75
60	180	160	150	130	110	60

(Fraenkel, 1997, p118)

Table 4 Handpump specifications

Detail	**Symbol**	**Units**	**Value**
Flow rate (discharge)	Q	litre s^{-1}	0.167
Head (maximum)	H	m	4
Inside diameter of riser	d	m	32×10^{-3}
Stroke length	l	m	0.3
cadence	n	Cycles s^{-1}	1.167

To determine the power required for the handpump operating under the specifications in section 2.1, and shown in Table 4 the following calculations show that if:

$P_0 = E.n$

where: P_0 = power (water Watts), E = output energy, n = cadence in strokes per second

and $E = mgH$

where: m = mass of water lifted per cycle, g = gravity, H = head

$m = v.\,\boldsymbol{r}$

v = swept volume of stroke, ρ = density of water

Therefore the swept volume of half cycle is:

$v = \pi . r^2 . l \quad = \pi \ (19.5 \times 10^{-3})^2 . \ 0.3 = \mathbf{3.58 \times 10^{-4} \ m^3}$

$E = 3.58 \times 10^{-4} \ m^3 \times 1000 kg \ m^3 \times 9.81 ms^{-2} \times 4m = \mathbf{14J}$

Therefore: $P = 14J \times 1.167 \ s^{-1} = \mathbf{16.38 \ Watts}$

If the pump is 40% efficient then the power input P_i = **41Watts**

From Table 3, it can be seen that a 20 year old human is capable of producing 220 Watts effort for a duration of 5mins. From this, we can see that for the power required for lifting water, at the given specifications, a direct lift type handpump would be suitable.

5.2. Losses in the system

It is inevitable that there will be losses for any pump and its prime mover, however for the purpose of this project the pump is the main concern. It takes power to lift the water and to overcome any losses in the system. These losses may be mechanical, hydraulic or combination of the two. The following list shows sources of power losses in a pump:

- Friction in straight pipes (hydraulic)
- Friction from sliding components (mechanical)
- Leakage through pipes and badly sealing valves
- Flow friction through valves
- Headloss at changes in cross-section or flow direction
- Water leaving the handpump has kinetic energy
- Valve operation (delays in opening and closing causes losses)

5.2.1. Pipe friction

To get a reasonable and quick value for frictional losses it can be easier to use charts (as shown in Appendix 4). Using the chart method for a flow rate of 0.3 litre s^{-1} and an internal pipe diameter of 32mm, the headloss equates to about 0.58m per 100m. This is for cast iron pipe and a modifying factor for smooth PVC pipe is given as 0.8, which gives 19mm for a 4m head. Therefore pipe friction at these low flow rates and low head can be regarded as a negligible. But if smaller pipes are used higher frictional head values will be found, for example a 20mm PVC pipe will have 200 mm headloss loss for the same flow rate.

6. Selection of suitable handpumps

From the taxonomy of pumps shown in Appendix 2 it can be seen that there are a number of pumps that are suitable with head ranges far beyond the 4m limit given in the specification at the beginning of this report. The main types that are within the specification are the direct lift reciprocating/cyclic types.

Because of the open access to the water surface for lowered 'container' type lifting devices these incur a high risk of contamination from the container. Moreover there is also a potential for mosquito breeding in any tank without a permanently sealed cover.

For the 'Persian wheel' types the physical size of the tanks makes it unsuitable for abstracting water.

The rotary velocity pumps (propellers, mixed flow, etc) are suitable for the required head but demand a high degree of manufacturing process and precision, which would take the handpump beyond the $10 cost. In addition, the manufacturing capabilities in Uganda or most of E. Africa are not adequate for this at present.

This leaves generally the suction and lift pumps and possibly the rope and washer pumps.

7. Four designs of handpump

From the materials, tools and manufacturing search carried out in Uganda as well as the points made in the above sections a suction pump and three lift pumps were chosen.

The suction pump was based on the Tamana handpump developed in Sri Lanka, which makes use of standard PVC pipe fittings. The three lift pumps chosen were:

- The DTU handpump. A simple bicycle pump modification using a leather washer as the piston (Thomas T, *et al*, 1997).
- The 'Harold' pump which uses a non-contacting simple moulded cup (Whitehead, 2000) and does not rely on any fine precision to produce a lifting action.
- An Enhanced inertia pump which has no piston and relies partially on the inertia of the water in the system.

Details on the manufacture of these four pumps are not included in this report as they are detailed in technical release No TR.-RWH 09 (Whitehead, 2000).

7.1. *The DTU Handpump*

The DTU Handpump, (an exploded view is shown in Appendix 5) is a simple lift pump and uses a leather stirrup-pump piston, which is available from most cycle shops. The principle of operation is as follows: As the handle is lifted, the water above the leather washer is lifted with it. During this stage, the footvalve is opened and the water fills the rising main below the leather piston. On the downstroke, the footvalve is closed and the water in the lower section bypasses the leather washer to the upper section. Repeating operations transfers water to the outlet. During operation of the handpump, water continues to be discharged from the outlet even on the downstroke: this is because the volume of the push rod displaces water within the rising main.

7.2. *The Tamana Handpump*

This slightly modified version of the Tamana handpump, (an exploded view is shown in Appendix 6) is a suction pump. The pump relies on a seal between the piston-valve and the bore of the PVC cylinder.

During the upstroke, the piston-valve closes (flat on a PVC support), this creates a negative pressure below the piston, and this draws water into the cylinder through the footvalve. On the downstroke, the piston-valve is opened and water flows through the holes in the support to the cylinder above the piston-valve. On both strokes water is discharged through the outlet, as with the previous handpump the volume of the pull rod displaces water within the cylinder on the downstroke.

Labyrinth seals (a series of seals) can increase the performance of the seal. This version uses only two as a demonstration but more could be added. A suitable length of 1½ PVC pipe is connected to a reducer at the bottom of the cylinder and leads in to the DRWH tank where a floating valve is used for the intake.

7.3. *The "Harold" handpump*

The Harold handpump is a lift pump (an exploded view is shown in Appendix 7), but differs in the fact that it does not rely on a seal or a flexible membrane within the rising main. The piston, as such, is a moulded plastic cup, which is slightly smaller than the bore of the rising main. This is shaped in such a way that it has greater resistance to leakage on the up stroke and water is lifted by the cup. A small, but acceptable, amount of water will leak past the annulus around the cup. If the cadence is very slow, the leakage past the cup will be large.

The sequence of operation is shown in Figure 4, on the upstroke a), the footvalve opens allowing water into the rising main. On the downstroke b), the footvalve closes, and the water within the rising main flows around and above the cup. Repeated operation c) lifts water to the outlet. Very little water is displaced on the downstroke because of the small volume of the pull rod.

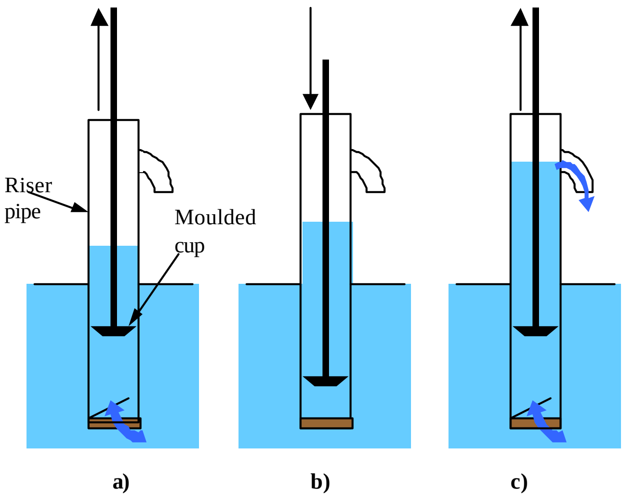

Figure 4 Sequence of operation for the Harold pump

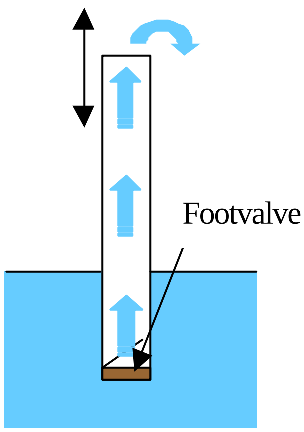

Figure 5 A 'joggle pump

7.4 The Enhanced inertia handpump

This pump, (an exploded view is shown in Appendix 8) does not rely on a seal within the rising main, but uses a central tube to lift the water, which overflows in to the rising main.

To explain the principle of operation it is first easier to see how the 'joggle' pump works. If an open top pipe with a footvalve is moved rapidly up and down the inertia of the water will gradually discharge water as shown in Figure 5. One limitation to this is that it will not work at very slow cadences.

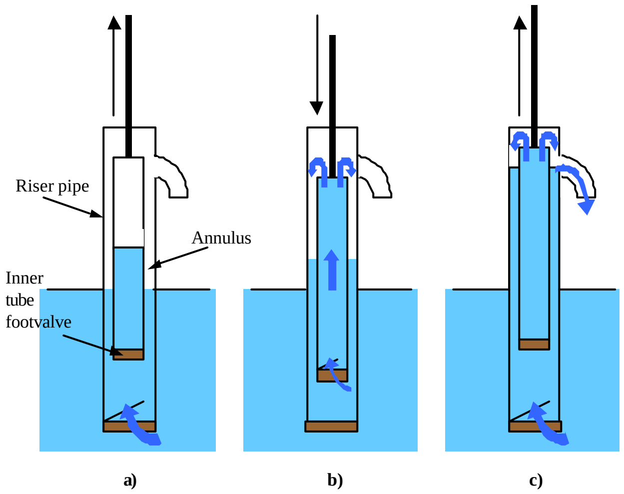

Figure 6 Sequence of operation for the Enhanced inertia pump

By combining this principle with an

outer tube, also with a footvalve, an enhanced principle is observed. A good commercial example of this is the "New Zealand Pump" (www.nzpump.co.nz). A very simplified sequence of operation is shown in Figure 6. During the upstroke a), the inner footvalve is closed and the main footvalve is opened letting water in to the rising main. On the downstroke b), the inner footvalve is opened letting water in to the central tube, meanwhile the main footvalve is closed. Repeated operations c) gradually brings water up the central tube, this then flows through a series of holes in the central tube in to the rising main and is eventually discharged at the outlet.

This handpump seems to operate best when short fast strokes are used. The flow is similar on both strokes of operation, again because of the high displacement from the central tube, which is full of water on the downstroke.

8 Critical components common to all four designs

8.1 Surface roughness and roundness of cylinders

The DTU and the Tamana handpumps rely on a good seal within the rising main cylinder, therefore it is preferable that the surface of the cylinder is as smooth and as round as practically possible.

To determine the smoothness of the bore several samples of uPVC pipe, from different hardware outlets in Uganda, were checked for surface roughness at the Centre for Micro-Engineering and Metrology at the University of Warwick.

At this level the surface roughness is expressed by its Ra value, and uses units in the µm range. Using a pump cylinder with as smooth a bore as possible can reduce the amount of friction (and subsequent wear on the piston) which the user may directly feel as a force to overcome by additional effort. The wear rate will also depend on the hardness of the material used for both the cylinder and the piston seal. A rough pipe surface (a high Ra value) can quickly wear the piston seal and reduce its out flow rate and hence its efficiency.

Table 5 shows the mean surface roughness of two sample cylinders for several popular handpumps available in the early 1980’s.

Table 5 The Ra value of several handpumps with various cylinder materials

Handpump Name	Cylinder material	Ra (mm) Sample 1	Ra (mm) Sample 2
Vergnet	Machined steel	0.57	0.60
Rower	Extruded uPVC	0.55	0.58
Volanta	Glass reinforced plastic	0.57	0.75
Briau Nepta	Extruded brass	0.06	0.21
Bangladesh No 6	Machined cast iron	2.40	2.40
Ethiopia BP50	Extruded uPVC	0.60	1.50
Vew A 18	Chromed brass	0.17	0.18
Bandung	Enamelled steel	0.33	0.60

Compiled from World Bank Technical Paper No 19

In comparison to the Ra values for the manufactured cylinders, Table 6 shows the results of two tests (carried out in the Centre for Micro Engineering, University of Warwick 9/11/00) on five different batches of uPVC obtained in Mbarara, Uganda. Tests 1 and 2 are the values from the same sample on two different areas. Table 6 Ra values from uPVC purchased in Uganda.

Table 6 surface roughness values from Ugandan purchased PVC pipes

Sample No	Ra (mm) Test 1	Ra (mm) Test 2
1	7.00	8.93
2	1.89	2.75
3	1.70	1.80
4	5.38	8.81
5	2.80	2.16

This shows, with the exception of the machined cast iron, the values of the uPVC from Uganda are all higher than those shown in Table 5.

The consequence of having a high surface roughness is that the performance of the handpump will diminish over time rather than preferably remaining reasonably constant. The peaks of the surface will abrade the outside of the piston and decrease its diameter.

9 Selection of two handpumps out of the four designs

To assist in the selection of two candidate pumps, any manufacturing difficulty or specific skill level, as well as the amount time required need to be considered.

9.1 Ease of manufacturing the four handpumps

As mentioned in section 2.1, it must be possible to manufacture and maintain the handpump within East Africa at village level with a set of basic hand tools. Table 7 shows a comparison of the manufacturing time, the number of tools required and the skill level required for manufacturing the handpumps. All the tools used to manufacture the handpumps were sourced from the local market.

Table 7 Manufacturing time and skill level required for the four designs

	DTU	Tamana	Harold	Enhanced Inertia
No of tools required	8	8	10	9
Time to manufacture (hrs)	4	4	3	2
Skill level required	high	Medium	Low	Low
Total number of parts	13	15	13	12
Technicians preferred choice[c]	-	-	1 x 1st choice 8 x 2nd choice	9 x 1st choice 1 x 2nd choice

(Whitehead, 2000)

[c] Based on 10 technicians choice after completing the manufacture of four pumps at a two day workshop at Kyera Farm, Uganda 23rd August 2000.

9.2 Pros and cons of the four designs

To assist in the selection process a review of the four handpumps was carried out, and the responses from technicians who attended the training workshop in Mbarara, Uganda August 2000 were also considered. The benefits and drawbacks of the four designs are given in Table 8.

Table 8 Benefits and drawbacks to the four handpumps

The DTU handpump	Pros:	Cons:
	• Low No. of tools required • Parts which need replacing are low cost and easy to obtain •	• Time to manufacture is long compared with other the handpumps. • Skill level for manufacture is high • Removal of handpump for repair is time consuming • Fairly high resistance during operation • The leather is susceptible to wear • The output for the input effort was low
The Tamana handpump	**Pros:**	**Cons:**
	• Removal of the pump is easy as it is separate from the tank • High output of water • Skill level required is medium • Very low cost • Very low additional cost per metre • Low no of tools required • Positioning of handpump is ergonomically better for most users	• The rubber pistons wear very quickly • Priming is required if the level of the water is lower than the cylinder • High resistance during operation • Cutting pistons to correct size is time consuming • Manufacturing time is comparatively higher
The "Harold" handpump	**Pros:**	**Cons:**
	• Lower manufacturing time than the previous two handpumps • Very little effort required for operation • Low skill level for manufacture • Expected reliability is good • Lower No of parts	• Highest No. of tools required • Pull rod prone to corrosion • Lower hydraulic efficiency because of gap round the moulded cup • Removal of handpump for repair is time consuming
The Enhanced inertia handpump	**Pros:**	**Cons:**
	• Low manufacturing time • Very little effort required for operation • Low skill level required for manufacture and maintenance • Very good expected reliability • Most favoured to make and use • Small fast stroke length gives a relatively steady flow rate • Acceptable hydraulic efficiency at operators preferred cadence	• Higher cadence required • Most expensive to manufacture • Lower output than other pumps • High additional cost per metre for deeper tanks • Steel screws for the flap valve prone to corrosion (no stainless screws found)

9.3 Costing of the handpumps

A limit of $10 was set as a maximum cost for a handpump as this represents a significant proportion (30%) of the total cost of a plastic tube tank (Rees, 200).

A cost comparison of the four handpump designs was carried out and this showed that all four designs could be manufactured for less than $10 for a 3.5m length pump. It can be seen that there is a significant increase in the cost for each metre added to the length of certain pumps. The individual costs for three lengths and cost per additional meter are given in Table 9 (Whitehead, 2000)

Table 9 Cost comparison for varying length of handpumps

Length	DTU ($)	Tamana[b] ($)	Harold ($)	Enhanced inertia ($)
1.5m	6.50	7.25	4.86	5.52
2.5m	8.14	7.89	6.16	7.68
3.5m	9.78	8.53	7.46	9.84
Additional cost/m of handpump	*1.64*	*0.64*	*1.30*	*2.16*

(Whitehead, 2000)

[b]This includes the footvalve and pipe work in to the tank.

This clearly shows that the Tamana is much lower cost per additional metre than the other handpumps. This arises because the only additional cost is the 1/2" uPVC pipe in to the tank. Compared with the Enhanced Inertia the Tamana is 60% lower in cost per metre.

From the four proposed designs, a selection of two handpumps were chosen on the balanced merits of performance, expected reliability, low precision demand and ease of manufacture as expressed by technicians trained in handpump manufacture in Mbarara, Uganda. The selection process eliminated the DTU and Tamana handpumps for the following reasons.

The DTU handpump gave the lowest discharge rate of the four pumps and the following points show that:

- The force required to operate the handpump was comparatively high.
- The pull rod is prone to buckling, at higher cadences (possibly leading to localised wear).
- Retaining the leather washer on to the pull rod is difficult.
- The leather washer became saturated after a short time and could eventually disintegrate.

- The surface roughness for uPVC pipe was high and would wear the piston.

The Tamana did have the highest discharge rate from the Ugandan performance tests, but summarising the following points, the Tamana showed that:

- The surface finish in the PVC bore was variable.
- The diameters of the pipes are inconsistent.
- The roundness of the pipe could not be guaranteed.
- Rapid wear occurred in the piston valves because of the surface roughness.
- Priming is necessary when the water level is lower than the bottom of the cylinder.
- It was one of the least preferred handpumps to manufacture.

This gave sufficient reason to eliminate the DTU and Tamana handpumps. The Harold and Enhanced inertia handpumps were considered more suitable for a number of reasons, these were:

- Neither of the pumps required any fine precision.
- The manufacturing times were much less.
- A lower skill level was required for manufacturing them
- The reliability was expected to be higher
- They were preferred choice of the technicians.

10 Valve Design and leakage tests

A footvalve is required so that the cylinder retains the water during the downstroke of the piston. There are many styles of valves which operate in different ways, for this project a simple design was required which could be made from easily obtained materials and be made with a set of basic tools. The first design is the DTU valve (Thomas *et al*, 1997), which is made from PVC pipe and a strip of rubber. The second is the Low cost valve (Whitehead, 2000) which is made from a wood and a small rubber disc. Wood was chosen because it is easily obtained, very low cost and is simple to work with. Both valves are shown in Appendix 9.

An ideal valve will have zero 'forward' flow resistance and infinite 'reverse' flow resistance. It will also have an instantaneous response, as the pressure gradient reverses, when opening and closing the valve. Two tests were carried out on the Low cost valves. Firstly, the ratio of the sum of inlet holes area to the pipe area was varied to see if this affected the flow. Secondly, the rate at which the valve leaked was found from a simple test. The DTU valve was only tested to determine the leakage rate. Table 10 shows the dimensional values for the pipes and the inlet holes for three 1mm incrementally larger sizes.

Table 10 Ratio of sum of inlet hole areas to the total inlet area (low cost valve)

Æ 1 1/2" - 40mm pipe	Units	No 1	No 2	No 3
Inside diameter of pipe	mm	34.25	34.25	34.25
Area of inner pipe bore	mm^2	921	921	921
Diameter of inlet hole	mm	6.0	7.0	8.0
Area of inlet hole	mm^2	28.3	38.5	50.25
No of holes in inlet	No	5	5	5
Flow passage ratio =		0.15	0.21	0.27
Æ 1 1/4" – 32mm pipe	**Units**	**No 4**	**No 5**	**No 6**
Inside diameter of pipe	mm	29.75	29.75	29.75
Area of inner pipe bore	mm^2	695	695	695
Diameter of inlet hole	mm	6.0	7.0	8.0
Area of inlet hole	mm^2	28.3	38.3	50.25
No of holes in inlet	No	4	4	4
Flow passage ratio =		0.16	0.22	0.29

The test on the low cost valve was carried out by operating the pump at different cadences and recording the time to fill a 5 litre container. The results of these are shown in Table 11.

Table 11 Results of low cost valve inlet ratio test

Test	Cadence cycles/min	Time to fill 5 litre container (seconds)
Valves: No1 & No4	40	58
Valves: No2 & No5	40	58
Valves: No3 & No6	40	55
Valves: No1 & No4	60	37
Valves: No2 & No5	60	38
Valves: No3 & No6	60	35

This shows that the ratio has almost negligible affect on the flow out of the handpump at these cadences. No detectable change in effort was felt by the operator as the inlet holes were varied.

A larger size hole may eventually collapse if the wall section between the inlet holes is too thin. It was observed that the inlet holes, after approximately 48hours, showed signs of becoming oval. This is arises because of the wood swelling and compressing perpendicular to the grain. A wood that resists water, or is little affected by it, should be used if available (i.e. in the UK Elm would be used). Alternatively, some method of protecting the wood could be done i.e. heating the inlet in food grade oil.

10.1 Valve leakage tests

Ideally, it is preferable that the handpump holds its prime so that next time the handpump is used the first stroke would discharge water. To achieve this the footvalve would have to seal perfectly, in practice, this would be almost impossible to achieve and from the specification we can tolerate a minimum leakage of 0.1 litre per min.

To determine the amount of leakage a series of short tests were carried out which involved filling the rising main with water and measuring the amount of water at timed intervals as it leaked past the valve. The valve end was placed above a container with graduated markings of 20 ml. At 15 second intervals the volume of water in the container was recorded. This test was carried out on both the DTU valve and the Low-cost valve. The graphical results of these tests are shown in Appendix 10, and these illustrate the different characteristics of both valves.

The graph of the DTU valve shows that the leakage rate actually rises (almost to a square law) with pressure across it. This suggests a roughly consistent leakage aperture. It was expected that the water pressure acting on the inner tube section over the perforated pipe would be greater at higher heads. Then at lower heads, the pressure would be less and the rate of leakage would increase but this was not the case.

The Low cost valve showed a more complex three-point characteristic. Initially at the higher head, leakage is high but falls as the pressure falls. Following this is a zone of almost constant leakage rate that is independent of pressure over a 0.5m range. Finally, the leakage rate rises over the last metre as the pressure falls. A fast leakage rate at the start may be because of some settling of the valve and/or some 'puckering' of the valve instead of laying flat over the inlet holes.

All this suggests that the leakage aperture varies with pressure. It was expected that the leakage rate would gradually increase as the pressure is reduced on the valve, and leaking faster as the head remaining tended to zero. The total time for the column to fully discharge was 6.5 minutes, showing that the low cost valve has a mean leakage rate twice that of the DTU valve. In both tests, the leakage rate varies with the pressure drop across the valve. The two mechanisms at work here are: a) higher pressure forces the water faster through the apertures in the valve body, b) the aperture size is reduced by the pressure forcing the valve flap harder onto the inlet holes in the valve body.

The low cost valve was chosen as the most suitable design mainly because the force required to operate the pump was significantly less than that for the DTU valve. The DTU valve performance depended on getting the right sized inner tube to the inlet pipe, older and less elastic tubes worked more efficiently. Whereas the response and efficiency of the low cost valve was much more desirable despite the lower leakage rate.

11 Performance tests

A series of performance tests were carried both in Uganda and within the laboratory at the University of Warwick. In Uganda, this consisted of some basic preliminary tests on four demonstration models to compare the handpumps performance. A spring balance was attached to the handpump handle to show the force required during the upstroke. A container was placed at the outlet, of known volume, and filled and the time subsequently recorded. The results given in Table 12, show that force required to lift water was 7 and 8 fold less for the Harold and Enhanced inertia handpumps over the DTU and Tamana handpumps respectively. The Harold and Enhanced inertia handpumps also showed lower flow rate output than the Tamana handpump, but higher flow rate than the DTU handpump.

11.1 Ugandan-based performance tests

Table 12 Performance comparison of the four handpumps

Variable	DTU	Tamana	Harold	Enhanced inertia
Internal diameter of rising main (mm)	39	39	39	39
Length of rising main (mm)	530	530	530	530
Stroke length (mm)	330	254	406	102
Kg force to lift water	8	7	1	1
No of cycles/jerrican	134	114	159	142
Output Litres/min	7.55	11.6	8.93	8.43
Minutes to fill 20 litre jerrican	2.65	1.91	2.24	2.37
Apparent vol. efficiency	0.38	0.58	0.26	1.16
Reliability[a]	low	low	Medium/high	High

(Whitehead, 2000)

[a] This is based on the limited field trials carried out in Uganda, and is the expected reliability: low = 2 months, medium = up to 6 months and high = 12 months.

The Table 12 shows that the volumetric efficiency of the DTU and Harold pumps are quite low. The volumetric efficiency of the Enhanced inertia is greater than unity. Though inertia type pumps, as mentioned earlier in section 3.4, can give a value greater than one it seems unlikely when there is a short column of water. There seems little else to explain this high value and a repeat of the test under the same conditions needs to be carried out to confirm this high value.

11.2 University based performance tests

The performance tests carried out at the University were achieved using the set up shown in Figure 7. During the tests the head, cadence and stroke length were varied over a suitable range. The time to fill a 5 litre container and the operators heart rates were recorded. Any comments by the operator were also noted. The results of the performance tests carried out in The University of Warwick are shown in Appendix 11

The performance tests had two main functions. Firstly, that both handpumps could be compared to each other show any differences in their performance. Secondly, to see what changes the variables have on the operator with respect to input effort. Three males and one female were used with ages ranging from 20 to late 30's.

The cadences used were 50, 60 and 70 cycles per minute, 40 cycles was used in the first tests but was regarded as too slow and consequently dropped from the remaining tests. The cadence that most operators preferred was 60 cycles/minute.

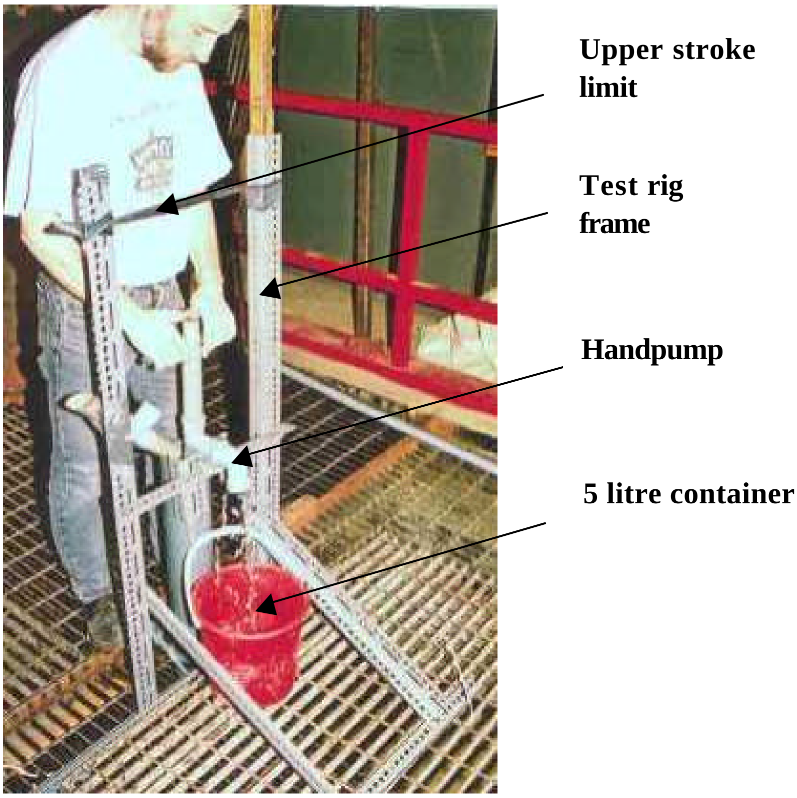

Figure 7 Performance test set up

It was expected that the flow rate and the volumetric (or hydraulic) efficiency would increase with higher cadence and longer stroke lengths, which it did. Though there is a limit to this, as it becomes increasingly difficult to operate at higher cadences with long stroke lengths. In addition, the returns on volumetric efficiency, for a higher cadence, are not worth the additional effort as will be seen later in section 12.

11.3 Heart rate monitoring

During the performance test each operator's heart rate was monitored with the aid of a standard electronic monitor worn around the chest as used by athletes. As the cadence and head was increased it was reasonable to expect an increase in the heart rate as well. This would give an indication of the amount of additional effort the operator had put in as the head and cadence were increased.

From the results in Appendix 11, it can be seen that there are some cases where the results are conflicting. For three of the operators, their maximum heart rates had increased by very much the same (avg. 12%). These had mainly occurred towards the highest heads and highest cadences. But one operator showed their highest heart rate increased on two occasions, firstly at the lowest head and highest cadence and secondly at a much lower cadence and a mid-range head.

The female operator showed a much larger increase in heart rate (33%), this had occurred at a higher cadence but also at a mid-range head.

In general, it has shown, given a small number of tests, that the increase in heart rate is small and did not show any of the operators to be expending much of there potential.

11.4 Moulded cup size tests for Harold handpump

To see how varying the diameter of the moulded cup affects the performance a short series of tests were carried out. This involved timing how long it took to fill a 5litre container at a cadence of 60 cycles and a 0.25m stroke length for five different diameter moulded cups. This showed that, as was expected, the volumetric efficiency increased as the cup size increased. It also showed that the effort required in pushing the handle down increased on the upstroke as the cup size increased. It may seem more desirable to either have the same or similar effort to operate the handpump on both the up and down strokes. To rectify this a series of holes were drilled around the cup and a valve incorporated. This had the desired effect but meant more work on the component was required. The results of the tests are shown in Table 10.

Table 10 Results of moulded cup tests for 0.25m stroke length

Cadence (cycles / min)	Bore diameter of pipe (m)	Diameter of moulded cup (m)	Time to fill 5 litre (s)	Flow rate (litre / min)	Upstroke effort (1 to 10)	Downstroke effort (1 to 10)	Volumetric efficiency
50	0.036	0.032	Too slow	-	0	1	-
60	0.036	0.033	240	1.25	1	2	0.08
60	0.036	0.034	70	4.29	2	3	0.28
60	0.036	0.035	30	8.57	2	6	0.56
60	0.036	0.036	25	12.00	6	9	0.79

11.5 Modification to designs

A modification to the design of the Enhanced inertia pump was required because UK-made pipe differed in size to that purchased in Uganda. This difference resulted in a reduced annulus and an unacceptable performance.

Figure 8 shows a cross-section of the Enhanced inertia pump clearly showing the annulus between the two pipes. The area of the annulus can be expressed as a ratio of its area to the outer pipes bore area. The annulus ratio for UK-made pumps was 0.14, and a higher value (0.17) was found for those made in Uganda. Even at slow to moderate cadences some of the water within the riser was unable to discharge through the outlet and vented through the annulus at the top of the rising main instead, as shown in Figure 9 a). This was solved by removing a 0.4m section of the upper central pipe and replacing it with a steel pull rod as shown in b). This was fixed to the

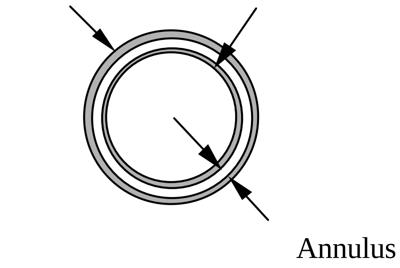

Figure 8 Cross-section of inner and outer pipes

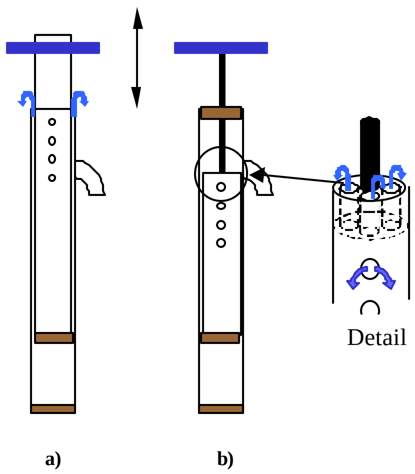

Figure 9 Modification of the pump and water flow path

inner pipe with a wood inlet as used in the footvalve. The details in Figure 9 b) shows the flow path through the wood inlet after the modification.

For a constant flow rate (Q) reducing the annulus area (A) increases the water velocity (v) (from mass continuity: Q = vA). Given the increased velocity caused by the reduced annulus area a significant fraction of the water continues the short distance to the top of the riser pipe and leaks out. By increasing the annulus, the velocity of the water is reduced such that all the water flows through the outlet.

One drawback to this modification is that using a steel pull rod will lead to corrosion and reduce the quality of the water. Stainless steel is not readily available in Uganda. Galvanising the pull rod may be an option as this process is used on corrugated roofing sheets in Uganda and would greatly reduce the level of corrosion.

12 Durability testing of the handpumps

It is important that the handpump performs satisfactorily over a period of time before the pump is either beyond repair or no longer lifts sufficient water for the household. A reasonable expected life for the pump had been decided in the specification as three years. If a family of five people use the handpump to abstract 20 lpcd over three years then this amounts to 109500 litre over the expected life of the pump. From the performance tests 15 litres / minute could be taken as a reasonable discharge rate, and this would equate to 122 hours or 5 days continuous use. To replicate this a durability test rig was designed and built at the University of Warwick to give a reciprocating motion powered by an electric motor and geared down through two variable speed gearboxes. The output speed could be varied between 17 and 400 cycles / min.

The output shaft of the final gearbox was attached to an arm 0.15m from centre of rotation, giving a stroke length of 0.3m. The head was set at of 2.65m. The reciprocating arm was linked to the motor arm and the pull rod with rod end bearings, This would allow for any slight misalignment in the motors rotational plane and the handpump's translational plane.

Because of the physical size of the test rig it was necessary to build it over an existing 2.5m deep pit in the Engineering workshop at the University. A sketch of the endurance test rig is shown in Figure 10 indicating the main components. The water discharged from the handpump was re-circulated back in to a large reservoir in the bottom if the pit, via a flow detection chamber. Because the discharged flow from the outlet is in a non-steady state and difficult to measure, the flow was diverted from the outlet in to a 15 litre container and the number of cycles to fill this was recorded with a tally counter. This was repeated during the test to show any changes in the outlet flow over the life of the handpump.

As the handpump was to run continuously over 5 days, there was a possibility that the motor would still run even if no flow occurred. Therefore, the flow detection chamber housed a horizontal float switch, and operated a relay to cut the power supply if the flow stopped.

A digital clock was fitted which showed the lapsed hours and minutes whilst flow occurred. As the flow rate per cycle is known a reasonably accurate number of litres pumped could be found.

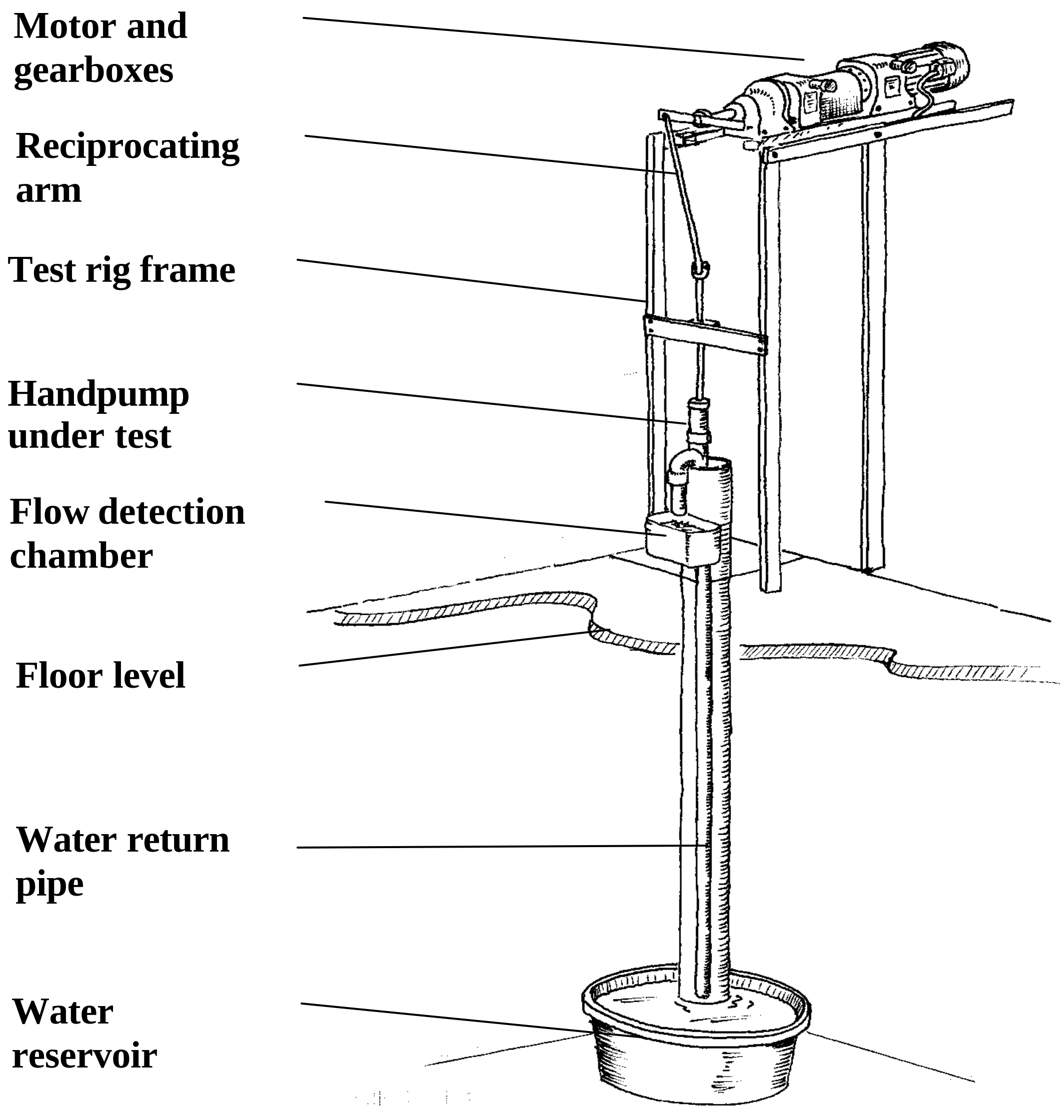

Figure 10 Endurance test set-up

The objectives of the durability test were to indicate the following points:

- The failure mode of the handpump
- Reduction rate of out flow over time
- Where any localised wear occurs and how much it may have worn by
- Time between failures
- Durability comparisons between each handpump

The Harold handpump was tested first and a number of dimensional checks were carried out before the test commenced. Firstly the moulded cup for the Harold handpump was measured across its diameter in three places (120°). This is because accurate roundness of the cup during manufacture can not guaranteed. The dimensions of the moulded cup are shown in Figure 11.

The hole size of the pull rod support bush was also checked, as this was regarded as high wear

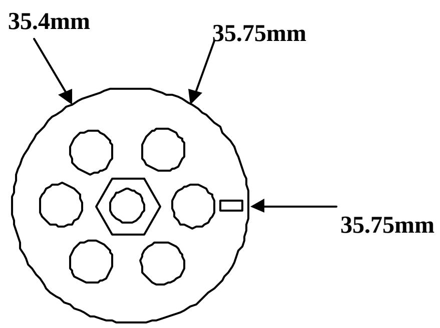

Figure 11 Dimensions of the molded cup at start of the endurance test

area. The diameter of the hole at the start of the test was ∅8.8mm.

The reason for failure most expected from the Harold handpump were that firstly, the wear in the moulded cup would reduce its performance until the flow fell below 10 litre per minute before the end of the endurance test. Secondly, one of the valves may fail (tears or splits) during its half-million plus cycles.

A two hours 'bedding-in' period was carried out prior to the tests so that any stiffness in the system may be reduced or that any problems with the set up could be detected and rectified. The results of the durability tests for the Harold and Enhanced inertia handpumps are shown in Table 12 and 13 respectively.

Table 12 Harold handpump durability results

Cumulative water lifted (litre)	Normalised Flow rate	Volumetric efficiency	Failure mode	Wear in piston Æ (mm)	Wear in rising main Æ (mm)	Diameter of hole in pull rod bush Æ (mm)
0	1.00	0.71	-	0	0	8.8
56,767	0.87	0.64	-	0	0	-
63,302	0.91	0.66	-	0	0	-
74,474	0.89	0.65	-	0	0	-
95,974	0.87	0.64	-	0	0	-
113,081	0.94	0.69	-	0	0	-
120,245	0.94	0.69	-	0	0	9.5

12.1 Observations of the Harold handpump

After completing 143 hours, and 590,000 cycles, of continuous running, the handpump was dismantled and the following points were observed:

- The inlet valve showed signs of indentation from the water pressure acting on the area of each of the five inlet holes (see Figure 12a)
- Moulded cup showed no visible sign of wear
- Stress marks evident on the edge of some of the holes in the moulded cup (see Figure 12b) N.B. these are not at the thinner sections between the holes but at the top of each hole.
- Moulded cup valve starting to show signs of being cut from the moulded cup holes (see Figure 12c)
- Bottom section of the handpump rising main was removed and no significant wear was detected, only small surface scratches on one side if the pipe.
- On removing the handpump, the volume of water remained in the rising main with a very low leakage rate. This was suspected to be fine debris settling and compacting under the valve and actually giving a better seal!

Figure 12 a) b) c)

It can be seen from the results in Table 12 that the volumetric efficiency had dropped by 7% during the first 57,000 litres, with a relatively level efficiency for the next 40,000 litres. After this, there is a rise to within 2% of the original efficiency. One explanation that could be given for this is that some particle may have become lodged under the moulded cup valve, of sufficient size to cause some back leakage. This then may have been dislodged before the last 25,000 litres. This would explain a lower volumetric efficiency and account for the reduction and final increase in the flow rate as shown in the normalised flow rate in Table 12.

12.2 Observations of the Enhanced Inertia handpump

Table 13 shows the results of the endurance test, which ran for 167 hours. During this period no mode of failure or decline in flow rate or efficiency was found.

Table 13 Enhanced Inertia handpump durability results

Cumulative water lifted (litre)	Normalised Flow rate	Volumetric efficiency	Failure mode	Wear in inner pipe Æ (mm)	Wear in rising main Æ (mm)	Diameter of hole in pull rod bush Æ (mm)
0	1.000	0.77	-	0	0	9.5
22,012	0.997	0.77	-	0	0	-
48,020	0.997	0.77	-	0	0	-
74,106	0.997	0.77	-	0	0	-
95,270	0.997	0.77	-	0	0	-
164,422	0.997	0.77	-	0	0	12.5

Inspection of the internal parts of the handpump, after the endurance test, showed little sign of wear either on the inner pipe or on the bore of the outer pipe. Both valves showed signs of deformation (similar to the Harold handpump) where the rubber had repeatedly been depressed into the wood inlet holes.

The only other indication was some localised surface scratches on the outer pipe bore where the inner pipe had contacted it during its 700,000 cycles. The only external part that had worn was the wood support bush for the pull rod, and this had become oval but of no detriment to the handpump’s performance.

Figure 13 shows the standardised flow rate against cumulative litre for both the Harold and Enhanced inertia pumps.

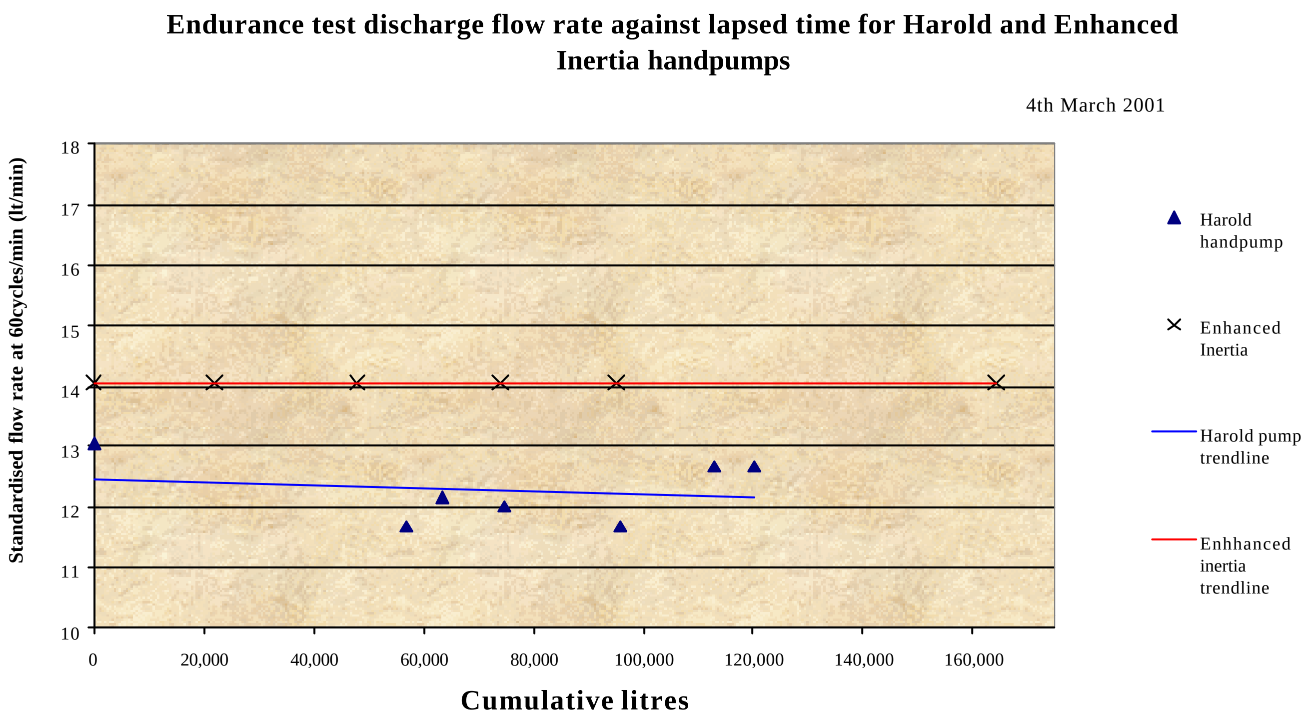

Figure 13 Comparison of the Harold and Enhanced inertia endurance tests

It was hoped that some failure or drop off in efficiency had occurred so that the handpump could be analysed and possibly improved. To try to cause a mode of failure the cadence was increased by 1.5 and run for a few hours. This resulted in a sudden failure rather than it being gradual as the riser pipe was forced off the outlet tee. The joint was thoroughly cleaned and re-cemented, and ran at the same cadence without any other failure for several hours.

Figure 14 shows a graph of volumetric efficiency vs. cadence for two stroke lengths, the dotted lines are the upper and lower limits for comfortable operation. This was done to see how a doubling of cadence and a halving of stroke length (which gives the same volume per unit of time) affects the efficiency. This shows for example at a cadence of 35 cycles per minute and 0.3 stroke length the efficiency is 62%, and if the speed is doubled and stroke length halved the efficiency is 60%, showing very little difference. Through the comfortable operating range, the longer stroke length is more efficient for a given cadence.

If the cadence were increased much beyond 70 cycles per minute an operator would find it difficult to maintain a 0.3m stroke length. The graph in Figure 15 shows the product of the two stroke lengths and cadence against efficiency. This shows that for lower cadences there is very little improvement in efficiency for given different stroke lengths. Though there is a tendency for the longer stroke length to show some slight improvement in efficiency at higher cadences.

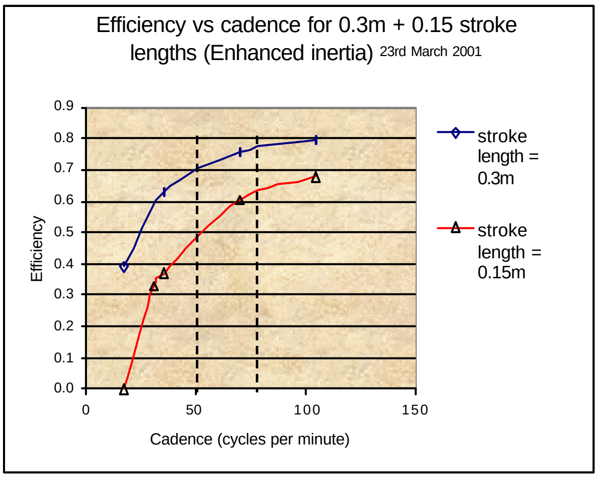

Figure 14 Graph of efficiency and cadence for two stroke lengths

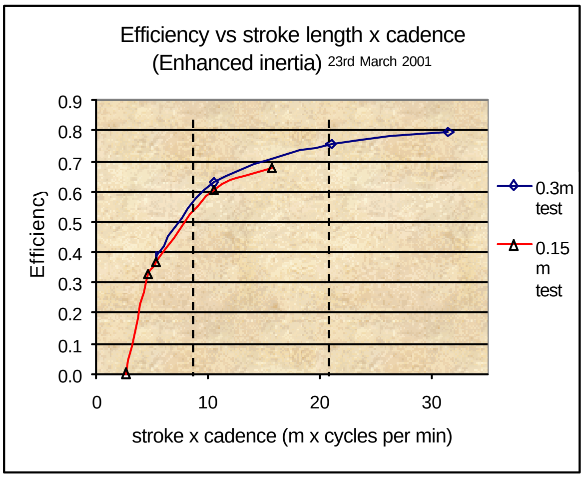

Figure 15 Graph for the product of stroke length and cadence vs. efficiency

In summary of the Enhanced inertia handpump endurance test: because there was no failure mode or a gradual decline in the flow or volumetric efficiency, very little can be said other than the handpump has been shown to be a very durable and reliable handpump. Also, that the handpump would need little maintenance and was more than capable of lasting three years under normal operating conditions.

Last minute update: after completing the Enhanced inertia endurance tests, the pump was further tested at a cadence of 70 cycles per minute and a 0.3m stroke length and was left to run until it stopped. The result of this was that it was still running after 267 hours, and had lifted 261,000 litres of water.

12.3 Safety aspects of the endurance tests

Because of the risk of injury to persons from the reciprocating motion and prolonged test period (two-weeks continuous running), a significant amount of thinking and work was done to assess and remove potential dangers as far as is practically possible. This involved some liaison with the Health and Safety Officer at the University and with the Chief Technician in the engineering workshop.

After consultation with the above, the main points considered and relative actions were as follows:

- Prior to building the test rig a PAT test was carried out by an electrical technician to ensure the electric motor was safe to use.
- Mesh guarding was put around all moving parts
- Bunting was put around the test rig area
- Electrical lights and conduits in the pit were checked as suitable for outdoor weather use
- Continuous running notice was attached to test rig (and relevant people informed: security)
- Power supply had:
  a) over current protection, b) no-volt drop out, c) earth leakage protection.
- A float switch was incorporated to detect handpump delivery flow: power cut out if no flow detected.
- Railings surrounded the pit, and bunting was put up within the pit on open floor level areas.
- Water flow was highly unlikely to reach 415v supply during testing

Table 14 shows possible modes of test rig failure and of the procedure or protection that was used to reduce the danger.

Table 14 Test rig failure and protection procedure

Area of failure	Protection/procedure
· Linkage/reciprocating arm/rod end breakage	· Flow from pump would stop and float switch will cut power to motor
· Frame and/or motor mounting bolts become loose	· Periodic checks to ensure tightness

13 Feedback from Uganda on training and handpumps installed on tanks

13.1 Training

Following a seminar on DRWH tanks built at Kyera Farm, which was attended by several members of NGO's from around E. Africa, a training workshop for handpump manufacture was held for ten representatives on August 22 - 23rd 2000. This involved each participant building four short demonstration handpumps. A handpump manufacturing manual and certificate was presented to each participant on completion.

Correspondence from Moses Byaruhanga, (a co-ordinator for URDT, Kampala) 17 weeks after the training course, stated that "so far from the knowledge we got from Kyera farm, we have trained another 20 new local masons in pump fabrication and repair"
A similar one-day workshop was held for the ten masons and labourers who built the tanks at Kyera Farm. One mason, who had attended the one-day workshop, was building a 25m^3 tank in Mbarara and had decided to make and install an Enhanced inertia handpump himself during September 2000 (no feedback on this at present).

13.2 Handpumps installed in Uganda

A Harold and an Enhanced Inertia handpump were installed on two plastic tube tanks (see Figure 13) built on Kyera Farm, Mbarara in August 2000. Both these handpumps were installed and made by the first group of trainees at the training workshop.
From returned survey forms for August to November on tank use the remarks for the Harold handpump were:

August:	Rust was evident in the abstracted water
September:	Not functioning
October:	Not functioning
November:	Functioning

The reason for not functioning for two months or how the handpump was repaired was not recorded. The Enhanced Inertia handpump functioned for four months without any problems.

A separate and more detailed survey from (see Appendix 12) was sent with specific questions relating to the Harold and Enhanced inertia handpumps performance. This was sent to Kyera farm in Mbarara, Uganda in December 2000, a summary of eight questionnaires returned showed that:

- The two Harold handpumps installed in August 2000 were used to fill one jerrican everyday for each household.
- The time to fill a 20 litre jerrican was between 5 and 6 minutes.
- One breakdown had occurred on one handpump in five months since installation: this lasted two weeks, this occurred because of the moulded cup becoming detached from the pull rod. This was repaired by one of the trainees who attended the workshop mentioned in section 13.
- Rusting was still a problem.
- Children found the pump difficult to use.

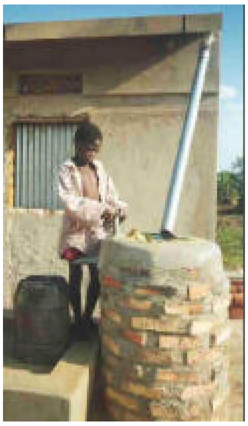

Figure 13 Pump height problem for a young boy

This clearly indicates, as shown in Figure 13 that the handpump is too high, at the bottom of the stroke the handle is above waist height. This would make any reasonable upstroke length difficult for the child.

The time to fill the jerricans was far too slow, and was equivalent of 3.5 to 4 litre per minute. This either suggests that the operator was using too low a cadence, an estimated time rather than an accurately timed one has been recorded or the poor performance indicates some malfunction of the valve or moulded cup. Also, the handpumps are not being used for abstracting anywhere near 100 litre per day. This would mean an extended life for the pump well beyond three years.

For the four Enhanced inertia handpumps that were installed the following main points were noted:

- Almost all the pumps were used to fill on average two jerricans each day.
- The average time to fill a jerrican was 4 minutes.
- No breakdowns had occurred, although on one occasion children had put stones through the outlet, but the pump was soon repaired.
- Children find the handpump difficult to use because of its height.

Again, the height of the pump is not suited to children, as the height set from the jerrican stand to the handle was 0.775m. It may have been better to measure the height of all users hands at their lowest position and found a compromise in favour of the most frequent users height before the handpumps were installed.

14 Final recommendations

There seems little doubt from the test results of all the performance and endurance tests that the Enhanced inertia pump has proved to be the most durable and reliable handpump of the two. This is backed up by the feedback from Uganda on the pumps installed in August last year showing the Harold handpump was much less reliable, and the Enhanced inertia pump was still working satisfactorily. On the strength of these points, the Enhanced inertia pump is recommended as the final choice of handpump to install.

The Harold pump could be recommended in circumstances where the cost to the user is of concern. From section 9.3 it was shown that for a 3.5m length pump, the Harold pump cost $2.4 less than the Enhanced inertia pump. However, if the pump is more prone to reliability problems, then the long-term cost of the Harold pump could be greater.

A set of technical drawings for the Enhanced inertia handpump is included at the back of this report.

15 Means of propagation

The purpose of propagation is to reach and disseminate such information specific to this work to those that may benefit from it. The benefit may be from actual use (an improvement in water quality, or a reduction in time spent walking to some other source) or that the handpumps could generate income and improve the wealth of the individual/family. Some means of propagation have already been mentioned in earlier sections but are reiterated in the following list:

- A one-day training workshop was held for 10 fundies (craftsmen) at Kyera farm, Mbarara, for handpump manufacture.
- A two-day training workshop for handpump manufacture was held for 10 NGO representatives in July 2000 at Kyera farm, Mbarara. Mostly
- The Technical release: '*TR-RWH 09 - Low cost handpumps for water extraction from below ground water tanks - Instructions for manufacture'*, has been on the DTU's web site since September 2000 accessible at: http://www.eng.warwick.ac.uk/DTU/workingpapers/tr/tr09/tr09.html
- The handpumps were signposted in 'Footsteps, No.46 March 2001' Appropriate Technologies, by Tear Fund, a quarterly newsletter for development workers around the world.

16 Further work

The Enhanced inertia handpump has shown that it is capable of pumping water on condition that some annulus size is met. The precise way this handpump operates has proved to be very difficult to analyse and remains to be explained. It was found that the pump's performance is sensitive to the size of the annulus and some optimum size or annulus area ratio needs to be satisfied. As pipe sizes can and do vary over different batches, checking the size is important. Further work is recommended to determine the pumping principle and from this find the optimum size of pipes to give the best flow rates. Some method of controlling the diameter, at the top section of the inner pipe, may prove better than replacing it with a steel rod as explained in section 11.5. This may be achieved by heating the top section and a pushing it through an orifice machined to the required size.

17 Conclusions

This project has proved successful in a number of ways and the majority of the criteria have been fulfilled. It is regarded successful inasmuch as the project was completed on time and one of the handpumps, which was thoroughly tested for endurance, can be recommended for a DRWH system. This has demonstrated that a handpump can be manufactured with very low precision at low cost and be capable of lifting water above 10 litre per minute.

The Enhanced inertia handpump has proved to be a very reliable and durable method of abstracting water for low heads and low flow rates. The performance tests showed that the pump exceeded the specified minimum by 50%, and at a cadence of 70 cycles per minute, 15 litres per minute could be discharged with little exertion by the user.

The specification gave a life of the handpump as 3 years, this may have been underestimated as the endurance test showed it capable of working the equivalent of at least 7 years (and lifting 255,000 litre). A 5 year working life may have been a better specification in retrospect.

One of the main criteria was the cost of the pump, though this was kept just under $10 (including labour cost) for a 3.5m length pump it is doubtful the cost could be reduced further unless material prices came down.

Feedback from handpumps installed in Uganda showed that the hydraulic efficiency is suspected to be low gauging from the time required filling a 20 litre jerrican. From the results of this project, some indication of optimising the efficiency, (higher speed and short stroke versus lower speed and longer stroke), needs to be disseminated with the handpumps. However, an operator's preference in cadence and a stroke length may probably over ride a higher efficiency.

The final two designs were regarded as suitable for production by artisans This was demonstrated by the technicians participating at the training workshop in Mbarara, Uganda who built the Enhanced inertia pumps in two hours! Though whether this would be an income generating activity remains to be seen.

The endurance test was run continuously over a number of days and can therefore be regarded as dissimilar to the actual operation of the handpump. On this basis, the handpump may fail for other reasons such as UV degradation, corrosion of any of the small steel screws in the valve or the wood inlet perishing. Some form of protection would be required to prolong the life of the pump.

The two main failings were firstly, that the low cost valve did leak faster than specified, but this is a minor problem as it takes very few strokes before water is discharged even at higher heads. Secondly, if a steel pull rod is used in the modification of the Enhanced inertia pump, corrosion will affect the quality of the water which would be unacceptable for potable water. However, this may be overcome by galvanising if the cost would permit it.

The enthusiasm of all the technicians and others who have come across the pumps via the web site have shown that there is a need for these pumps. By installing an appropriate DRWH system and incorporating an Enhanced Inertia handpump, a large number of people's lives could be improved.

Appendix 12 Handpump questionnaire

Handpump Questionnaire

Handpump type (Harold or Enhanced inertia)

Enter today's date:

Date or month of handpump installation:

1	Who uses the handpump mostly (tick any which apply)	Girl	Woman	Boy	Man
2	How old is the boy girl that uses the pump?				
3	Does the child find it hard to use the pump? (right height etc)				
4	How many days is the handpump used each week?				
5	How many jerricans are filled on average each day?				
6	Is the time to fill a jerrican too slow or acceptable? (if possible give the time it takes and who filled it: boy or girl etc)				
7	How hard is it for a child to use and fill a 20 litre jerrican (easy, moderate or difficult)				
8	Has it broken down since it was installed. (if the answer is no go to question 9)				
8a	If so what was the reason for the breakdown.				
8b	How long was it before it was repaired (days)				
8c	Who repaired it? (Were they trained at or by Kyera farm)				
9	What are your feelings about the handpump? i.e. What do you think is good about the handpump. Is there any improvement that could be made to the handpump? Any other comments

EDAT 3rd Year Project Report

The Effect of Fines in Sand for the Fabrication and Application of Concrete in Developing Countries

Victoria Fernandes
9902930

Department of Engineering
University of Warwick

23rd April 2002

Summary

This project focuses mainly on the needs of developing countries, where operations are basic and money is short. Good quality sand is available in developing countries but is in short supply and is expensive due to the high transportation costs. Poor quality sand, which consists of a significant proportion of clays and silts and is poorly graded, is readily available but needs to be improved if it is going to be used for building with.

After an insight into the aggregate industry had been gained, experimental laboratory work commenced and the first original objective of examining the effect of 'low quality' sand on mortar was investigated. During the third week of the project, a significant finding was made. It was discovered that when the seven day dry compressive strength tests of comparable concretes with identical water-cement ratios were measured, the strength of the concrete *unexpectedly increased* as the fraction of fines in the concrete increased. This was a fairly surprising result since the original aim of the project was to wash sand to remove the fines to make it a better quality. This result caused me to revise my original aims and the focus point of the project was changed to examining the properties of concrete made from sand with a high fines content.

The properties examined were strength, shrinkage and cyclic movements. Construction materials and processes were optimised and strength was measured using a destructive compressive strength test and the PUNDIT test. Drying shrinkage and cyclic movements were measured using point dial gauges.

It was discovered that despite the suitable dry compressive strength of the material with a large number of fines, that the use of this material will be hindered due to its large cyclic movements and drying shrinkage. This type of sand is only suitable for concrete and mortars in unconstrained applications such as block making and lintels and in situations where the material does not undergo cyclic movements, such as non water-proof rendering. If this material is used for applications such as bricklaying then the wall should be built in small sections, maybe one metre per day, without expansion joints.

There are many other properties of concrete, other than strength, drying shrinkage and cyclic movements that can be specified, but the duration of this project limited the amount of factors that could be examined. It is expected that other research in this field will be carried out to improve the quality of concrete made with 'high fines' sand, possibly by washing it, as the original project suggested.

1. Introduction

1.1 Background

This project focuses mainly on the needs of developing countries, where operations are basic and money is short.

"Sand is primarily used as an aggregate or bulking material, in the main for concrete and mortar, accounting for approximately 75% of total production", (Mineral Resources Consultative Committee, 1988).

Good quality sand is available in developing countries, but is in short supply and is expensive due to the high transportation costs. Poor quality sand, which consists of a significant proportion of clays and silts and is poorly graded, is readily available but needs to be improved if it is going to be used for building with. This project was originally established to identify an effective method of improving the quality of readily available poor quality sand to make it more fit for use in making concrete or mortar. This was to be done by exploring existing methods of washing poor quality sand, such as sieving and sedimentation and modern methods used in the commercial industry in the UK.

Within this overall aim, the original study had three specific objectives:

- To examine the effect of "low quality" sand on mortar to define a just satisfactory standard.
- To compare sieving and sedimentation techniques for manually washing poor quality sand up to that standard under artisanal conditions in a developing country.
- To develop an effective method of, or a machine for improving sand, possibly by washing it, to make it more fit for use in making concrete or mortar. The method should be compatible with the operations, finances and normal sand sources of an artisanal builder in a developing country, such as Africa.

The project was started with little knowledge about the aggregate and concrete industry. It was assumed alongside the general opinion of the aggregate industry in the UK and in accordance with the British Standard BS 812, that a high 'fines' (silts and clays) content in sand for fabricating concrete is unacceptable, and to improve the quality of concrete the majority of the fines should be removed. Gill Mill Quarry in Witney, Oxfordshire was visited to get a general feel of the sand and aggregate industry, and to examine the existing methods of sand washing to remove the fines, (The letters of correspondence for this visit are shown in Appendix A1). Removing these smaller particles from the sand is a very costly process in terms of energy and money, and the existing sand and aggregate plants in the UK do not deliberately remove the fines from the sand, but instead grade the different sizes of sand and gravel particles. When separating the larger sizes of particles, wet screening is used, which permits the sand, aggregate and water to fall through a various number of sieves of different sizes that are at 20° to the horizontal.

Figure 1.1: Wet screening at Gill Mill Quarry, Oxfordshire

Figure 1.2: A Hydro-cyclone

The remaining sand and water enters a hydro-cyclone, which imparts a rotational effect to the mix, with the resulting centrifugal force causing the heavier particles to be pushed against the inside surface of the hydro-cyclone. As a result of the continuing feed of material and the inverted cone shape, the heavier sand particles fall and the water and fines pass upwards into the overflow and are discharged away through an overflow pipe into a settling pond. The overflow pipe induces a syphon effect, which in turn creates a vacuum in the hydro- cyclone. This vacuum is sufficient to hold the discharge regulator closed thus trapping the majority of the water and fines, which are discharges via the overflow. When the weight of the solids inside the hydro-cyclone becomes sufficient to overcome the vacuum, the discharge regulator is forced open and allows discharge of the sand.

It was decided that this method of separating the different sizes of particles is too sophisticated and energy costly for developing countries to use, so either an alternative method for improving the quality of sand for concreting needs to be established, or it needs to be demonstrated that washing the sand is not essential.

1.2 The Project Report

The project report has been organised into the following chapters (after this introductory chapter 1):

- Chapter Two explains the aims and objectives of the research, and how the objectives were changed from the original ones
- Chapter Three includes the literature review, describes the purpose of the project and discusses the expected problems associated with using a high fines content in sand when making cementitious materials.

- Chapter Four details what materials were to be tested, what factors would be examined and methods of experimental testing were chosen.
- Chapter Five describes the methodology of each testing method and how the analysis of each result should be carried out.
- Chapter Six is the results section. Each factor has been divided into a sub section and discussed individually. Statistical analysis has been performed on applicable results, graphs have been drawn, and explanations of results have been given.
- Chapter Seven states what these results mean in terms of its use to builders in developing countries. It explains whether building with a material with a high fines content is advisable, and whether it would be suitable for some purposes, rather than others.
- Chapter Eight recommends future work, followed by conclusions in Chapter Nine.

2. Revision of Project

After an insight into the aggregate industry had been gained, experimental laboratory work commenced and the first original objective of examining the effect of 'low quality' sand on mortar was investigated. During the third week of the project a significant finding was made as it was discovered that when the seven day dry compressive strength tests of comparable concretes with identical water-cement ratios were done, the strength of the concrete unexpectedly increased as the number of fines in the concrete increased. This was a fairly surprising result since the original aim of the project was to wash sand to remove the fines to make it a better quality. This result suggested that washing sand prior to use, to remove the fines is unnecessary and indicated that further experiments needed to be done to determine the effect of a high fines content in concrete. This caused me to revise my original aims and objectives of the study.

The new main objective of this study was to test whether sand with a high fines content can be used in the fabrication and application of concrete. The purpose of this was to make a useful contribution to the living standards in developing countries through the development of appropriate technologies. In this case the 'appropriate technology' is the use of local sand 'as found' rather than the use of transported 'no fines' sand.

Within this new overall aim, the study had two specific objectives:

- To use the strength of concrete as a constraint to optimise water content, workability, vibration compaction time, the number of 'fines' and curing time, with respect to costs and skills related to developing countries.
- To determine the effect of the presence of 'fines' on shrinkage and swelling of concrete.

For the remaining duration of this project, laboratory based experiments have been conducted to satisfy the new objectives, and it is hoped that the research will be of use to artisanal builders in developing countries.

3. Fines in sand in cementitious materials

3.1 The Cement Literature

Books have provided little information on the actual effect of fines in concrete but have proved useful in the Properties of Concrete. As an overview on general aspects of concrete, A.M Neville and J.J Brooks provide a highly accessible and relevant text. J.M Illston also provides a very useful introductory section on the basics of concrete.

For concreting aspects related to developing countries, Spence and Cook provide an excellent section on the problems of skill, equipment and climate. This enabled a clear distinction between concrete technology in the UK and developing countries.

During the examination of the strength of concrete, Popovics book was very useful. It provided detailed descriptions with clear explanations, especially in the testing of concrete. Another book which proved useful on this area was "Testing of Concrete Structures" by J.H Bungey and S.G. Millard.

Statistical analysis was explored using various textbooks such as "Statistics and Experimental Design in Engineering and the Physical Sciences" by N. Johnson, but the clearest explanations were in "Statistics 2", written by G. Attwood and G. Dyer.

Due to the complexity of the analysis of shrinkage and swelling due to a high fines content, full descriptive analysis was not incorporated into this report. However, the basics of shrinkage and swelling are described in the general concrete books mentioned above, and additionally a detailed account of the behaviour of clay is given by J.K. Mitchell, "The Fundamentals of Soil Behaviour".

Other literature that was often consulted was the Building Research Establishment Report, 1998 and the British Standards. The British Standards were accessed through the World Wide Web at www.bsonline.co.uk. The main relevant standards that were consulted were:

- *BS 12: 1978*: Ordinary and Rapid Hardening Portland Cement.
- *BS 812: Part 1:1975*: Sampling, shape, size and classification.
- *BS 1881: Part 3: 1970*: Methods of Making and Curing Test Specimens.
- *BS 1881: Part 115*: 1983: Specification for Compression Testing Machines of Concrete.
- *BS 1881*: *Part 116: 1983*: Method for the Determination of Compressive Strength of Concrete Cubes.
- *BS 1881*: *Part 202: 1986*: Measurement of the Velocity of Ultrasonic Pulses in Concrete.
- *BS 5497: Part1: 1979*: Guide for the Determination and Repeatability and Reproducibility for a Standard Test Method.

3.2 Review of Issues

In the UK, it is stated in the British Standard BS 812, that it is considered unacceptable to make cementitious materials with a high fines content. It is thought that the reason for this is that fines interfere with the bond between the aggregate and the cement paste, causing abnormal and variable behaviour of the properties of concrete. This is suggested in Neville and Brooks (1987), but the exact reasons of why fines in sand should not be used could not be found in literature.

In the UK, the main properties of concrete that are considered and tested are wet and dry compressive strength, shrinkage, cyclic movements, permeability, durability, and resistance to freezing and thawing, (Neville & Brooks, 1987). The extra fines in the sand are likely to have some effect on all of these properties, and it was the aim of this project to examine certain properties, to discover how the changes in behaviour would affect the use of concrete in certain applications. It was expected that the strength, shrinkage and cyclic movements would be affected greatly by a high fines content in the sand. However since this project focuses on concrete for use in the (high-temperature) tropics, properties such as resistance to freezing and thawing did not need to be examined.

The application of cementitous materials in developing countries is mainly for bricklaying, rendering, and as reinforced concrete. There has been a trend in recent years to manufacture housing components such as lintels, roofing, and hollow core flooring units in an effort to reduce costs. In India, pre-cast concrete frames for doors and windows have been investigated because of the expense of conventional wooden frames, (Mohan and Rao, 1977).

The strength of the concrete is important for most of the applications stated above, but is not so critical for bricklaying and rendering. Concrete compressive strength is typically between 10-70MPa for most applications and is not generally used at strengths lower than 10MPa.

Concrete is strong in compression but weak in tension. Concrete in compression can withstand 2000 μ-strain and in tension approximately 200 μ-strain (Tensile stress is approximately 1/10 the compressive stress). Hence, cracks could occur due to tensile forces or strains exceeding the tensile capacity of the concrete. Tensile forces and strains can arise from many causes, including cyclic movements and shrinkage, and they give rise to many different forms of cracks.

For bricklaying, the concrete should not have large changes in volume, since if this happens unevenly around a building, cracking may appear in the brickwork. Consequently, if the brickwork if jammed between two rigid elements, it could cause the wall to bow. If the brickwork is in compression, it is expected that the wall can withstand about 600 μ-strains, so this magnitude of shrinkage can be tolerated. If the brickwork is in tension, then a much lower value can be tolerated, typically 200 μ-strains.

Typically renders use gypsum since it doesn't crack, but as a cheap alternative, cement renders can be used. Cracks can be dangerous if they occur in a wall between two points, but are also a nuisance and should not be visual. It is thought that waterproof renders can only tolerate small cyclic movements, generally <100 μ-strain, and non-waterproof renders should not shrink or expand more than 200 μ-strain. If renders are used for decorative value then a millimetre crack per metre is visible, and would be unacceptable.

Steel reinforcement in concrete is common in the UK, but structural steel is rarely used in developing countries for building because of its cost but steel is obviously essential for the reinforcement of concrete. As few countries have sources of iron ore suitable for steel making, they must resort to importing pig iron and processing it to make steel. When steel reinforcement is used, movement of a section in the concrete member should be prevented because a gradual transfer of load from the concrete to the reinforcement results. If there is an external constraint and the concrete expands, it is being prevented from moving and compressive stresses develop uniformly across the section. If large shrinkage occurs, typically over 600 μ-strains, the concrete is being prevented from contracting so that tensile stress is induced. In consequence, cracking will take place across the section.

Changes in concrete properties for the fabrication of lintels should not cause any problems, since it is common practice to leave a gap in the mortar of about 10mm at both ends to allow it to expand without cracking. If the cyclic movements are larger than 1000 μ-strain then the gap can be expanded.

This project examined the effect of fines in sand when making concrete to decide whether a high fines concrete can be used for the applications mentioned above, for the building industry in developing countries.

4. Choosing the Sand and Method for Testing

4.1 Sand chosen for testing

"Natural sand and aggregate is formed by the decomposition of rocks, and through the subsequent removal, transportation, sorting, deposition and weathering of the products of decomposition", (Spence & Cook, 1983).

In some areas, some or all of the products of weathering remain in place, in conjunction with the parent rock. These are typical of broad, flat, poorly drained upland areas such as Africa and Indian plateaux. In other areas, the products of weathering are transported, that is they are removed by water or ice, or sometimes wind. In the process of the transportation by water larger particles are further broken down, shaped and resorted, and then deposited in river terraces or lakes. Dissolved silicates react with the soluble salts of sodium, potassium and calcium to form new minerals with distinctive properties known as clay minerals.

Clay, those particles of less than 0.002mm in size, consists predominantly of the clay minerals. Clay may be present in sand in the form of surface coatings which interfere with the bond between the sand and the cement paste. In addition silt, which has a grain size between 0.002 and 0.06mm, may be present either as surface coatings or as loose material.

"It is assumed that clay particles should not be present in large quantities because, owing to their fineness and therefore large surface area, they interfere in the bond between the sand particles and the cement paste matrix", (Spence & Cook, 1983).

It is also thought that excess fines cause an increase in the water demand and as a result the strength of the concrete will decrease, (as a consequence of the water cement ratio rule, which is investigated later).

Sand used for building purposes in the UK follow the recommendations in the British Standard BS 812, that only good quality sand is used with a minimal amount of fines. This is also shown on the U.S Bureau of Public Roads Classification System (for soil) which is based on particle size analysis. The chart is divided into 10% bands, with clay occupying the top third of the chart, sand and silt in the bottom corners, and sand-silt-clay mixtures between them. UK standards specify for use the material in the bottom left hand corner of the chart, usually between 90-95% sand, as shown in blue. In order to test a less well selected aggregate, a synthetic ‘poor sand’ “X” was devised comprising of 75% sand, 4.8% silt and 20.2% clay, as shown in red. This material will be tested against the same sand but without the large clay proportion, which is denoted as material “Y”. Material “Y” is comprised of 95% sand, 4.8% silt and 0.2% clay, and is shown on the diagram in green.

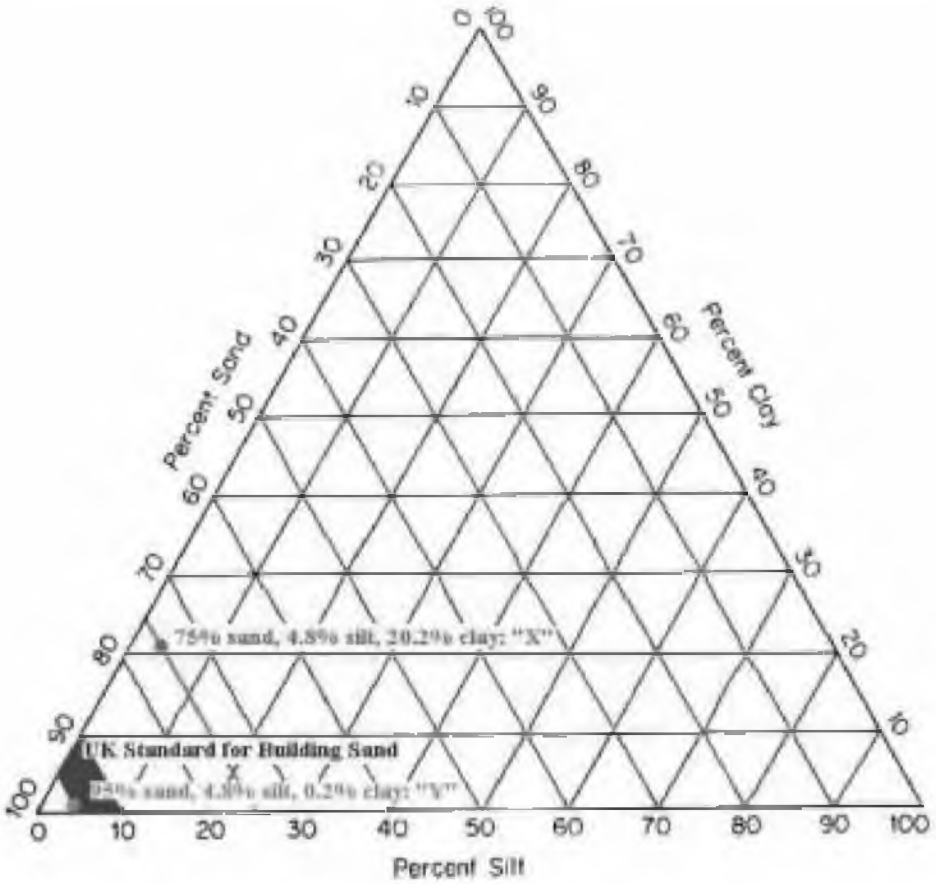

Figure 4.1: U.S Bureau of Public Roads Classification System

Ideally, the effect of a significant amount of silt as well as clay in concrete needs to be examined. Pure clay is readily available but it was not possible to find a source of pure silt, although several attempts were made. Material from a settling pond was collected to examine how much silt was present, but unfortunately the material contained 89% clay, with only the remaining amount being silt, (see Appendix A2 for the sedimentation test and result of the determination of silt content). It was decided that this material could not be used to represent silt, so the fines added to the sand to degrade it will be clay only.

The clay used was Kaolin as it is relatively inexpensive and easily available at the University. Degrading the sand to this quality is adjusting the sand so that it is of a “poor” but not “extremely poor” quality. It was decided that for the purpose of this project that this would be the only type of sand tested, as the project has time constraints with many other factors to be investigated.

Sand and aggregate used in the UK for the purpose of building is usually well graded, as the graduation of particles affects strength. This is because if there are voids present in the concrete due to the inability of the aggregate to fill the voids, then a high strength cannot be achieved. Figure 4.2 is a particle size distribution graph which shows a good sand and aggregate distribution, (drawn in blue), which lies within the limits (shown dashed) recommended by the British Standard BS 812 for medium sand. This good particle size distribution is represented by a shallow curve which slopes from left to right and meets the top of the chart at the size of the coarsest particles present. The builders “Y” sand that was used to make the very poorly graded sand “X” is shown in green. This was already outside the grading limits set by BS 812 as it had 5% more fines than recommended and 12.2% extra 0.6mm particles than the maximum allowed. It also had very few particles exceeding 2.36mm resulting in the sand being deficient in larger particles. Extra clay was added to this sand to give an even poorer distribution, increasing the fines content from 5% to 25% higher than the recommended limit. This material “X” is represented by the curve shown in red. Throughout the duration of this project sand “X” represented by the red curve and sand “Y” represented by the green curve have been used for experimental work.

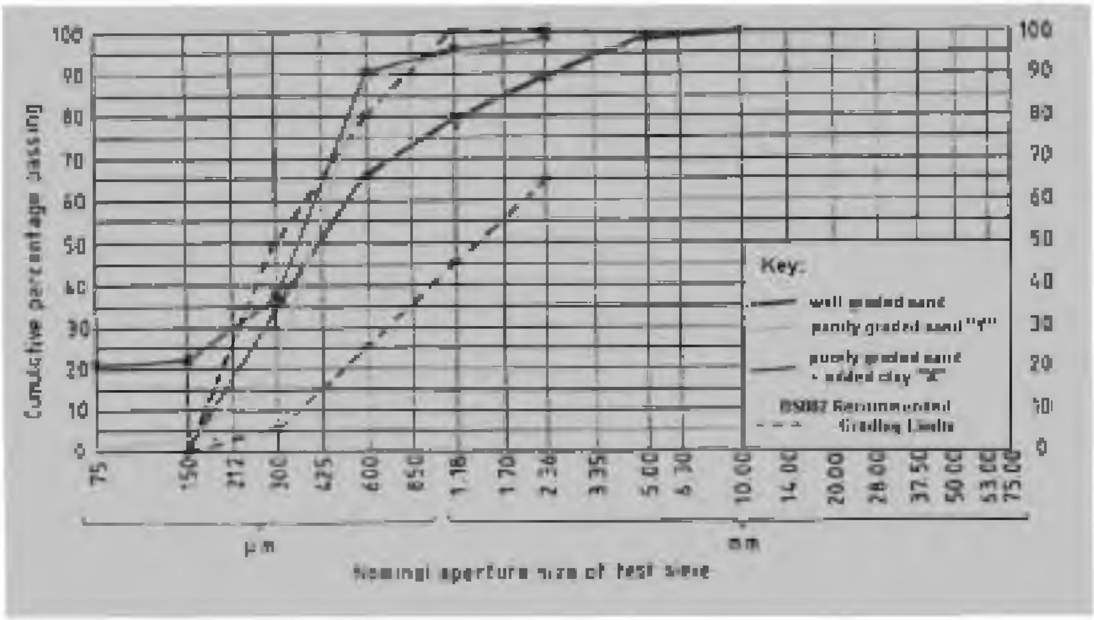

Figure 4.2: Particle Size Distribution Graph

4.2 Factors & method chosen for testing

4.2.1 Strength

Concrete is a structural material, so it is understandable that the most sought-after property of a concrete is strength. The strength of concrete is its resistance to rupture. Structural elements must be capable of carrying the imposed load and the maximum value of bearable stress is usually taken as the strength.

"Concrete strength appears to be a good index of a number of other technically important properties and routine strength tests in general are relatively simple to make", (Kesler, 1966).

Some of the many important properties of concrete that improve with an increase in strength are density, resistance to deterioration, porosity and permeability; hence strength may be used as a criterion of general quality.

It was therefore decided that strength would be an important factor to test, but the type of strength to be tested needed to be decided. In structural situations concrete is subject to one of a variety of types of loading, resulting in different modes of failure.

Knowledge of the relevant strengths is therefore important. There are 7 main different types of strength:

- *Compressive strength*: Required for columns or reinforced concrete beams.
- *Tensile strength*: Important for the cracking of concrete slabs. Tensile strength is about 10% of the compressive strength.
- *Shear strength*: Important in reinforced concrete beams to control the diagonal cracking of the beam. The pure shear strength is about 20% of the compressive strength.
- *Torsion strength*: Important for a reinforced concrete beam in pure torsion before cracking. The torsion strength of concrete is calculated by plastic theory and is usually higher than tensile strength.
- *Impact strength*: Important in concrete piles and in certain military establishments. Impact strength is approximately half of the compressive static strength.
- *Fatigue strength*: Has a practical significance since the majority of structures are subjected to repeated loading.
- *Multi-axial loading*: Important because concrete in structures is practically always subject to multi-axial combination of compression, tension, shearing and torsional stresses.

The two most common types of strength that can be tested for concrete are tensile strength and compressive strength. The tensile strength of concrete has a fundamental role in the fracture mechanism of hardened concrete. It is an accepted view that the fracture in concrete occurs through cracking caused by tensile stresses. This means that concrete fracture is essentially tensile failure regardless of whether the fracture is caused by compression, freezing, or other factors. Therefore, the mechanical properties of a hardened concrete are controlled to a great extent by the fact that its tensile strength is about one tenth of the compressive strength. To avoid undue cracking in structures such as concrete beams and slabs, the tensile strength is of special importance, despite its low magnitude. The case of uni-axial tension is rarely encountered in practice and in laboratory tests can only be obtained with care.

"The compressive strength of concrete is one of the most important technical properties. In most structural applications concrete is employed to withstand compressive stresses", (Popovics, 1998).

In those cases where other stresses (e.g. tensile stress) are of primary importance, the compressive strength is still frequently used as a measure of the resistance because this strength is the most convenient to measure. For the same reason, the compressive strength is generally used as a measure of the overall quality of concrete.

It was therefore decided that compressive strength would be tested, but a decision had to be made on whether the wet or dry compressive strength should be used. In the stabilised soils literature it can be seen that the compressive strength is mainly referred to as the wet compressive strength, but in the concrete literature the dry compressive strength is used.

It was expected that the sand being used would affect the wet compressive strength dramatically showing a cyclic loss of mass in the material as well a decrease in strength. It was decided that the shrinkage and swelling would be important factors to investigate due to the high fines content in the sand, so would be examined independently, and not combined with the strength test to form one single test. The wet compressive strength indicates what happens to the strength as well as taking into account the shrinkage and swelling, but the compressive strength indicates the strength only and was chosen to be tested.

According to Witmann, (1968) the dry compressive strength of concrete is higher than that of a comparable wet concrete because dryness decreases the volume of the hardened cement paste. The volume reduction is caused by surface tension that increases in the water filled small pores during drying, pulling adjacent grains of solid together: thereby reducing the average distance between surfaces in the hardened cement gel. This increases the secondary bonds between the surfaces, increasing the strength. Since rewetting the hardened cement paste causes volume increases, and therefore an increase in the average distance between surfaces of the cement gel, this would explain the lower strengths of wet cement paste and concrete specimens.

Compressive strength can be tested at various specific ages, where various ages only give a proportion of the final strength.

"The strength developed by a concrete made with given materials and given proportions increase for many months under favourable conditions, but in the majority of specifications the strength is specified at an age of 28 days", (Building Research Establishment Report, 1988).

Traditionally, concrete strength is determined 28 days after casting and rejection of a particular batch of concrete, or adjustment of the concrete production is delayed by the substantial time difference between casting and testing. It was therefore decided to test the specimens at an age of 7 days to begin with in order to get a respectable number of results to be analysed. After the main trends that the factors were following for 7 day tests, specimens were made to be tested after 28 and 56 days.

Numerous test methods have been recommended for the determination of concrete strengths. Some of these methods measure fundamental properties of the concrete whereas others do not. Also, various simplifying assumptions are used in the procedures of different test methods to convert a measured load to a calculated failure stress. Some of these procedures require more doubtful assumptions than others, which may considerably influence the relationships between various concrete strengths.

The principle laboratory test methods that could have been used were:

- *Destructive Compressive Strength Test*
- *PUNDIT Test*
- *Schmidt Hammer*
- *Penetration Resistance*
- *Pull-out Test*

A summary of the principle test methods are shown in the table below:

Method	Standard Number	Principle Applications	Principle Properties Assessed	Surface Damage	Type of Equipment	Remarks
Destructive Compression Test	BS 1881	Strength Measurement	Compressive Strength	Completely	Mechanical	Load rate should be of a few minutes
PUNDIT Test	BS 1881-203a	Comparative Surveys	Elastic Modulus	None	Electronic	Two opposite smooth faces preferably needed, strength calibration affected by moisture and mix
Schmidt Hammer	BS 1881-202	Comparative Surveys	Surface Hardness	Very Minor	Mechanical	Greatly affected by surface texture
Penetration Resistance	BS 1881-207a	In Situ Strength Measurement	Strength Related	Moderate / Minor	Mechanical	Specific calibrations required, surface zone test
Pull Out Test	BS 1881-207a	Quality Control (In Situ Strength)	Strength Related	Moderate / Minor	Mechanical	Pre-planned usage

Table 4.3: Summary of Principle Test Methods

It was decided that the compressive strength would be measured using the standard destructive *compressive strength test*, as recommended in the British Standard BS 1881, and the non-destructive *PUNDIT test*. Because the PUNDIT test is quick and non-destructive it allowed a large number of readings to be taken without damage to the blocks so as to retain some blocks to obtain further readings as the specimens aged. The detailed procedure of these two tests and problems associated with them are described in the research methodology.

The Schmidt hammer, also known as the rebound or impact hammer was also considered as a non-destructive test method that could have been used. The test is based on the principle that the rebound of an elastic mass depends on the hardness of the surface against which the mass impinges. The spring loaded mass has a fixed amount of energy imparted to it extending the spring to a fixed position; this is achieved by pressing the plunger against a smooth surface of concrete which has to be firmly supported. This is illustrated in figure 4.4.

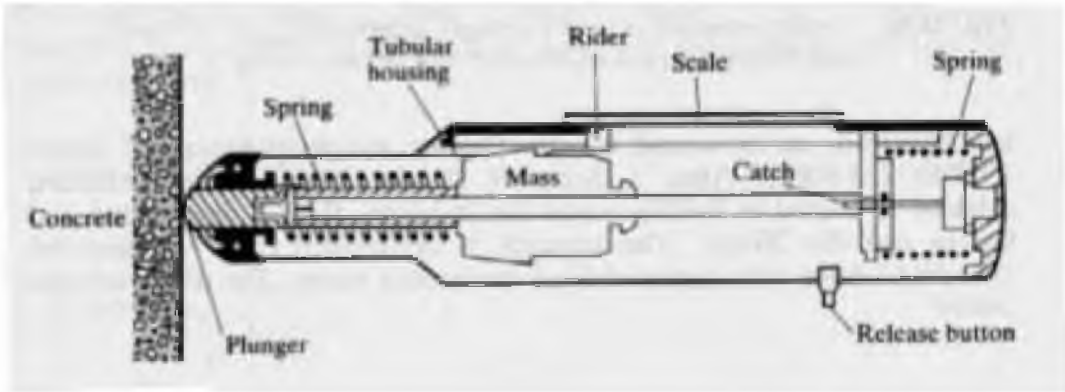

Figure 4.4: Schmidt Hammer

Upon release, the mass rebounds from the plunger, and the distance travelled by the mass, expressed as a percentage of the initial extension of the spring is called the rebound number; it is indicated by a rider moving along a graduated scale. The rebound number is an arbitrary measure since it depends on the energy stores in the given string and on the size of the mass. This test was rejected for this research as the concrete was not hard enough indicated by when the mass rebounded it indented the concrete.

The *penetration resistance test* and the *pull out test* were rejected as they are partially destructive tests. The penetration resistance test estimates the strength of the concrete from the depth of penetration by a metal rod driven into the concrete by a given amount of energy generated by a standard charge of powder. The pull out test measures the force required to pull out a previously cast-in steel rod with an embedded enlarged end. Because of its shape, the steel rod assembly is pulled out with a lump of concrete in the approximate shape of a frustum of a come. The pull out strength is calculated as the ratio of the force to the idealised area of the frustum. As it was decided that all specimens would be crushed using the compression test after intermediate readings had been taken, using any of the partially destructive tests would damage the specimens. Damaging the specimens and the crushing them would result in an unrealistic low compression strength and since the destructive compression test is the most reliable and accurate test available, the compression test method was adopted.

It is expected that the concrete made with sand "Y", the good sand, will give a 7day dry compressive strength of approximately 12 MPa, which is within the range of a 'normal' concrete. The range of concrete strength is usually between 10-70 MPa, which means that the estimated value is nearer the lower value. This is because it is expected that the method for making the specimens is more basic than methods used in normal UK concrete making.

It is expected that concrete made with sand "X", will have a 20% lower dry compressive strength than sand "Y", at approximately 9.6MPa. This is explained in the literature by the extra fines interfering with the chemical reaction in the cement and the water. Concrete is not generally used at strengths lower than 10MPa, so it is expected that sand "X" will not be suitable for use in concrete.

4.2.2 Shrinkage / Swelling

As mentioned previously, due to the high fines component in the composition of the sand of the concrete, shrinkage and swelling were considered to be important factors to be investigated. This is because:

"The high fines fraction in the material being tested means there is a high proportion of small particles having surface electrostatic charges to which a layer of water becomes attached", (Spence and Cook, 1983).

The thickness of this layer depends on the normal pressure to which the soil mass is subjected, and this gives fines, especially clays, their characteristic ability to swell and shrink as they take on and lose moisture.

Shrinkage can be divided into three main categories. They are,

- *Plastic,*
- *Autogenous,*
- *Drying.*

Plastic shrinkage is the shrinkage which occurs before the concrete has set or has attained any significant strength. The principle cause of such shrinkage is the rapid evaporation of water from the concrete surface. The restraint of the mass of concrete will cause tensile strains to be set up in the near surface region, and as the concrete has near zero tensile strength, plastic shrinkage cracking may result. Any tendency to plastic shrinkage cracking will be encouraged by greater evaporation rates of the surface water which occurs.

Autogenous shrinkage results in volume change without the loss of moisture. The contraction is relatively small and of significance only in large structures. This type of shrinkage is not examined in this report.

Drying shrinkage occurs when concrete is hardened and cured and allowed to dry. First, the water saturating the voids in the concrete dries out. This continues until the total moisture content is reduced by about half. Further drying results in water being drawn out of the mass of small capillaries which permeate the cement gel. This process continues on an ever decreasing scale for a long time. The rate at which the shrinkage occurs depends on the speed of water loss and on the moisture movement through the concrete; therefore in hot, dry and windy climates rates of shrinkage will be high.

So, when cement, aggregate and water are mixed together the gross volume decreases as the finer particles arrange themselves in the interstices of the larger particles. The shrinkage continues as the concrete is being worked into place, i.e. when still plastic. Evaporation of water in the mix also decreases the volume of such concrete.

Shrinkage, when the concrete is in a fluid state, does not matter structurally because no internal stresses can be instigated. When the concrete changes from a fluid to a solid state, further shrinkage of the concrete will cause internal stresses and even cause cracks to occur. If a mass of concrete shrinks or expands uniformly and its movement is not restricted by any external forces, then no internal stresses can be induced in the concrete. This seldom happens in practice; usually any movement of the concrete is restricted internally by reinforcement imbedded in the concrete, and often externally by its surroundings. Also, the surface of the concrete will often dry out (and therefore shrink) faster than the internal particles of concrete. It was therefore decided that drying shrinkage would be measured during the curing period of 56 days.

Shrinkage after the concrete has solidified continues as and when further water evaporates. The chemical reaction of cement with water, and thus the shrinkage, continues in the concrete seemingly indefinitely. A gel is formed which contracts upon desiccation and becomes very hard. If the concrete is submerged in water the cement gel expands with considerable force, so that the whole mass of the concrete expands and swells. This expansion, however, can never equal the shrinkage which has already taken place. On drying the concrete in air shrinkage again occurs. Therefore, when concrete is subjected to continual wetting and drying, it experiences corresponding expansions and contractions, (shrinkage and swelling). This is illustrated graphically in figure 4.5. It was decided to measure these expansions and contractions to examine the effect of a high proportion of fines had on these movements as it was expected that the specimens would be susceptible to damage on exposure to wetting and drying cycles.

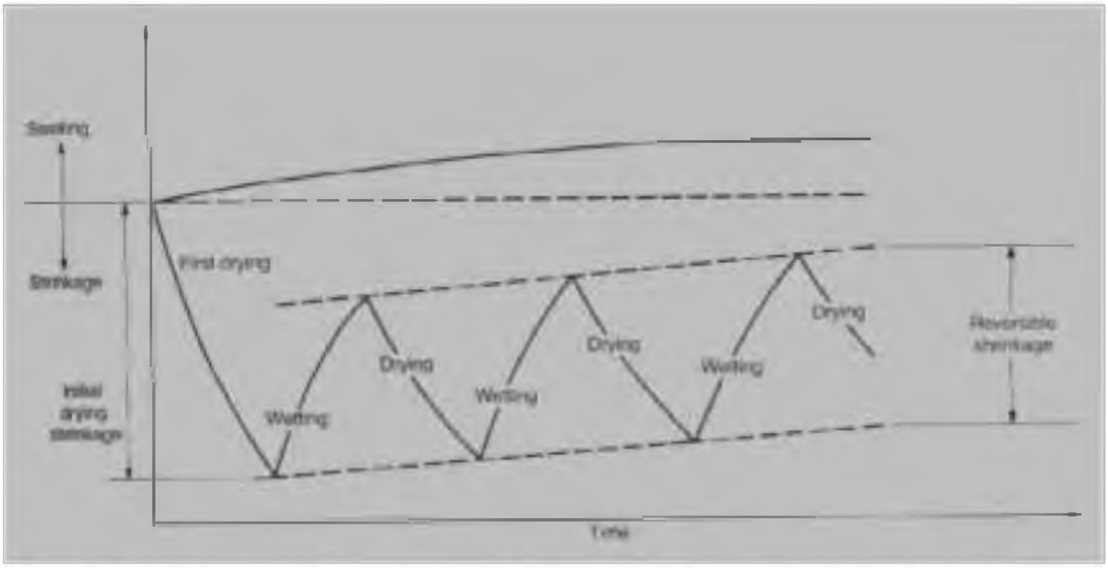

Figure 4.5: Schematic of volume changes in concrete due to alternate cycles of drying and wetting.

Maximum shrinkage occurs on the first drying, and a considerable part of this is irreversible; i.e. it is not recovered on subsequent rewetting. Further drying and wetting cycles result in more or less completely reversible shrinkage. The diagram also shows the continuous but relatively small swelling of the hardened cement paste (hcp) on continuous immersion of water. The water content first increases to make up for the self-desiccation during hydration and to keep the paste saturated. In principle the stronger the hcp structure, the less it will respond to the forces of swelling and shrinkage.

Shrinkage and swelling were measured using dial gauges that were set up on the specimen cubes. This was the only method considered as it is a cheap and effective way of measuring the volume changes with the specimens that had already been made for testing compressive strength. With a 100mm cube, strains could be measured to a resolution of ~ 100 μ-strains. Using the same specimens allowed better time management and enabled a larger range of results. The details of the procedure are described in the research methodology.

According to Illston, (1994), 'normal concrete' usually shrinks between 300-600 μ-strains in one year of drying. Therefore, it is expected that concrete made with the good sand, sand "Y", will have a drying shrinkage of approximately 600μ-strain, the upper limit, allowing for the 5% extra fines than recommended in BS 812. It is expected that concrete made with sand "X", will have a larger drying shrinkage, approximately 20% more shrinkage, of about 720μ-strain, since there is a larger proportion of fines. Cyclic shrinkage is thought to follow the usually pattern described above, but with increased shrinkage and swelling movements. Usually cyclic movements change between $\pm$400μ-strain, so it expected that concrete made with sand "X" will have movements between approximately $\pm$600μ-strain.

5. Research Methodology

5.1 General Approach

This project examined the factors affected by a high fines content when making concrete. This means that several iterations were used, each to change a factor, while holding all others constant to obtain a result. When a new result was obtained, a new understanding was gained and different avenues were explored. This structure led to most of the project being devoted to experimental work in the laboratory and analysing results. Alongside the experimental work, secondary data was collected to support the laboratory work and to justify the findings.

5.2 *Making the specimens*

The compressive strength test that was used uses a concrete cube and is the standard destructive test in the UK set out by the British Standard, BS 1881: 1983. The cube size tested was 100mm, as recommended for maximum aggregate sizes of 20mm or less. Some of these cubes were also used for the PUNDIT test and for the shrinkage and swelling measurements.

The mix components were chosen for experimentation was based on a soil-cement ratio of 4:1 by weight. This ratio was chosen because for high strength concrete a ratio of 3:1 is normally used, and for rendering, a ratio of 5:1 is commonly used. It was decided to use an in-between value in order to keep it constant throughout the duration of the project, so not to have another variable. The water content, vibration time, and mixing time were varied until the optimum, or best operating point was found, (this will be discussed in the analysis). The approximate density of the concrete to be tested was 2000kg/m^3, and the volume of the cube was 0.001m^3. Since:

Density (kg/m^3) = mass (kg) / volume (m^3), the mass needed for each block was approximately 2kg. That is, 1.6kg of aggregate and 0.4kg of cement.

The cubes were cast in lubricated steel moulds, accurately machined to ensure the opposite faces are smooth and parallel. A thin layer of lubricant was applied to the inside surfaces of the mould in order to prevent bond between the concrete and the mould. The concrete was placed and compacted using a vibrating table, as soon as the mix was made. This was so there would be no effect from the delay of moulding.

A vibrating table can be considered as a case of formwork clamped to the vibrator. A rapidly rotating eccentric weight makes the table vibrate with a circular motion but, by having two shafts rotating in opposite directions, the horizontal component of vibration can be neutralised, so that the table transmits a simple harmonic motion in a vertical direction only. The concrete was fully compacted by external vibration and filling the mould in two stages. The details of this procedure are prescribed by BS 1881: Part 108: 1983. When the mould was filled the surface was trowelled smooth.

The moulded specimens were stored for 48 hours at a temperature of 23 °C since curing at a higher temperature would result in a higher initial strength development, but a lower 28 day strength. If a much lower temperature was chosen, the concrete would also have a lower strength. Subsequently, the de-moulded cubes were stored at the same temperature in a polyethylene bag until the prescribed age of testing.

5.3 Compressive strength tests

5.3.1 Destructive compressive test

The cube testing machine has two heavy platens through which a uniformly distributed increasing axial compression load was applied to the concrete.

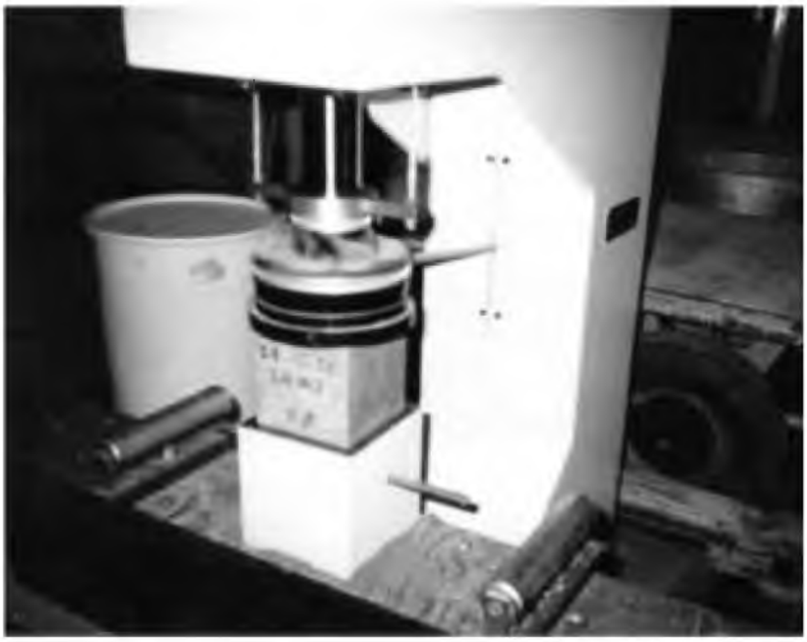

Figure 5.1: Compression Test Machine

The bottom platen is fixed and the upper one has a ball seating which allows rotation to match the top face of the cube at the start of loading. This then locks in position during the test. The load was applied to the pair of faces which were cast against the mould, i.e. with the trowelled face to one side. This ensured that there were no local stress concentrations which would result in a falsely low average failure stress.

The strength of concrete increases as the rate of loading increases so it is necessary to define the rate for testing purposes. McHenry and Shideler (1955) have shown that if the specimen is not subjected to impact or if the load is applied in a reasonable period of time, the rate of loading does not significantly influence strength. Therefore, a rate to reach the ultimate load in a few minutes is recommended, so a loading rate of 50kN/ Min was chosen. When the specimens had failed, the maximum load and type of failure was recorded.

The cracking pattern within the cube produced a double pyramid shape after failure, (see figures 5.2a & b).

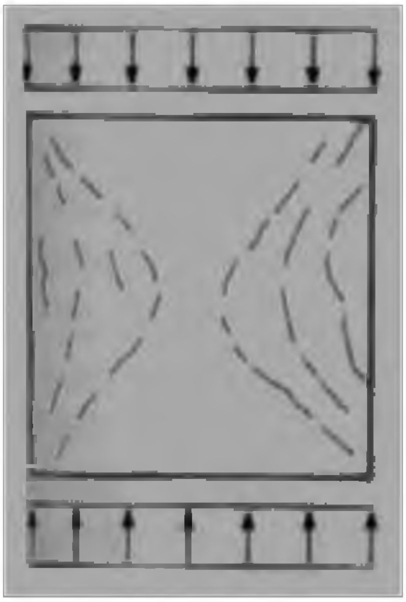

Figure 5.2a: Cracking Pattern Of a Cube

Figure 5.2b: Cube after failure

From this, it was immediately apparent that the stress within the cube was not uniaxial. The compressive load induced lateral tensile strains in both the steel platens and the concrete due to the Poisson effect. This mismatch between the elastic modulus of the steel and the concrete and the friction between the two resulted in lateral restraint forces in the concrete near the platen. The concrete cube was therefore in a triaxial stress state, with consequent higher failure stress than the true, unrestrained strength. This was the major objection to the cube test, but the test was relatively simple to perform and is capable of comparing different concretes.

The strength was expressed as the ultimate compression load per cross sectional area. This reading was converted into MPa for a reading of strength. This type of test is a destructive test and was applied to the cubes after seven days. No other results from the specimens tested could be obtained. Therefore, in order to obtain more results during the project time, it was decided to use an in-situ test which is a type of non-destructive test up until an age of 56 days and then crush them.

5.3.2 PUNDIT test

The PUNDIT test (Portable Ultrasonic Non-destructive Digital Indicating Tester), was used to indirectly test the compressive strength of the cubes made as described above.

Figure 5.3: PUNDIT in laboratory

Three types of waves are generated by an impulse applied to a solid mass. Surface waves having an elliptical particle displacement are the slowest, whereas shear or transverse waves with particle displacement at right angles to the direction of travel are faster. Longitudinal waves with particle displacement in the direction of travel are the most important since these are the fastest and generally provide the most useful information. Electro-acoustical transducers provide waves primarily of this type; other types generally cause little interference because of their lower speed.

The underlying principle of this PUNDIT is the recognition that factors that increase the concrete strength usually increase the velocity of the acoustic wave propagations in the material as well. The PUNDIT generates low frequency ultrasonic pulses and measures the time taken for a wave to propagate through the specimen of length 100mm. This enables the velocity to be determined from:

Pulse Velocity = Path length / Transit time

Path lengths and transit times were measured to an accuracy of ± 1%. This is because the pulse velocities for most concrete mixes lie within a narrow range so it is therefore necessary to measure both the transit time and path length to this accuracy. To acquire a high accuracy of transit time, good acoustic coupling between the transducer face and the concrete is needed. This was achieved by covering the transducer face with medium grease. A zero control is incorporated in the instrument since the zero is likely to change when different transducers are used. The instrument indicated the time taken for the earliest part of the pulse to reach the receiving transducer measured from the time it left the transmitting transducer when these transducers were placed on opposite surfaces of the specimen, (see figure 5.4). It was important that the readings were repeated by complete removal and re-application of transducers to obtain a minimum value for the transit time.

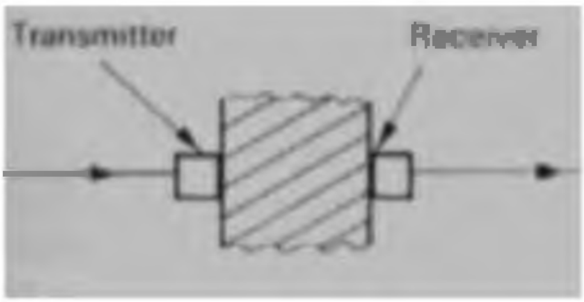

Figure 5.4: Diagram of PUNDIT on specimen

This arrangement for taking readings was the direct transmission arrangement, and is the most satisfactory method of taking readings since the longitudinal pulses leaving the transmitter are propagated mainly in the direction normal to the transducer face. Pulses were not transmitted through large air voids in a material, and if such voids existed directly in the pulse path, the instrument would have indicated the time taken by the pulse which circumvents the void by the quickest route.

It can be shown theoretically that the wave velocity depends upon the elastic properties, and hence if the mass and velocity of wave propagations are known it is possible to assess the elastic properties. The compression wave velocity is given by:

$$V = \sqrt{\frac{K.E}{\rho}}$$

Where V = Compression wave velocity (km/s)

$K = \dfrac{(1-v)}{(1+v)(1-2v)}$, (typically K = 1.3)

E = dynamic modulus of elasticity (kN/mm^2)

ρ = density (Kg/m^3)

v = dynamic Poisson's ratio, (typically 0.3).

In practice the velocity of such pulses travelling in concrete is very closely related to the elastic modulus since changes in the density or Poisson's ratio give rise to proportionately greater changes in elastic modulus.

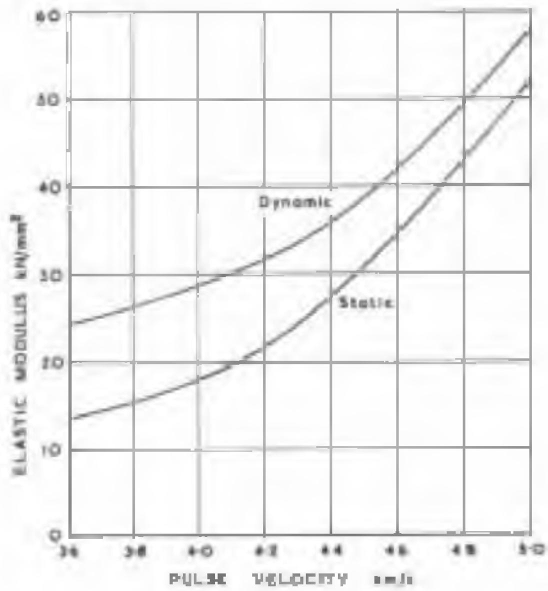

Figure 5.5: Curves relating Pulse Velocity with Static and Dynamic Elastic Modulus

The elastic modulus of concrete increases as its mechanical strength increases so that pulse velocity can be related empirically to cube strength. The exact relationship cannot be defined simply by consideration of the properties and proportions of individual constituents. This is because of the influence of the aggregate particle shape, efficiency of the aggregate, matrix interface and variability of the particle distribution, coupled with changes of matrix properties with age. There is no single curve which relates concrete strength to pulse velocity although, for a given cement content and aggregate type, a reasonable correlation exists between velocity and cube strength when this is varied by changing either the water cement ratio or the age at test. This correlation could not be used in the experimental work since the aggregate type is different to the "norm". In order for the Pundit Test results to be related to compressive strength, experimental collaboration of the specimens was necessary. Strength calibration was attempted as readings were taken between both pairs of opposite faces of cubes, which were then crushed in the usual way. Ideally, at least 10 sets of three specimens should be used, but time constraints did not allow this, so only 3 blocks for each type of specimen were crushed at 7 and 56 days. 6 pulse velocity readings were taken for each cube, and each individual reading was within 5% of the mean for that cube.

Although the precise relationship is affected by many variables, the curve is usually found to be of the general form:

$$f_c = Ae^{B\nu}$$

Where f_c = equivalent cube strength

e = base of natural logarithms

ν = pulse velocity

and A and B are constants.

Hence, a semi-logarithmic plot of pulse velocity against cube strength is linear for a particular concrete. It is therefore possible to use a curve derived from reference specimens to extrapolate from a limited range of results. This process is done in section 6.1.8.

5.4 Shrinkage & swelling measurements

Shrinkage and swelling measurements were done on the cubes made for the PUNDIT test. During the curing process, once the specimens had been removed from the moulds, the blocks were set up as shown in the photograph in figure 5.6.

Figure 5.6: Specimen during the curing process

Point dial gauges were set up on the side face of the specimens, and readings were taken at 7, 14, 28, and 56 days respectively. This allowed measurements of the drying shrinkage to be made. As it can be seen from the photographs, the blocks were covered in a polyethylene bag to keep the curing conditions the same for each specimen. Because of stick and hysterisis in the dial gauges, measurements were always approached from one side (above), so that the friction in the spring could be ignored. At 56 days, the specimens were measured using callipers and were then placed in a drying oven at 105°C and left to dry out for 7 days. After this period of time the cubes were re-measured, then submerged in water with a dial gauge set up on it. The movement in the specimen was recorded after 7 days, and the drying wetting cycle was carried out again.

The point dial gauges measure to an accuracy of ± 0.005mm and the callipers to an accuracy of ± 0.05mm. It was necessary to use the callipers for the drying part of the cycle, since the drying oven was not large enough to set up a dial gauge. This meant that the accuracy of the shrinkage measurements during the cycle were much less accurate than the swelling measurements.

6. Results & Analysis

6.1 Strength

The first property of the concrete that was tested was the dry compressive strength, after a curing period of 7 days. When the strengths of comparable concretes, (i.e. the sand with a high fines content, and the one without), with identical water-cement ratios were made, the strength of the concrete unexpectedly *increased* as the fines content increased. This is shown in table 6.1 below.

		Maximum load (kN)				
	Water-cement Ratio	Block 1	Block 2	Block 3	Mean Maximum Load (kN)	Mean Pressure (MPa)
Sand "X" Cube	0.95	122.2	120.1	121.1	121.1	12.1
Sand "Y" Cube	0.95	79.9	79.3	79.2	79.5	7.9

Table 6.1: Comparable concretes with identical water-cement ratios after 7 days

This was an unexpected result since it was expected that the fines would interfere in the bond between the hardening cement paste and the aggregate. The strength of concrete originates from the strength of the hardening cement paste, which originates from the hydration products in the form of a rigid gel, the cement gel.

"It is reasonable to assume that the bonds of the gel particles to each other, to the sand particles, and to other bodies in the concrete are responsible for strength", (Popovics, 1998).

A likely explanation as to why the compressive strength was higher for the cubes with more fines is that the bond to the hardening cement paste to aggregate particles of larger sizes is weaker than the bond to smaller sizes because of the specific surface of the former. Also, the 'fines' are siliceous substances of high surface area that react with the excess alkali in the cement to form additional 'pozzolanic' gel.

The strength being discussed is this research is the strength of small samples. The strength of these small samples is generally higher than that of core samples taken from a structure and there are several reasons for this:

1. The cube specimens were compacted, cured and tested under controlled conditions; a structure (or core samples taken from it) is not subjected to the same controlled conditions. Compaction and curing in a structure is generally less than the optimum that would be achieved with the test specimens.
2. The concrete is a structure is subjected to restraint stresses due to the reinforcement member geometry and other factors, and this pre-test load will influence strength of a core taken from a structure.

Interpretation of the Strength Readings

The strength of the concrete samples made from the same mix and tested in the same manner are variable and if a population (or large sample) of results are considered, the variation follows a normal distribution. The characteristics of a normal distribution are the arithmetic mean (x), which is the sum of the strength results divided by the number of results, the standard deviation (σ), which is the root mean square deviation of a set of results from their arithmetic mean, and the coefficient of variation ($v_c = (\sigma/x) \times 100$), which is a measure of the relative variability of a set of results. The results are said to follow a normal distribution if they are equally spaced about the mean value and if the largest number of cubes have strength close to the mean value, the number falling off as the results are much greater or less than the mean value. In some cases it may be considered doubtful as to whether actual results lie within a normal distribution, but for the purpose of statistical analysis they are considered to do so. The range of a set of strength results will be reflected in the values of standard deviation and coefficient of variation; the higher these values the greater the range. The variability of concrete is a reflection of the manner in which it was made and tested, i.e. the degree of quality control.

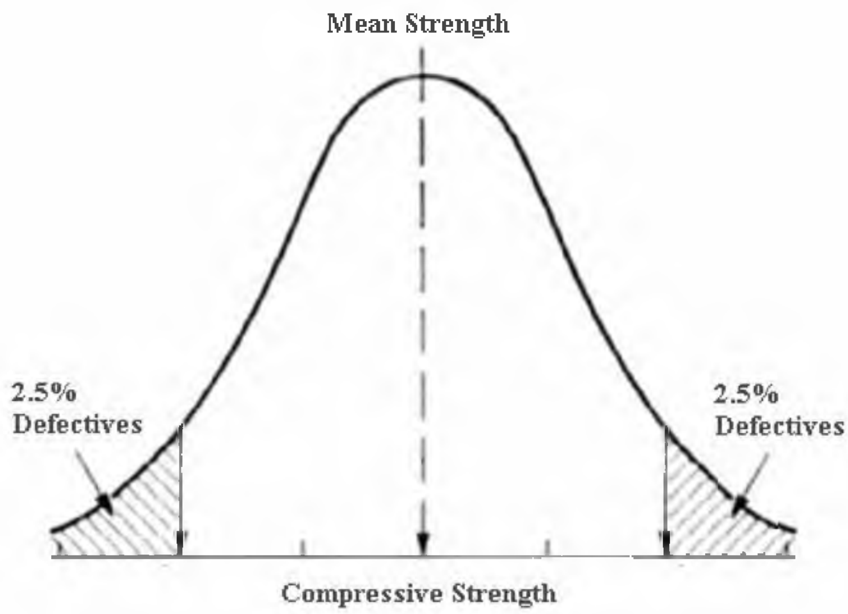

Figure 6.2: Normal distribution for concrete strengths

The mean value of a number of results gives no indication of the extent of variation of strength. The extent of variation can be determined by relating the individual strengths to the mean strength and determining the variation from the mean. The variations which occur in compressive strength test results, even when testing all the concrete from one batch, are not due to faulty workmanship but are inherent in the making and testing of concrete. The amount of scattering is in itself a measure of quality; where the sampling of concrete is not restricted to one batch but is spread over a number.

The variability of the properties of concrete can only be determined by testing, but testing itself can introduce error. Precision is the general term used for the closeness of agreement between replicate test results, and two terms are relevant: repeatability and reproducibility.

BS 5497: Part 1: 1979 defines repeatability as the value below which the absolute difference between two single test results, obtained with the same method on identical test material under the 'same' conditions (i.e. same operator, same apparatus, same laboratory, and a short interval of time), may be expected to lie within a specified probability (usually 95%). On the other hand, reproducibility is defines as the value below which the absolute difference between two single test results, obtained with the same method on identical test material under 'different' conditions, (i.e. different operators, different apparatus, different laboratories, and/or different times), may be expected to lie within a specified probability (usually 95%).

Values of repeatability and reproducibility are applied in a variety of ways, e.g.

- to verify that the experimental technique of a laboratory is up to requirement;
- to compare the results of tests performed on a sample from a batch of material;
- to compare test results obtained by a supplier and by a consumer on the same batch of material.

Using this statistical analysis, it can be shown that the results from comparable concretes with identical water-cement ratios can be proved to be statistically significant:

Testing for a difference between two normal distributions

	Result number	Water-cement Ratio	n	x	σ_{n-1}
Sand "X"	X_1	0.95	3	12.1	0.105
Sand "Y"	X_2	0.95	3	7.9	0.038

Table 6.3: Data on the 2 different batches of concrete for significance testing

If two sets of results, X_1 and X_2, have independent normal distributions with means of x_1 and x_2 and standard deviations σ_1 and σ_2 respectively then the difference Δ between two populations is another normally distributed entity

$$\Delta = X_1 - X_2 \sim N(x_1 - x_2, \sigma_1^2 + \sigma_2^2)$$

Since X_1 and X_2 are based on sample sizes of n_1 and n_2, respectively from the above two normal populations then

$$\bar{X}_1 - \bar{X}_2 \sim N\left(x_1 - x_2, \frac{\sigma_1^{\ 2}}{n_1} + \frac{\sigma_2^{\ 2}}{n_2}\right)$$

and the statistic $\bar{X}_1 - \bar{X}_2$ can be used to test hypothesis about the values of x_1 and x_2.

If $X_1 \sim N(x_1, \sigma_1^{\ 2})$ and the independent random variable $X_2 \sim N(x_2, \sigma_2^{\ 2})$ then a test of the null hypothesis H_0: $x_1 = x_2$ can be carried out using the test statistic

$$Z = \frac{\bar{X}_1 - \bar{X}_2}{\sqrt{\left(\frac{\sigma_1^2}{n_1} + \frac{\sigma_2^2}{n_2}\right)}} \sim N(0,1^2)$$

So, the null hypothesis is

$H_0 : x_1 = x_2$ $\qquad$ $H_1 : x_1 \neq x_2$

In this comparison of strength of cubes made with sand “X” and sand “Y” respectively:

$\sigma_1 = 0.105$, $n_1=3$, $\sigma_1 = 0.0.38$ and $n_2=3$

$x_1 - x_2 = 12.1 - 7.9 = 4.2$, where σ and x are measured in MPa.

Thus, for this experiment, the test statistic Z has the value:

$$Z = \frac{\bar{X}_1 - \bar{X}_2}{\sqrt{\left(\frac{\sigma_1^2}{n_1} + \frac{\sigma_2^2}{n_2}\right)}} = \frac{4.2}{\sqrt{\left(\frac{0.105^2}{3} + \frac{0.038^2}{3}\right)}} = 65.15$$

The 5% (two tailed) critical values for z are $Z_{95} = \pm 1.96$

Hence 65.15 is a statistically significant value (i.e $z >> z_{95}$) and H_0 can be rejected. It can be concluded that there is significant evidence of a difference in means of the two results.

This statistical analysis was applied to all relevant results, and is used in later sections of the analysis. The main factors which affect strength are taken to be quality of water, cement, mixing time, vibration compaction time, curing conditions, workability, water-cement ratio and curing age. Each of these factors will be looked at it in turn.

6.1.1 Water Quality

Water is one of the main constituents of concrete. It has various functions; it reacts with the cement powder, causing it to set and harden, and it is a lubricating liquid which enables the concrete to be placed as a semi-fluid and so facilitates compaction.

"It is generally accepted that water which is fit for drinking is suitable for mixing concrete", (Neville & Brooks, 1987).

In this country it is doubtful whether there is any justification for using anything other than water supplied for domestic purposes. In some situations, however, it is necessary to use sea water. Sea water contains sodium and magnesium chlorides and sulphates. The action of the chloride ions is to accelerate early strength development while the sulphate ions reduce the later age strength. Mindless and Young (1981), indicate that the 28 days strength can be reduced by as much as 20% if sea water is used as mix water. Also, the addition of chloride ions to concrete increases the risk of corrosion of the reinforcing steel. Hence, because of the generally poor standard of concrete construction in the Third World countries, it is considered that sea water should, as far as it is practical, not be used. For the purposes of this study, only tap water was used for mixing.

6.1.2 Cement quality

Cement is the most important and expensive ingredient of concrete, on a price per tonne basis. It was patented by J.Aspdin in the UK in 1824 and he called his product Portland cement because of the 'artificial stone' (concrete) made with it resembled Portland stone.

The chemical composition of Portland cement consists essentially of four main elements; lime, silica, alumina and iron oxide. These elements interact with one another in the kiln to form a series of more complex products. Of these, four of the products are considered to be the major constituents of cement:

- Tricalcium silicate, C_3S
- Dicalcium silicate, C_2S
- Tricalcium aluminate, C_3A
- Tetracalcium aluminoferrite, C_4AF

Each grain of cement consists of an intimate mixture of these compounds.

There are several types of Portland cement available commercially, but the most common type used in concrete construction is Ordinary Portland Cement. Its related British Standard is BS 12:1978. Over the years, there have been changes in the characteristics of ordinary Portland cement: modern cements have a higher C_3S content and a greater fineness than 40 years ago. In consequence, modern cements have a higher 28 day strength than in the past, but the later gain is smaller. For the purposes of this research ordinary Portland cement was used to make the cubes since it is the cheapest and most widely available cement for builders in developing countries to use.

6.1.3 Mixing time

"For onsite mixing or in the laboratory, the essential requirement in mixing concrete is to produce a uniform mixture in as short a time as possible", (Spence and Cook, 1983).

The mixing operation consists of essentially of rotation and stirring, the objective being to coat the surface of all the aggregate particles with cement paste, and to blend all the ingredients of concrete into a uniform mass. Mixing can be achieved in pan or drum type mixers, or it can mixed by hand which is generally less effective in achieving the objective above. Nevertheless, hand mixing was used to make the concrete mix since this is the most likely method to be used in developing countries.

It is essential to mix the concrete well since the strength of concrete is also affected by the efficiency of mixing. Poor mixing results in a bad distribution of the coarse and fine aggregates through the mix, so that some parts are lean and some parts are rich in cement. The lean parts are not fully compacted, whilst the rich parts may be over compacted, resulting in some wet segregation.

Mixing time is considered to have an asymptotic effect, so provided it was 'very high' its actual value would not affect the strength of the concrete. However, in case this assumption was unreliable, some attempt was made to hold the mixing time constant. It was decided to hold the mixing time constant at 5 minutes for a mix of 5 kg. This time was chosen not in relation to the optimum mixing time, but instead was chosen due to the time constraints on a builder in a developing country. Although mixing for a much longer period increases the strength it is not done in practice, so an arbitrary value was chosen.

6.1.4 Vibration compaction time

The compaction of concrete is the process whereby the amount of voids is reduced to a minimum and the particles of aggregate are constrained to pack more closely together so as to achieve the minimum potential density and strength from the concrete.

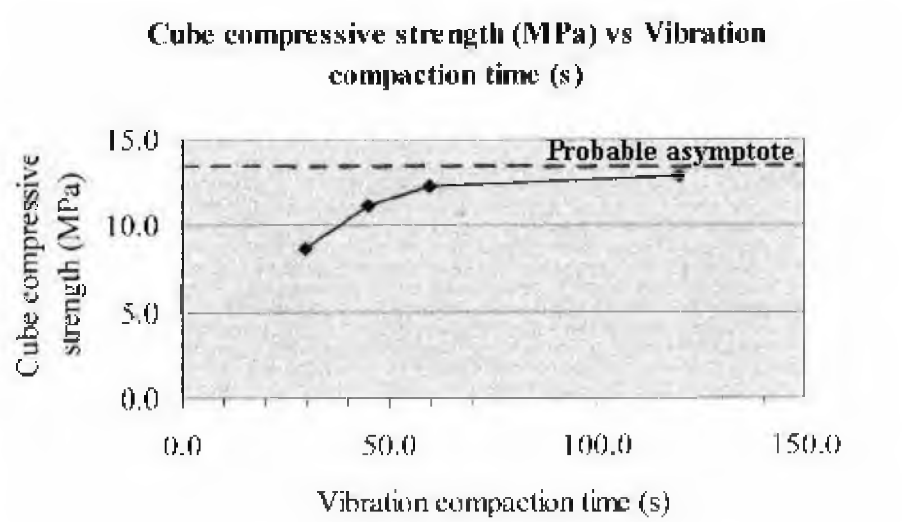
Vibration does not increase the workability of concrete and can be detrimental by causing segregation of the constituents of the concrete, the gravel particles tending to sink to the bottom, and the sand and cement to float to the top of the concrete. The vibration employed should *only just be sufficient* to make the concrete flow into the sharp corners of the mould and around the reinforcement.

Four batches of three specimens were made to test the effect of vibration time on compressive strength when using a high fines content concrete. The batches were vibrated for 30 seconds, 45 seconds, 1 minute and 2 minutes respectively.

It was discovered the compressive strength increases with vibration time in the form of an asymptotic relationship. The difference of 2 minutes vibration time compared to 1 minute gave a 5% increase in strength, whereas between 45 and 60 seconds, there was a 10% increase in strength. Therefore in terms of costs, one minute vibration time was considered sufficient, as this time is nearing its probable asymptote. This is shown in figure 6.5.

	Maximum Load (kN)					
Vibration Time (seconds)	Block 1	Block 2	Block 3	Mean Maximum Load (kN)	Mean Pressure (MPa)	Load Normalised to Max. Load
30	87.5	87.2	87.4	87.4	8.7	0.68
45	111.2	111.4	111.7	111.4	11.1	0.86
60	122.8	122.7	123.4	123	12.3	0.95
120	129.4	129.1	128.9	129.1	12.9	1.00

Table 6.4: Vibration compaction time against Cube compressive strength



Graph 6.5: Vibration compaction time against Cube compressive strength

6.1.5 Curing Conditions

Curing is the name given to procedures used for promoting the hydration of cement, and thus, the development of strength of concrete, the curing conditions being control of the temperature and of the moisture movement from and into the concrete.

Although there are several ways to cure concrete, including curing under water, the project focuses on methods used in developing countries.

In tropical and subtropical countries, the temperature during the day can regularly exceed 30°C and special precautions have to be taken, otherwise the concrete may crack and its strength will be impaired.

"Curing in developing countries means that there is a difficulty with fresh concrete because the temperatures are above 'normal', meaning that the concrete can stiffen before it is compacted and finished", (ACI Committee 305, 1982).

The specific harmful consequences of this on the fresh concrete are:

- Increased water demand
- Increased rate of slump loss
- Increased rate of setting resulting in greater difficulty of handling and curing
- Increased tendency for dry shrinkage
- Decreased durability
- Increased creep.

During placement the concrete temperature should be kept low. The optimum temperature range for the setting and early hardening of concrete is between 10 to 20°C. Control of concrete temperature through the temperature of ingredients can only be done at the point of batching and mixing. According to Popovics (1998), since the greatest portion of concrete is aggregate, reduction in aggregate temperature brings about the greatest reduction in concrete temperature. This can be done by shading the supplies.

These hot climate conditions have not been simulated, since it would be too expensive to do so, but it is assumed that the aggregate is kept well shaded, at a temperature of approximately 18°C.

At present, many builders in developing countries do not understand the consequences of curing concrete at high temperatures, and wrongly assume that leaving the concrete to cure in the sun is acceptable. In fact, a higher temperature maintained throughout the life of a concrete will result in higher short term strengths but also, lower long term strengths. A temperature of fresh concrete higher than normal results in a more rapid hydration of cement and leads therefore to accelerated setting and to a lower long-term strength of hardened concrete since a less uniform framework of gel is established.

Also, as water is relatively scarce, so it is unlikely that artisanal builders would be willing to adopt under-water curing methods. It has therefore been suggested that concrete should be cured in tightly sealed polyethylene bags in developing countries. This method has been adopted for the purposes of this study.

6.1.6 Workability

The strict definition of workability is the amount of useful internal work necessary to produce full compaction. The useful internal work is a physical property of concrete and is the work or energy required to overcome internal friction between the individual particles in the concrete. In practice, however, additional energy is required to overcome the surface friction between the concrete and the formwork. Also, waste energy is consumed by vibrating the form and in vibrating the concrete that has already been compacted.

More usefully, workability means the ease at with which the concrete can be handled from mixing to its final fully compacted position. Workability is influenced by the type of aggregate, its maximum size, shape and grading. Since the sand being tested contained a large number of fines, more water was needed to increase the workability to an acceptable level. A higher workability of concrete means it is easier to place and handle, but if the workability exceeds a certain limit for a particular type of material, a lower strength and durability will result. A balance needed to be made between the workability and water content in order to produce an optimum mix. The water content was optimised to obtain “the highest strength compatible with acceptable workability”, and will be discussed in the next section.

Therefore, the workability chosen was the lowest workability consistent with efficient handling and placing of the concrete into the moulds. The workability was deemed acceptable if the fresh concrete was able to be mixed relatively easily by hand, and as a general rule the workability was considered optimised when the mix was just about to reach its plastic limit, as judged by eye.

6.1.7 Water-cement ratio

"The water cement ratio is defined as the ratio of the mass of free water to the mass of cement in the fresh concrete", (Newman, 1959)

The quantity of water and cement are expressed in kilograms, which provides the water-cement ratio by mass. The total water in a concrete mix divides between the water absorbed by the aggregate to bring it to a "saturated surface dry" condition, and the free water available for the hydration of the cement and for the workability of fresh concrete.

The basis of the concrete strength versus water-cement ratio relation is that an increase in the water-cement ratio produces more capillary pores in the matrix portion of concrete. The higher the water cement ratio, the more diluted the cement paste becomes; therefore the weaker it will be at any stage of hydration. But, this relationship between concrete strength and water-cement ratio is only approximate because it may be affected by secondary factors.

A high strength concrete requires to be as free from voids as possible. If water in excess of the amount required for the chemical reaction with the cement is present in the mix, the water remains in a free state and the concrete sets around the drops of water. Such particles of water form pores and voids in the concrete, resulting in weakness and permeability. Dependent on curing conditions, they may freeze and expand, causing corrosion and / or eventually evaporating into the atmosphere.

The water cement ratio was altered in the experiments by changing the water content while keeping the cement content constant. When the cement content is kept constant and the water content is changed, the concrete consistency changes dramatically. When the consistency of a concrete is already so stiff that its workability is just barely suitable for the available method of compaction, any reduction in the water cement ratio caused by a decrease in the water content will lead to an overly dry consistency. The consequence of this is a reduction in the concrete strength because the impaired workability will result in incomplete compaction. By contrast, if the consistency is fluid, it is difficult to achieve a homogeneous, cohesive concrete without significant segregation.

Therefore, experiments were carried out in the laboratory to find the optimum water-cement ratio in relation to dry compressive strength using sufficient workability as discussed previously. The results are shown in figure 6.6 and 6.7.

Before the water was added to the mix, a soil moisture test was carried out on the sand with the extra fines to see how much water is already within the material. If the amount of water already in the material was considered significant it would be added onto the water content when calculating the water-cement ratios.

80g of sand "Y" & 20g of Kaolin was placed in a heat proof dish. (This is the composition of sand "X"). The combined dish and material was weighed to an accuracy of ± 0.005g and then placed in a drying oven which maintained a temperature of 105°C. After 7 days the combined dish and material was re-weighed. The difference in weights between these two readings is the amount of water, in grams, that the material contained. This amount excludes those water molecules bonded so tightly to solid surfaces that even a temperature of 105 °C will not detach them.

Soil Moisture Test Results

Sand "Y" and Kaolin = 100g
Dish = 157.78g
Combined weight before drying = 257.78g
Combined weight after 7 days in drying oven = 257.14g
Amount of water loss = 257.78g – 257.14g = 0.64g = 0.64%

Kaolin was also tested for moisture on its own, and showed no decline in weight, hence it contained no water. It can therefore be concluded the sand contained 0.64% of water. It was decided to take this value into account when working out the water-cement ratios, so 0.64% of water was deducted from every amount of water added to the concrete.

Optimum Water-cement Ratio Results

Sand "X"		Maximum load (kN)					
Water normalised to optimum	Water-cement Ratio	Block 1	Block 2	Block 3	Mean Maximum Load (kN)	Mean Pressure (MPa)	Load normalised to max. load
0.56	0.53	78.2	78.1	78.4	78.2	7.8	0.64
0.74	0.7	112.1	112.6	112.4	112.4	11.2	0.92
0.85	0.8	113.4	113.5	113.2	113.4	11.3	0.93
0.9	0.85	116	115.8	116.2	116	11.6	0.95
0.95	0.9	117.8	117.5	117.4	117.6	11.8	0.97
0.97	0.92	119.1	119.5	119.3	119.3	11.9	0.98
1	0.95	122.2	120.1	121.1	121.1	12.1	1
1.11	1.06	117.5	117.3	117.2	117.3	11.7	0.96
1.2	1.14	80.9	80.5	80.7	80.7	8.1	0.68

Table 6.6: Water-cement ratios versus compressive strength of Sand "X" cubes, (75% sand, 4.8% silt and 20.2% clay).

Sand "Y"		Maximum load (kN)					
Water normalised to optimum	Water-cement Ratio	Block 1	Block 2	Block 3	Mean Maximum Load (kN)	Mean Pressure (MPa)	Load normalised to max. load
0.76	0.53	62.1	61.1	57.1	60.1	6	0.55
0.86	0.6	80.2	80.5	80.4	80.4	8	0.73
0.93	0.65	107.7	107.3	107.9	107.6	10.8	0.98

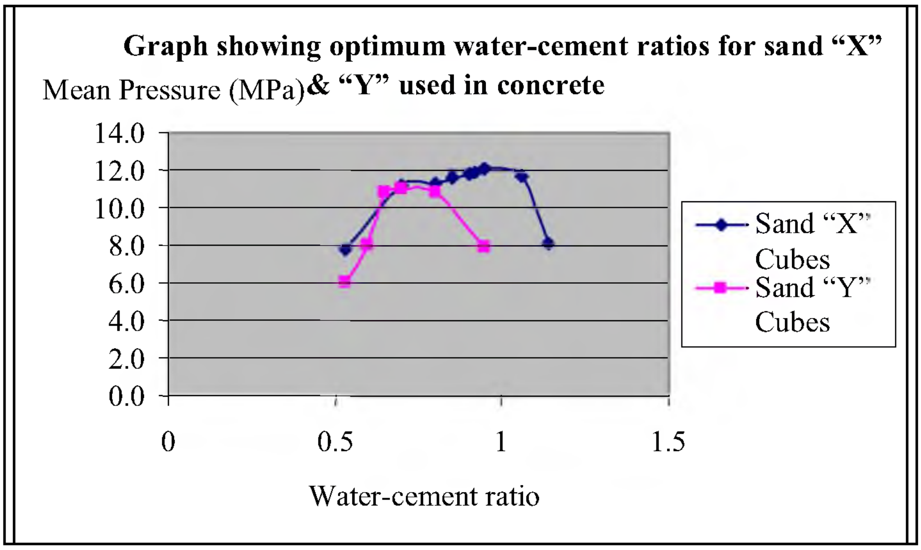
1.14	0.8	108	107.8	108.1	108	10.8	0.98
1.36	0.95	79.9	79.3	79.2	79.5	7.9	0.72

Table 6.7: Water-cement ratios versus compressive strength of Sand "Y" cubes,(95% sand, 4.8% silt and 0.2% clay).



Graph 6.8: Graph showing optimum water-cement ratios for sand "X" and sand "Y" used in concrete.

Statistical analysis, similar to the method used in 6.1, was carried out on these results and is shown in Appendix A3.

As it can be seen by the figures shown in red, it was found that the concrete made from sand "Y" had an optimum water-cement ratio of 0.7, compared to a water-cement ratio of 0.95 for the sand "X" concrete. These optimum water-cement ratios were determined using compressive strength after seven days of curing.

"The ratio of water to cement for concrete made from 'good quality' concreting sand usually varies between 0.36 and 1.0 depending on the richness, and is usually approximately 0.4", (Akroyd, 1962).

The water-cement ratios for the materials used in this project are higher than the water-cement ratio recommended in the literature. This is because the concreting sand that was used had a poor grain distributions and a large amount of fines. Fines cause an increase in the water demand by the concrete to produce a specific workability. As a result, the strength of the concrete *should* decrease, as a consequence of the water-cement ratio rule. The reasoning associated with this is described below.

The important effect of the water-cement ratio, by weights, on the strength of concrete was published in 1918 by D. Abrams of Chicago, who stated that the strength of any workable concrete, of constant materials other than water, was dependent on the water-cement ratio alone, assuming the same cement, and degree of compaction are used and the conditions of curing and age at comparison of strengths are constants. The concretes compressive strength is inversely proportional to the water-cement ratio. This means that as the amount of water increases above that necessary for complete hydration of the cement it produces a more porous structure and results in a decrease in strength.

But, as can be seen from the results, *a higher water-cement ratio produced higher compressive strengths*. This was probably due to the fines "stealing" water from the cement and hence more water was needed to allow the full chemical reaction to occur with the cement. Once the chemical reaction had occurred with a sufficient amount of water, the bond of the hardened cement paste to the aggregate particles of larger sizes was weaker than the bond to the smaller sizes because of the smaller specific surface of the larger particles, hence increasing the compressive strength. But, the results also show that if the water cement ratio increased to 12% over the ideal, the decrease in dry compressive strength is large, approximately 68% of the strength for the optimum water cement ratio. This implies that the fines have "stolen" the water they need and too much is available for the chemical reaction, diluting the cement water paste and hence decreasing the compressive strength.

6.1.8 Curing age

It is experienced that the strength of a concrete increase with the progress of the hydration, that it, with age. When the hydration process stops, the strength development also stops. Hydration stops when any of the following three conditions occur:

- No more un-hydrated cement is available in the concrete.
- There is not enough free water.
- Diffusion can no longer take place.

Regardless of the hydration process, no retrogression in strength is permitted at any age. Such retrogression is always the warning sign of deterioration of the concrete due to some attack from the outside, faulty cement, reactive aggregate, or other cause.

Experiments were undertaken in the laboratory to verify this relationship. The two different concreting sands were used to make 12 cubes of each type. 7 day dry compressive strengths had previously been noted, so PUNDIT readings were taken at 7, 35 and 56 days. Ideally, readings should have been taken at 14 and 28 days but the timing of the Christmas vacation did not allow this. The full PUNDIT results tables for the two different types of specimens are shown in Appendix A4. The blocks were then crushed, and a calibration curve was drawn. The calibration results table is shown in Appendix A5 and graphs are shown in figures 6.9a and 6.9b below.

As mentioned previously, the precise relationship between the Pulse velocity and Compressive strength if affected by many variables, but the curve usually takes the general form:

$$f_c = Ae^{Bv}$$

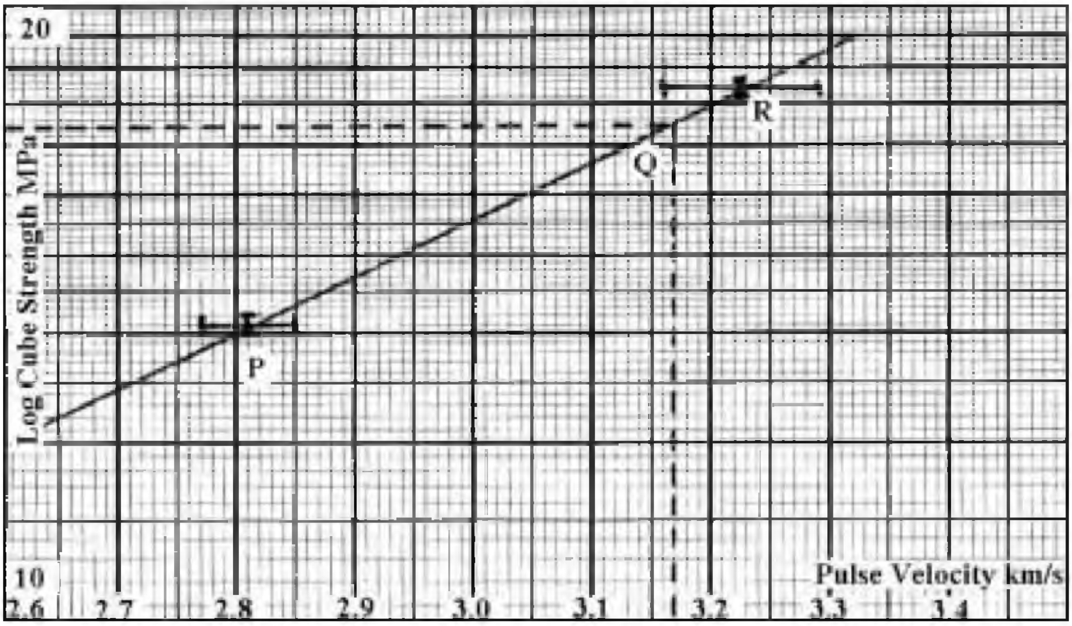
Where f_c = equivalent cube strength

e = base of natural logarithms

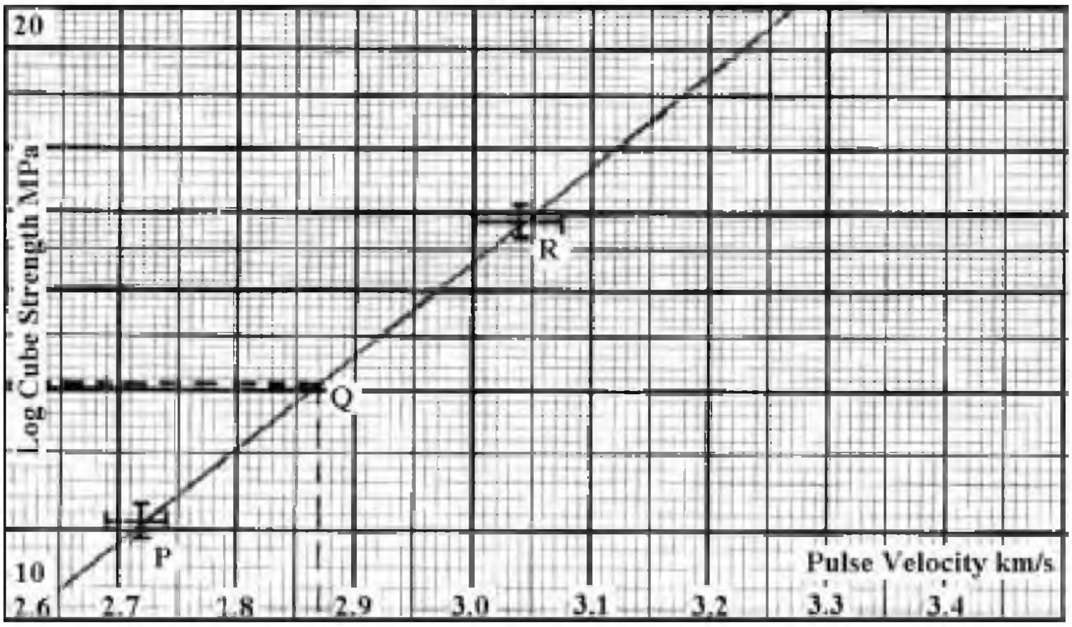
v = pulse velocity

and A and B are constants.

Hence, a semi-logarithmic plot of pulse velocity against cube strength was plotted, and a straight line was achieved.



Graph 6.9a: Calibration graph of Cube Strength against Pulse Velocity for Sand "X" Cubes.



Graph 6.9b: Calibration graph of Cube Strength against Pulse Velocity for Sand "Y" Cubes.

In graphs 6.9 a & b;

Point P represents strength-velocity calibration with 7 day specimens.

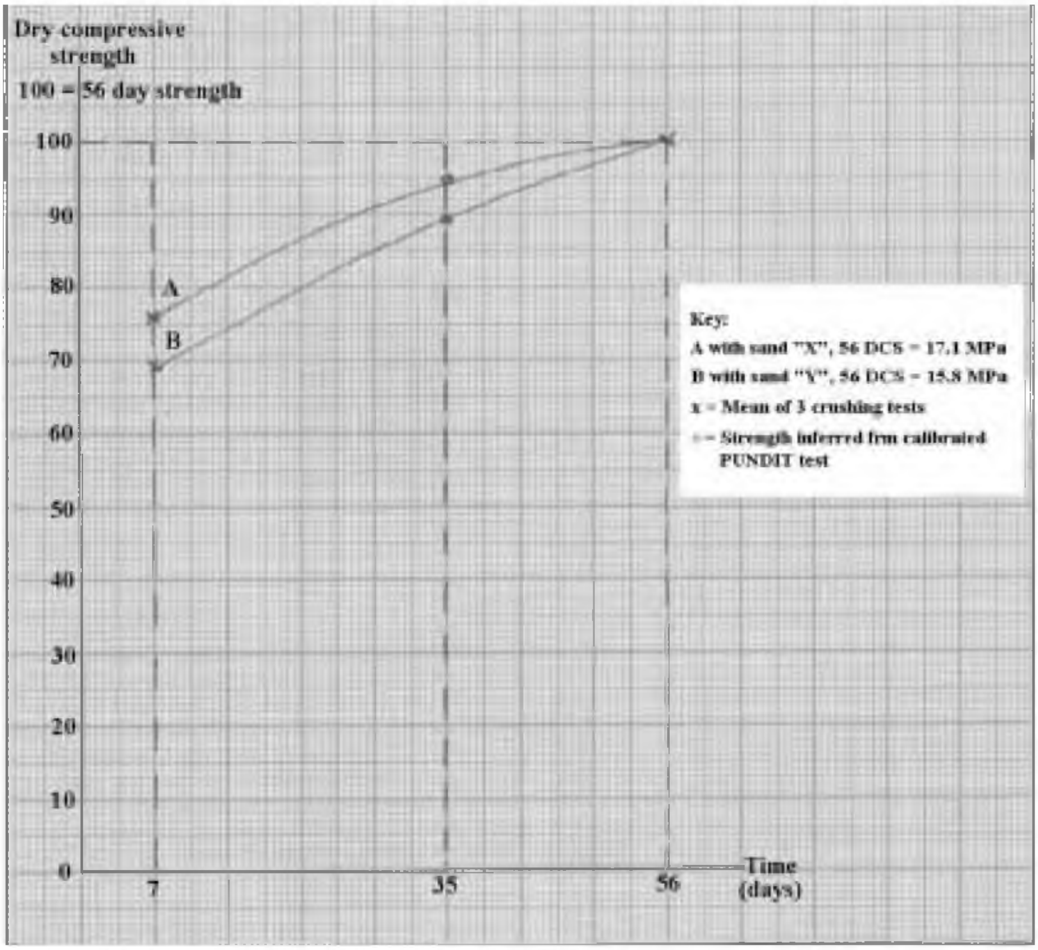
Point R represents strength velocity calibration with 56 day specimens.

Point Q is the inferred strength from the velocity measured at 35 days.

The graphs show the range of results so the line could have been drawn at any angle through the plotted lines. This shows there is some variation in results, especially in the pulse velocities, so the line of best fit has been drawn. The dotted lines on the graphs show the pulse velocity readings at 35 days, where no cube strength was measured. The predicted cube strength at this age is 16.4 MPa for the Sand “X” cubes and 13.1 MPa for the Sand “Y” cubes.

As it can be seen from both sets of results the degree of hydration increases with age, leading to the effect of age on strength. But, the hydration reactions are never complete, and in the presence of moisture, concrete will continue to gain strength for many years, although the rate of increase after such times will be very small.

The following graph, figure 6.10, shows the dry compressive strength development over a period of 56 days. Curve A shows the strength development of the concrete made with the poor sand “X”, and curve B is plotted for the good sand “Y”.



Graph 6.10: Graph showing the development of dry compressive strength over time

This graph shows that concrete made with sand “X” has a higher initial strength at 7 days, but has a slower development of strength to 56 days than sand “Y”. Concrete made with sand “Y” has a greater development of strength over a period of 56 days. This implies that if both types of concrete were left for many years, it could be possible that concrete made with sand “Y” could eventually develop a higher dry compressive strength than sand “X”.

This graph can also be used to obtain a factor by which to multiply the 7 day dry compressive strength results to obtain ‘standard’ 28 day characteristics. In concrete literature, it is more usual to specify the 28 day strength rather than 35 days, but as stated previously vacation timing did not allow the 28 day readings to be taken. The graph implies that for concrete made with the good sand “Y”, the 28 day strength is a 1.16 times more than the 7 day strength, implying that the 28 day strength is 12.64

MPa. For the concrete made with sand "X", the 28 day strength is 1.06 times more than the 7 day strength, implying that the 28 day strength is 13.78 MPa.

6.2 Shrinkage / Swelling

6.2.1 Drying Shrinkage

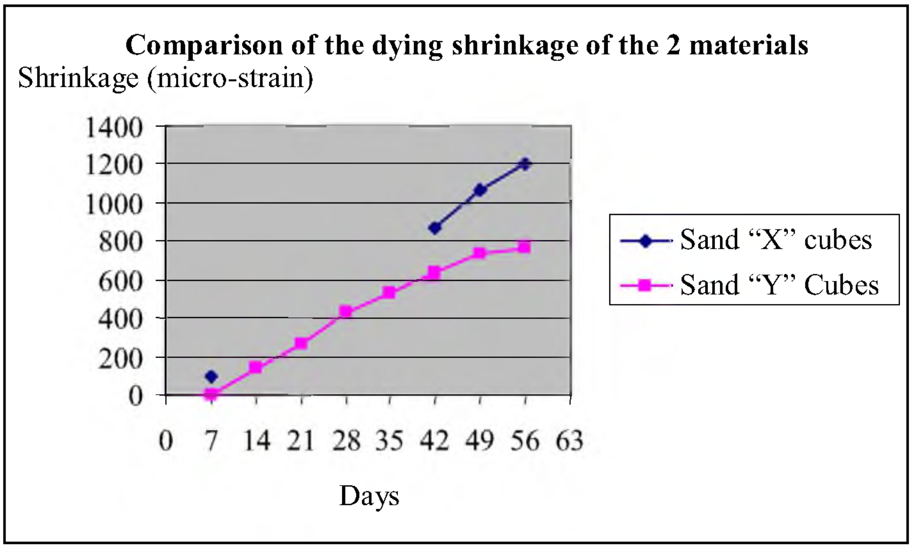
During the curing period of 56 days the shrinkage was measured. The specimens that were tested were ones that were made using the optimum water-cement ratio and using all other suitable conditions as described earlier. These specimens produced the following results:

		Total Curing Shrinkage (in μ-strains) after								
Sand "X" Cubes	Block Number	7 days	14 days	21 days	28 days	35 days	42 days	49 days	56 days	Direction of Movement
Dry cured	3	100	holiday	holiday	holiday	900	1100	1200	1300	Shrinkage
Dry cured	6	100	holiday	holiday	holiday	600	800	900	1000	Shrinkage
Dry cured	9	100	holiday	holiday	holiday	600	700	1100	1300	Shrinkage
Wet cured	16	-100	holiday	holiday	holiday	-500	-600	-700	-800	Swelling

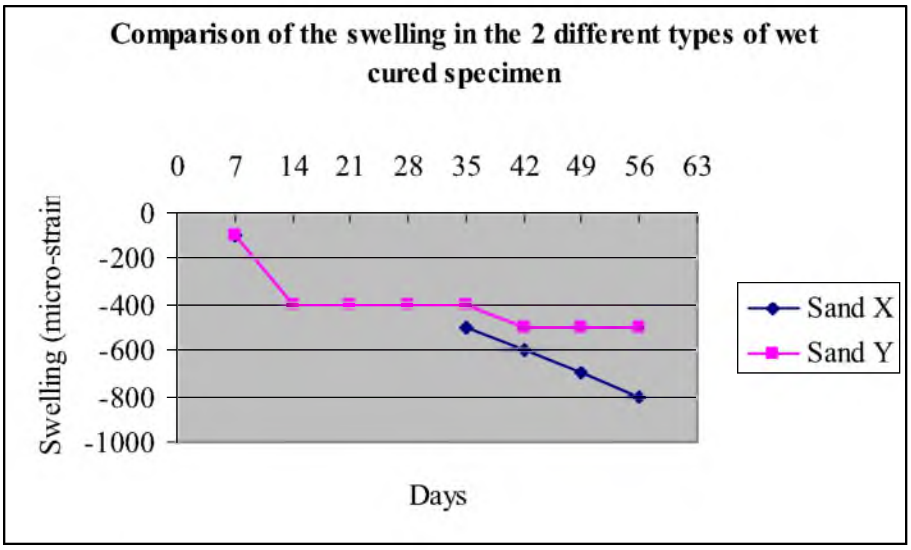
Table 6.11a: Drying Shrinkage during Curing in Sand "X" Cubes

		Total Curing Shrinkage (in μ-strains) after								
Sand "Y" Cubes	Block Number	7 days	14 days	21 days	28 days	35 days	42 days	49 days	56 days	Direction of Movement
Dry cured	3	0	100	200	400	500	600	700	700	Shrinkage
Dry cured	6	0	200	300	500	600	700	800	800	Shrinkage
Dry cured	9	0	100	300	400	500	600	700	800	Shrinkage
Wet cured	16	-100	-400	-400	-400	-400	- 500	-500	-500	Swelling

Figure 6.11b: Drying Shrinkage during Curing in Sand "Y" Cubes



Graph 6.11c: Graph showing the drying shrinkage of the dry cured specimens for the two materials.



Graph 6.11d: Graph showing the comparison of the swelling for the two different wet cured specimens.

Measurements have been converted into micro-strain using:

μ-strain = $\frac{\delta l}{l}$ x 10^6, l is in millimetres

Measurements to the nearest 10 microns

Only four dial gauges could be set up for each type of concrete, since the department did not have any others that could have been used over a long period of time. This means that there could be some error in the wet cured specimens, as there were no other results to compare them with. Some measurements for the Sand "X" cubes were missed due to the Christmas vacation, and unfortunately, this could not have been avoided.

Analysing these results shows that the dry cured concrete made with sand "X" has shrunk 56.7 % more than the concrete made with sand "Y". The wet cured specimens *unexpectedly* swelled upon curing, visibly absorbing the water that it was curing in. The concrete made with sand "X", the poor quality sand, swelled 300μ-strain more than material "Y".

Shrinkage is influenced by the aggregate, which restraints the amount of shrinkage of the cement paste that can actually be realised in the concrete. The maximum size of grading of aggregate does not influence the magnitude of shrinkage of the concrete with a given volume of aggregate and a given water-cement ratio. However, larger aggregate permits the use of a leaner mix at a constant water-cement ratio, so that larger aggregate leads to lower shrinkage. This is a likely explanation of the results, since the Sand "X" cubes consisted of a larger amount of smaller particles and more water, hence shrunk more upon dry curing than the Sand "Y" cubes.

The likely mechanism that could explain these results involves complicated soil mechanics theory, and more detailed information can be found in Mitchell, 1993, "The Fundamentals of Soil Behaviour". A basic explanation of the results is provided below.

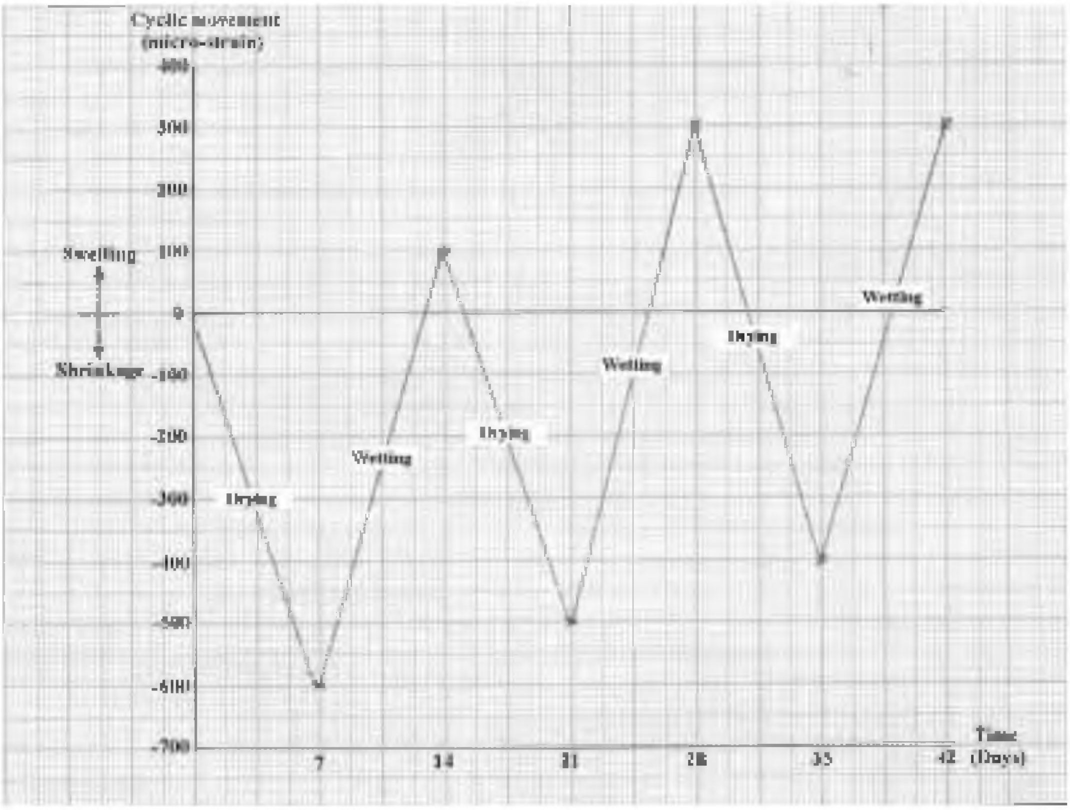
"The high clay fraction in the material being tested means there is a high proportion of small particles having surface electrostatic charges to which a layer of water becomes attached", (Spence and Cook, 1983).

As the saturated clay in the concrete is dried it shrinks, with capillary tension in the pore water balancing the pressure between the clay particles, and the friction caused by the pressure gives the clay a degree of cohesion. The difference in pressure between the pore water and the surrounding atmosphere is balanced by surface tension which can be considerable if the diameter of the pores is very small. Beyond a certain point, further drying causes no reduction in volume because the bulk of the water is removed, but the particles are held tightly together by small water droplets at their points of contact. When such a dried concrete is then wetted, water is absorbed into empty pores in the body of the clay and the capillary suctions are reduced, allowing the clay to soften rapidly as the pressure between the soil grains is reduced, and also to swell.

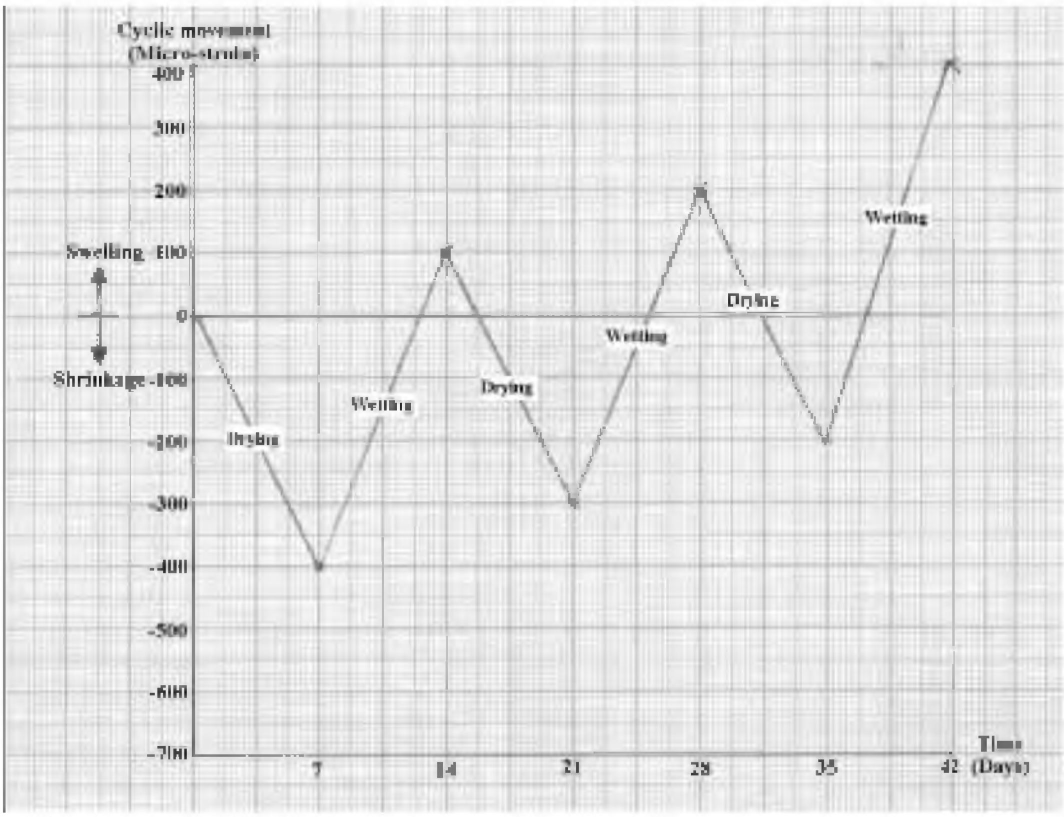
These results are not conclusive for this type of concrete since there is a considerable complication in interpreting and comparing drying shrinkage measurements. Although all the specimens tested were of the same size, the actual size of the specimen will affect the result. Water can only be lost from the surface and therefore the inner core of the specimen will act as a restraint against overall movement; the amount of restraint and hence the measured shrinkage will therefore vary with specimen size.

6.2.2 Cyclic Movements

After 56 days, the cubes were wetted for 7 days, then placed in a drying oven for 7 days, and underwent this cyclic process for three cycles. This was done on both types of concrete, and the results are shown in figures 6.12a and 6.12b.



Graph 6.12a: Cyclic shrinkage of concrete made with sand "X".



Graph 6.12b: Cyclic shrinkage of concrete made with sand "Y".

The results show that drying and wetting cycles result in more or less completely reversible shrinkage. Shrinkage after the concrete has solidified continues as and when further water evaporates. The chemical reaction of cement with water, and thus the shrinkage, continues in the concrete seemingly indefinitely. A gel is formed which contracts upon desiccation and becomes very hard. If the concrete is submerged in water the cement gel expands with considerable force, so that the whole mass of the concrete expands. This expansion, however, can never equal the shrinkage which has already taken place. On drying the concrete in air shrinkage again occurs. Therefore, when concrete is subjected to continual wetting and drying, it experiences corresponding expansions and contractions.

The concrete made from the good sand, sand "Y" has smaller cyclic movements than that of the concrete made with sand "X". Sand "X" has movements of ± 800 μ-strains, whereas sand "Y" has movements of ± 500 μ-strains. These results were expected since the extra fines in sand “X” were expected to absorb water every time the concrete was submerged in water, as well as the cement gel expanding.

7 Discussion

The high fines content in the concrete produced with sand “X” *enhanced* the dry compressive strength implying that fines in sand for fabricating concrete is not problematic. A higher strength of 12.1 MPa indicates that this type of concrete would be suitable for many applications of building in developing countries. Typically the range of concrete strengths is between 10-70MPa, so although the concrete made with sand “X” has a strength of 12.1 MPa, it is at the lower end of the range. Care should be taken when using this material for high strength applications, such as reinforced concrete columns in tall buildings.

Although this type of material seems advantageous as a building material due to its strength, shrinkage experiments produced contradictive results. ‘Normal concrete’ usually shrinks between 300-600 μ-strains in one year of drying, but the concrete made from sand “X” shrunk 1300 μ-strain in 56 days. This drying shrinkage was larger than an estimated value of 720 μ-strains, probably due to a bigger effect of the fines. This is not necessary a problem in itself since concrete in compression can withstand 2000 μ-strains. The major problem occurs when the concrete is in tension as it can only withstand 200μ-strains and material “X” expanded by 800μ-strains, four times greater than the tolerable amount.

So, when determining whether this material is suitable for applications of concrete, these shrinkage movements need to be considered. For pre-made concrete blocks, providing the drying shrinkage has already occurred, it is expected that these concrete blocks can be used. Care needs to be taken if they are expected to experience continual wetting and drying since the cyclic movement is ± 800μ-strains, and cracks are likely to occur.

Brickwork in compression is expected to withstand about 600 μ-strains and in tension 200 μ-strains. It is therefore not advisable to use this material for brickwork as the movements are too great despite the good strength value. If it is necessary to use this material "X" for bricklaying, then the wall should be built in small sections, maybe one metre per day, without expansion joints.

This material is suitable for non water-proof renders since the drying shrinkage of 1200 μ-strains can be tolerated as concrete in compression can withstand up to 2000 μ-strains. If the cracks are about one metre apart and unrelieved the rendering will look acceptable. It is not advisable to use this material as a water-proof render since when the material is in tension it will fail. The material can only withstand 200μ-strains in tension whereas the cyclic movement is $\pm$ 800μ-strains.

Shrinkage in steel reinforcement concrete can be a maximum of 600μ-strains which indicates that it would not be advisable to use this material. Large cracking would occur, causing a dangerous structure. Fortunately, this material "X" can be used for lintels since it is common practice to leave a gap in the mortar at both ends to allow it to expand and contract with cracking. Therefore, the gap can be made large enough to accommodate the cyclic movement of $\pm$ 800μ-strains in material "X".

8 Future Work

This report concentrates on two main factors only, strength and shrinkage. There are many other properties of concrete that can be specified, but the duration of this project limited the amount of factors that could be investigated. Although the large shrinkage and swelling movements of the concrete tested limits its use in the building industry, it does have a better compressive strength, so other research could be carried out on this 'low quality' concrete to identify other properties that can be improved. It is expected that the examination of 'poor quality' sand in concrete and how to improve the quality will be carried out by other third year project students in the future.

9 Conclusions

The purpose of this project was to investigate the affect fines have on the properties of concrete. Initial results showed that making concrete with sand with a ‘high fines’ content *unexpectedly* increases the strength of concrete. Material “X”, made with poor quality sand, was tested for its dry compressive strength and its optimum water-cement ratio of 0.95, mixing time of 5 minutes and vibration compaction time of one minute. This material exceeded the expectation that its seven day dry compressive strength would be approximately 9.6MPa, and was instead 12.1MPa. Since concrete strength used for building purposes lies within 10-70MPa, material “X” has a suitable dry compressive strength.

Despite the suitable dry compressive strength, it has been discovered that the use of this material will be hindered due to its large cyclic movements and drying shrinkage of approximately $\pm 800\mu$-strains and 1300μ-strains respectively. Due to the restricted sample sizes the accuracy of the results from the material testing may be limited. The purpose of testing was to get approximate values for the strength and the shrinkage, since testing under conditions in the developing world may produce different results.

This project supports the statement published in British Standard, BS 812, that sand with a ‘high fines’ content is unsuitable for making good quality concrete, but sand “X” is suitable for some applications in developing countries where operations are basic and money is short. It can be used for concrete and mortars in unconstrained applications such as block making and lintels and in situations where the material does not undergo cyclic movements, such as non water-proof rendering. If this material is used for applications such as bricklaying then the wall should be built in small sections, maybe one metre per day, without expansion joints.

There are many other properties of concrete, other than strength, drying shrinkage and cyclic movements that can be specified, but the duration of this project limited the amount of factors that could be examined. It is expected that other research in this field will be carried out to improve the quality of concrete made with ‘high fines’ sand, possibly by washing it, as the original project suggested.

11 Glossary

Many terms have different meanings for different applications. The definitions used in this report are:

Aggregates: A granular material obtained by processing natural material.

Clay: It is the fraction of a soil composed of particles smaller than 0.002 mm in size.

Concrete: The essential ingredients of concrete are cement, aggregate (sand and gravel), and water. When mixed in carefully prescribed proportions, they produce a workable mass, which can take the shape of any formwork into which it is placed and allowed to harden in.

Fines: Any solid material passing a 75μm sieve.

Grading: Particle size distribution.

Sand: The fraction of soil composed of particles between the sizes of 2mm and 0.06mm, i.e. the smallest grain size than can be discerned by the naked eye.

Silt: The fraction of a soil composed of particles between the sizes of 0.06mm and 0.002mm.

29.9.01

Dear Sir / Madam,

I am a penultimate year student at Warwick University studying Design Engineering. This year of study involves me undertaking a large project in which I will be developing an effective method of, or a machine for improving sand, possibly by washing it, to make it more fit for use in making concrete or mortar.

Although the design task I face is looking at a method that will be compatible for operations, finances and normal sand sources of a builder in Africa, it would be useful to find out about the current methods in the UK as research for this project. It could also be interesting to find out whether the current methods in the UK could be improved in terms of cost and efficiency. I was hoping that your company would be able to assist me in this process. I would be very grateful if I could visit your company for part of a day in the near future for a brief discussion with somebody concerning the methods that are used.

Due to this project only running over the course of one academic year, the time scale for me to develop my ideas is short. I would therefore appreciate it if you could contact me as soon as possible if you are able to help. If this is not possible, it would be very much appreciated if you could send me some names and addresses of other companies that may be able to assist me.

My email address is vicky.fernandes@vizzavi.net and my telephone number is 07833 970966.

Thank you very much for your time in reading this letter, and I hope to hear from you in the near future,

Yours Faithfully,

MISS VICKY FERNANDES
3rd Year Engineering Design Student, Warwick University.

Tuesday 2nd. October 2001

Dear Miss Fernandes,

Re: <u>Site Visit to Gill Mill Quarry, Witney.</u>
<u>Study of Sand Plant Operations.</u>

I am in receipt of your letter to our Head Office of 29th. September and it has been passed to me to see if I can assist you. This site has a 200 tonnes per hour sand and gravel washing plant and has recently installed a new sand recovery plant which is highly efficient in addition to having a sand cyclone tower for fine sand production.

However, I have considerable experience with which I may be able to advise you. I am an Engineer with HNC's in Marine and Mechanical Engineering, I am a Fellow of the Institute of Quarrying and I have spent a considerable period of my life working overseas in Africa, the Middle East and the Pacific and am very familiar with Third World conditions and materials.

I am enclosing an Indemnity Form which I would be obliged if you could fill in and return to me as soon as possible. Perhaps you would call me on 01993 779514, Fax 01993 779383, to discuss a timetable. The site address is on the top of the Indemnity Form.

I am looking forward to hearing from you.

Yours Sincerely,
Smith and Sons (Bletchington) Ltd..

17.10.01

Dear Mr. Bacon,

Thank you very much for your knowledge and time spent helping me on my research project. It really helped my understanding of the processes you use to improve the quality of your sand, and your added experiences of developing countries has given me a better idea of what type of cleaning methods I will need to develop.

Thank you again for all your help and advice, it was very much appreciated.

Yours Sincerely,

MISS VICKY FERNANDES.

Appendix A2
Sedimentation Test (Syphon)

Sedimentation Test (Syphon)

A material from Gill Mill Quarry in Witney in Oxfordshire was tested for its silt content. This was done to see whether the material contained enough silt, to represent a silt content for the sand chosen to be tested.

The test used was adapted from a similar test described in the University of Warwick's working papers. The working paper used was number 38, written by Mr. D.E. Gooding called "Soil Testing for Soil-Cement Block Preparation, 1993".

Equipment: 1 Flat bottomed glass jar, approximately 1 litre capacity.

1 Flat circular disk on a stem such that it may be lowered into the cylinder.

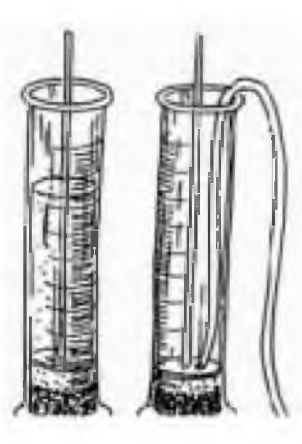
1 Flexible rubber siphon tube to remove suspended material from the cylinder.

1 Stopwatch or clock.

1 Weighing balance accurate to at least 0.1g, preferably 0.01g.

1 Heat proof container to receive the syphoned suspension.

Method: Weigh out a representative 60g sample of dry soil and place it in the cylinder. Add clean water to 200mm. Close the cylinder with a rubber bung and shake vigorously end over end to produce a uniform suspension of soil. Once a uniform suspension has been formed place the cylinder on a flat steady level surface and begin to time 20 minutes.



At the end of 20 minutes slowly lower the disk to cover the settled material, taking care not to disturb it. The top layer of material is silt. (It the disk is allowed to rest on the surface then some silt will be forced up around the edge of the disk. Any silt forced back into suspension will give a misleading low value for the silt fraction). The remaining suspended material can be siphoned off with the rubber siphon tube. The siphon operation is simpler to perform if the tube is tied to the stem just above the upper face of the disk. This stops the tube from floating or curling.

The material remaining in the jar is the silt fraction, so is put in a heat proof dish, and is dried. It is then weighed and recorded as the silt and sand fraction. These two materials are further separated by dry sieving. The material passing the 0.063mm sieve is the silt fraction.

Results: Mass = 60g

Clay fraction = (weight of container + clay) – weight of container

= (313.03 - 275.07) + (268.25 – 257.86)

= 49.12g

Sand and Silt fraction = (weight of container + silt) – weight of container

= 324.60 + 314.49

= 10.88g

After dry sieving:

Sand fraction = 4.90g

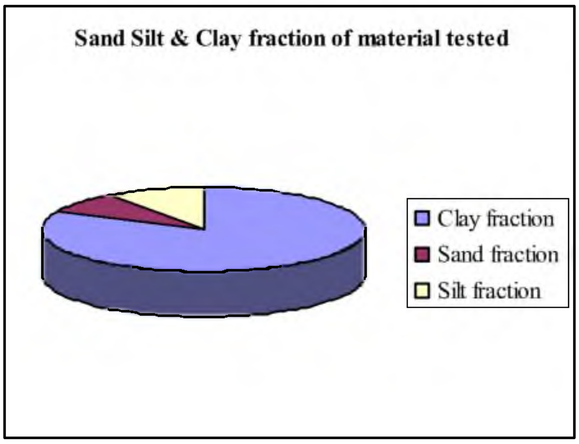
Silt fraction = 5.98g

Results as a percentage:

Clay fraction = 81.9%

Sand fraction = 8.2%

Silt fraction = 9.9%



These results showed that there was only 9.9% of silt present in the material, and hence not a good source of silt to use for my project. This material was rejected, and it was decided that Kaolin, a type of clay, would be used to represent fines, and no other silt would be added.

Appendix A3

Statistical Analysis on Water-Cement Ratios

Statistical Analysis on Water-cement Ratios

Sand "X" Mix	Maximum load (kN)								
Water-cement Ratio	Block 1	Block 2	Block 3	Mean Maximum Load (kN)	Mean Pressure, x (MPa)	n	σ	x_1-x_2	z
0.53	78.2	78.1	78.4	78.2	7.8	3	0.0152	-3.4	-200.69
0.7	112.1	112.6	112.4	112.4	11.2	3	0.0251		
0.8	113.4	113.5	113.2	113.4	11.3	3	0.0153	-0.3	-20.64
0.85	116	115.8	116.2	116.0	11.6	3	0.02

0.92	119.1	119.5	119.3	119.3	11.9	3	0.02		
0.95	122.2	120.1	121.1	121.1	12.1	3	0.105	0.4	6.53
1.06	117.5	117.3	117.2	117.3	11.7	3	0.0153		
1.14	80.9	80.5	80.7	80.7	8.1	3	0.02		

Sand "Y" Mix	Maximum load (kN)								
Water-cement Ratio	Block 1	Block 2	Block 3	Mean Maximum Load (kN)	Mean Pressure, x (MPa)	n	σ_{n-1}	x_1-x_2	z
0.53	62.1	61.1	57.1	60.1	6.0	3	0.2646	-2	-13.07
0.6	80.2	80.5	80.4	80.4	8.0	3	0.0152		
0.65	107.7	107.3	107.9	107.6	10.8	3	0.0306	-0.2	-8
0.7	110.1	109.9	110.5	110.2	11.0	3	0.0306		
0.8	108	107.8	108.1	108.0	10.8	3	0.0153	2.9	122.9
0.95	79.9	79.3	79.2	79.5	7.9	3	0.0379		

Statistical Analysis can be performed on any two sets of results. This appendix only compares results next to each other in the table.

The null hypothesis is

$H_0 : x_1 = x_2$ $\qquad$ $H_1 : x_1 \neq x_2$

$$Z = \frac{\overline{X}_1 - \overline{X}_2}{\sqrt{\left(\frac{\sigma_1^2}{n_1} + \frac{\sigma_2^2}{n_2}\right)}}$$

The 5% (two tailed) critical values for z are $Z_{95} = \pm 1.96$.

It can be seen that all results are statistically significant since they are larger than 1.96, so H_0 can be rejected. It can be concluded that there is significant evidence of a difference in means between each set of results.

COUNTERING SHRINKAGE CRACKING IN RENDERS

S. MOEED

23RD APRIL 2002

3rd Year Undergraduate Project, 2001-2002,
School of Engineering, University of Warwick

Summary

An investigation was performed into ways of reducing shrinkage cracking in cementitious renders used to line rainwater harvesting tanks. Crack reduction was measured via both leakage rate through the renders and direct measurement of the cracks propagated. Emphasis was placed on crack distribution and how this affected leakage rate. Methods of reinforcing mortar were used, the most successful being wire mesh reinforcement which reduced the leakage rate by a factor of ten. Mesh reinforcement was also the most successful in reducing shrinkage. Other renders tested included fibre reinforcement and an expansive additive to compensate for shrinkage. This investigation was a refinement of previous work carried out by Tom Constantine in 2001 but looking into different methods of waterproofing renders.

Contents

1. Introduction

1.1. Rainwater Harvesting

River flows together with the annual turnover of groundwater account for less than 40% of the rain and snow, which falls on the world's land surfaces[1]. For people in many developing countries rainwater harvesting is a viable and relatively inexpensive option to overcome water shortages. In many countries there is the problem of irregular rainfall throughout the year with heavy precipitation over certain periods but drought at other times. Therefore a system of collection and storage needs to be implemented, such as collection of roofwater, which is channelled through drainage pipes into a tank (see figure 1 below).

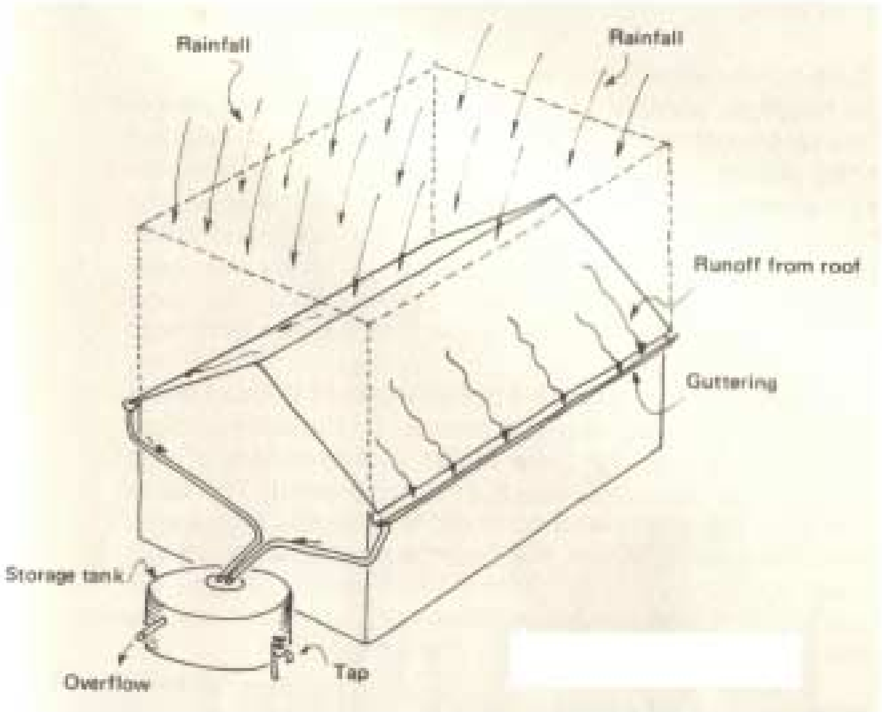

Figure 1: Arrangement of roof catchment tank (from Watt 1978)

This project deals with the render used to line the tanks to ensure they are waterproof. Tanks of up to 15m³ can be made from either bricks, rammed earth, or be dug in sitú. Earth and bricks are permeable and therefore a mortar is applied to the inside of the tank as a render. As this mortar dries it tends to shrink and the lining will therefore crack as the mortar is constrained on the tank walls. This cracking leads to leakage in

[1] Pacey pg.1

the tank, which is obviously undesirable. The leakage of rainwater harvesting tanks can be reduced if measures are taken to reduce the cracking in renders. It is important that the tanks are cheap to produce and that any materials used are available locally.

1.2. Methods to reduce cracking and leakage

A number of different methods can be used to counteract shrinkage cracking in mortar or just reduce the leakage rate through the mortar:

1. Crack distribution (by the use of a reinforcement such as chicken mesh or fibres). So that a few large cracks are replaced by many small ones.
2. The use of a non-shrinking mortar or a substance, which swells to counter the shrinkage, for example ettringite cement.
3. Filling the cracks once formed or using a waterproofing paint on the surface once the cracks have formed.
4. Applying the mortar in two layers possibly with a cement-water wash in between.
5. The use of super-plasticisers, which reduce the amount of water required for workability and hence the shrinkage during curing.
6. The use of other chemical admixtures such as strength increasing admixtures or waterproofing admixtures.

For the purposes of this study not all of these methods could be tested, as there were a limited number of test rigs and a limited amount of time. Previous projects had looked into the use of admixtures but there had been less research into reinforcing the mortar with mesh or fibres. It was decided to investigate the effects of crack distribution on the leakage rate, this was therefore the main focus of the study. It was also decided to look at applying two layers of mortar and the effectiveness of a swelling agent to counteract shrinkage.

1.3. Previous studies

Tom Constantine conducted research into this topic in the academic year 2000 – 2001. He found there was a problem with obtaining accurate results, particularly with the leakage tests in the second study. This was therefore the initial focus in the project as it is necessary to have a method of testing which is reliable and therefore gives credible results on which a conclusion can be reached.

1.4. Project Objectives

- To measure leakage flow through renders in order to recommend methods of effective waterproofing for water tank construction.
- To improve on the experimental method used in the previous year to yield more credible results.

2. Background Theory

2.1. Tank Construction

Tanks can be made of brick, rammed earth or built in sitú. The Development Technology Unit (DTU) at Warwick University is involved in the research, design and building of roofwater harvesting tanks. Probably the strongest of tanks would be those dug in sitú as the surrounding earth provides a strong tank wall and good base for the render.

2.2. Ferro-cement tanks

Water tanks made from wire-reinforced cement-mortar can be used as an alternative to earth or brick tanks. They are built by hand trowelling mortar onto a mesh of wire reinforcement, which forms the walls and shapes the tank (see figure 3 below). This forms cylindrical tanks with thin walls, which vary in thickness from 3 to 10cm depending on the size of the tank[2].

[2] Watt pg.11

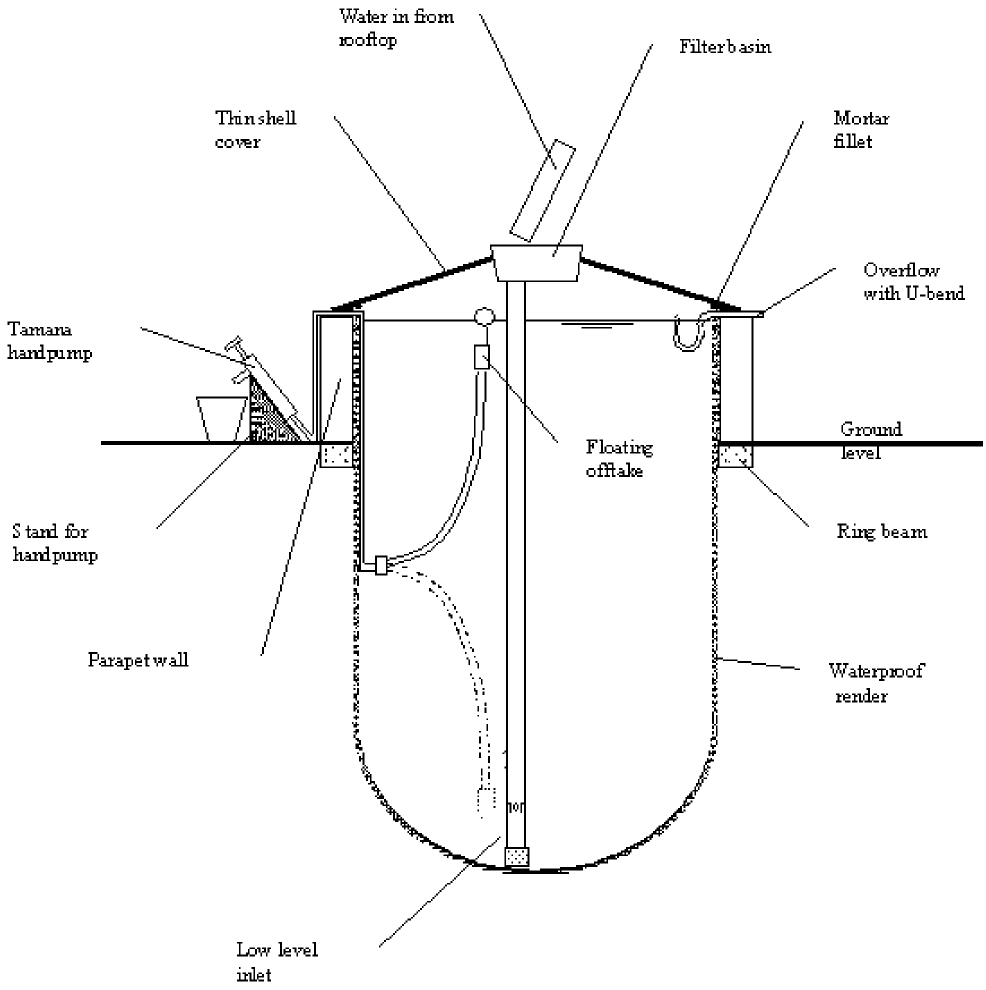

Figure 2: Diagram of partially below ground rainwater harvesting tank (DTU Website)

2.3. Mortar

Mortar is made from mixing building sand cement and water in certain proportions depending on the application. The material used for lining RWH tanks is a cement rich mortar, with a cement to sand ratio of 1:3, for this application it is beneficial to keep the water content down to a minimum as this improves the quality of the mortar once cured. The cement used is Ordinary Portland Cement.

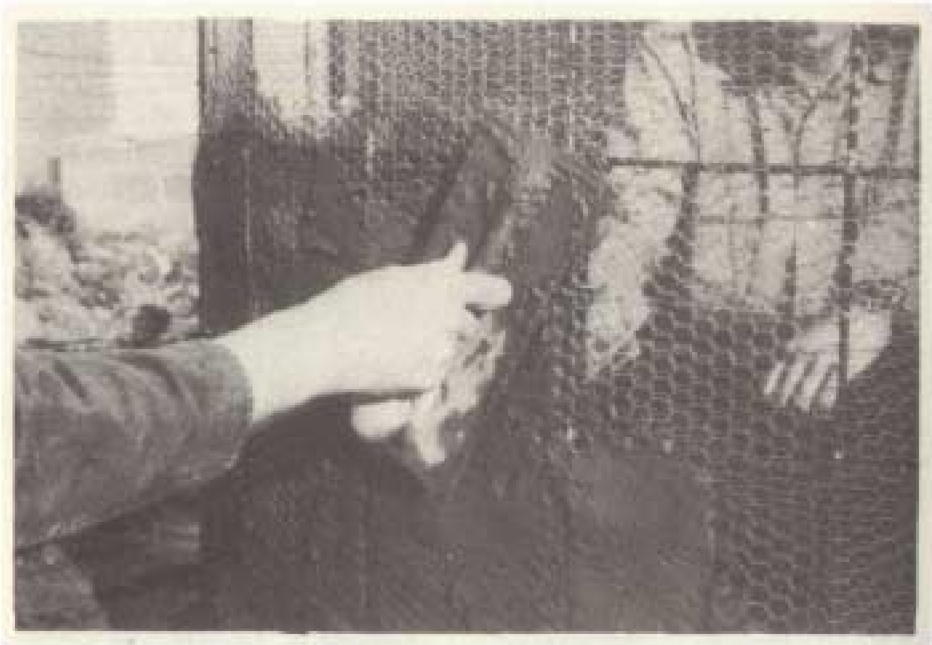

Figure 3: Construction of ferrocement tank wall (from Watt 1978)

2.4. Hydration of cement

The main compounds of Portland cement are Tricalcium silicate, Dicalcium silicate, Tricalcium aluminate and Tetracalcium aluminoferrite. In the presence of water, the silicate and aluminates listed above form products of hydration, which in time produce a firm and hard mass – the hydrated cement paste. Figure 4 below details hydration product development over time for ordinary Portland cement.

When cement is mixed with water, for an initial period the consistency of the cement-water paste remains relatively constant. Initial set occurs between two and four hours after mixing at normal temperatures, at this point the mix begins to harden at a much faster rate. Strength gain does not start until after the final set which occurs some hours later. The rate of strength gain is rapid for the next one or two days, and continues, but at a steadily decreasing rate, for at least a few a months. In order to increase the strength of cement or mortar, there needs to be ample water supplied during hardening in order to maintain the ongoing hydration reactions. For this reason mortar is cured in a humid environment. Curing is discussed in greater detail in section 3.3.1.

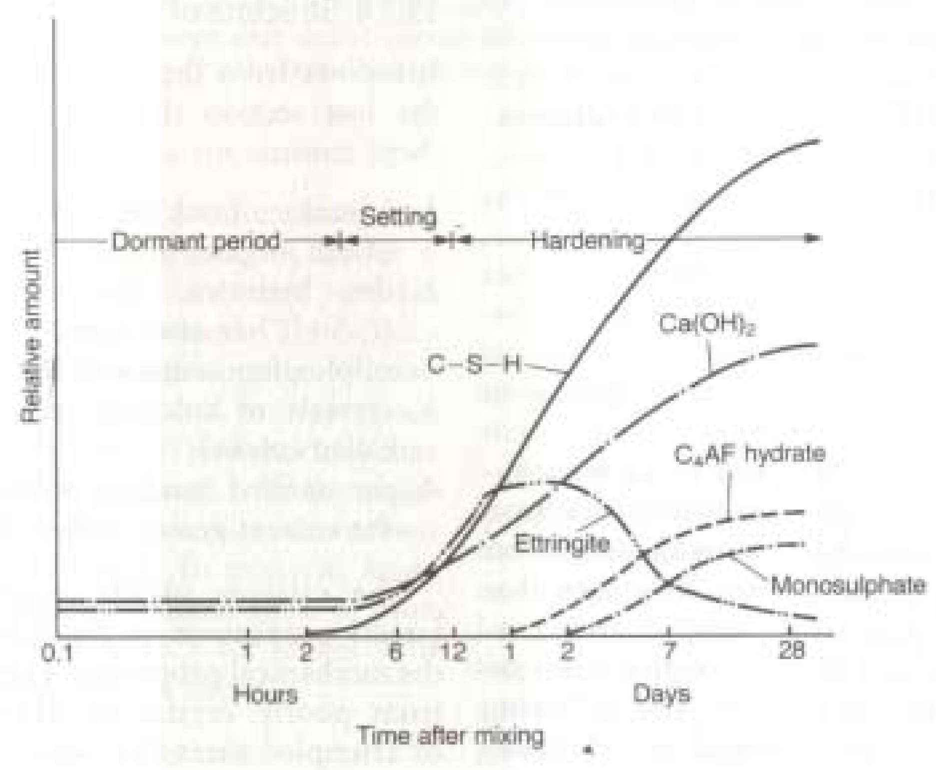

Figure 4: Typical Hydration product development in Portland cement paste (Illston 1994)

3. Literature Review

3.1. Previous studies

Constantine T, 2001

In 2001 Tom Constantine, a Warwick student, conducted an investigation into the shrinkage and cracking of mortar. Constantine experimented with various admixtures for concrete :–

- Silica fume, which reduces the porosity of concrete and therefore increases strength, which can lead to a reduction in cracking.
- Superplasticiser, which increases the workability of concrete therefore requiring less water, which also leads to less porosity as well as a reduction in shrinkage cracking.
- Harilal leak seal, an Indian admixture for waterproofing concrete.

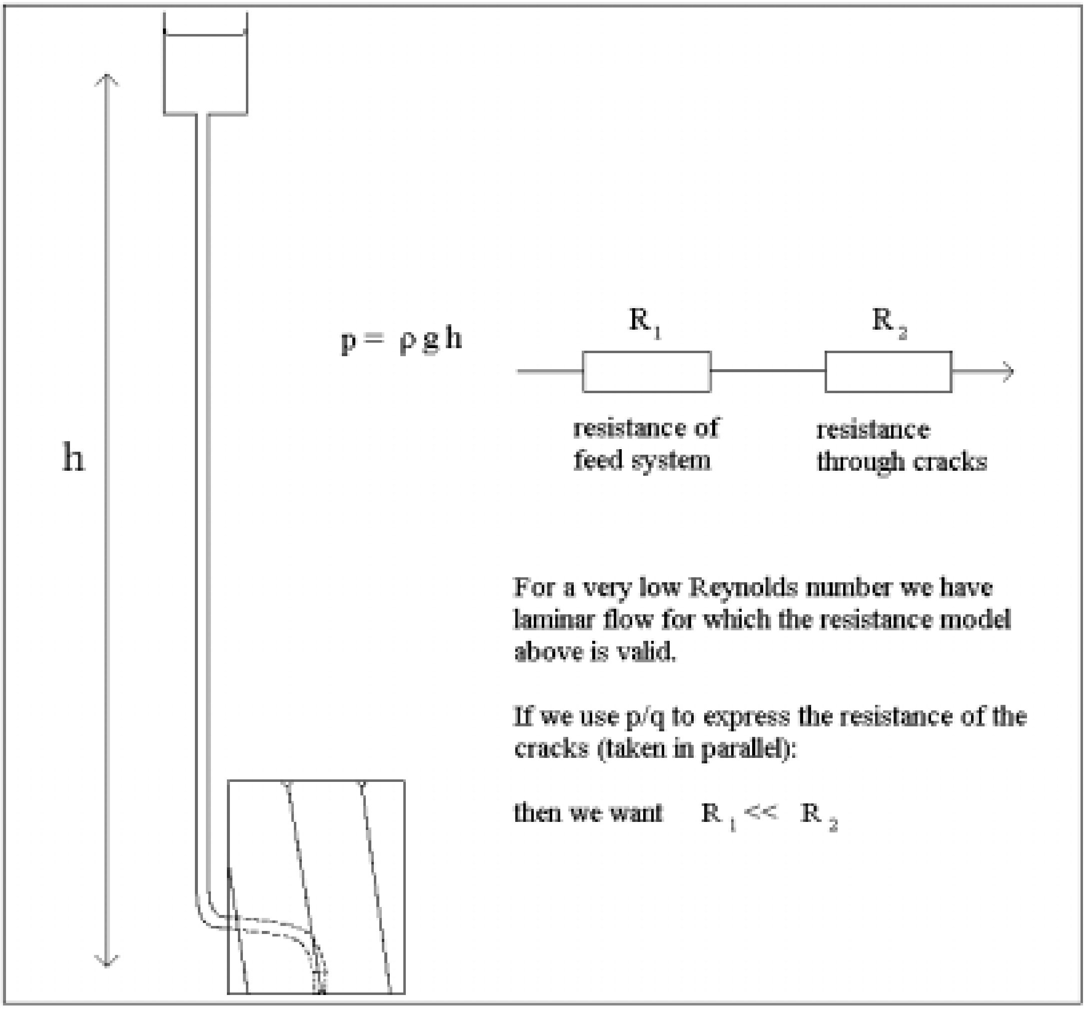
He also tested a sample of plain mortar. In the leakage tests, over a period of 55 minutes the total water lost was as follows:

Sample	Water lost in 55 minutes (ml)
Plain mortar	77.6
Mortar containing Silica Fume	39.5
Mortar containing Harilal Leak Seal	40.7
Mortar containing Superplasticiser	32.5

Table 1: Summary of Constantine's leakage test results with respect to total water loss

He found the mix with Superplasticiser to give the lowest leakage rates.

However, as can be seen from the results above, the rate of water loss is very small. Tom experienced problems with his test rigs and due to this low leakage rate it was believed that the resistance in the rig was too great (see figure 5 below), and therefore there was no guarantee that all the cracks were being fed.



3.2. Shrinkage and cracking of concrete

Neville 1995:

When water moves out of a porous body, which is not fully rigid – contraction takes place. During hydration, while the cement paste is plastic, it undergoes a volumetric contraction (of the order of 1% of the absolute volume of dry cement). However the extent of hydration prior to setting is small and as the hydrating cement becomes rigid, contraction induced by loss of water is restrained.

Water can also be lost by evaporation from the surface of the concrete while it is still plastic. Similar loss can occur by suction by the underlying dry concrete or soil. This is called Plastic Shrinkage as it occurs while the concrete is still in a plastic state.

Magnitude of plastic shrinkage is affected by amount of water lost from the surface, which is influenced by temperature, ambient relative humidity and wind velocity. The rate of water lost does not necessarily predict shrinkage, a lot depends on the rigidity of the mix.

Water can be bought to the surface of concrete by bleeding. Water in the mix tends to rise to the surface of freshly placed concrete, this is caused by the inability of the solid constituents of the mix to hold all of the mixing water (water having the lowest specific gravity). If the amount of water lost per unit area by evaporation exceeds the amount bought to surface by bleeding, surface cracking can occur, this is called plastic shrinkage cracking.

3.2.1. Plastic shrinkage

Plastic shrinkage is greater the greater the cement content of the mix. Retardation of setting allows more bleeding and leads to increased plastic shrinkage, on the other hand greater bleeding capacity prevents too rapid a drying out of the surface of the concrete reducing plastic shrinkage cracking. In practice it is cracking that matters, however, in this case, due to the mortar being constrained, cracking occurs due to shrinkage.

3.2.2. Thermal cracking

This occurs only in large volumes of unreinforced concrete. The heat of hydration (hydration is an exothermic reaction) causes expansion. Cooling from the temperature peak of this reaction results in cracking, due to a temperature gradient and internal stresses. This form of cracking is not applicable to the mortar lining situation as the layer of mortar is too thin for a substantial temperature gradient to form.

3.2.3. Carbonation shrinkage

This occurs due to the reaction of Carbon Dioxide present in the atmosphere with the hydrated cement. This is not a major concern in this application as drying shrinkage leads to the vast majority of shrinkage and cracking in the constrained mortar.

3.2.4. Concreting in hot weather

The deformation of mortar also depends on the surrounding environment. In practice the tanks will be built in hot conditions and therefore the effect of heat needs to be taken into consideration. Plastic shrinkage can be prevented by keeping down the rate of evaporation of water from the surface of the concrete, $1kg/m^2$ per hour should not be exceeded. Evaporation is increased when the temperature of the concrete is much higher than ambient temperature, then plastic shrinkage can occur even if the relative humidity of the air is high. It is therefore best to protect concrete from the sun and wind, place and finish fast and start curing quickly. Avoid placing concrete on a dry subgrade. Another type of cracking is caused by differential settlement of fresh concrete due to obstruction to settlement e.g. large particles of aggregate or reinforcing bars, this is plastic settlement cracking.

3.2.5. Drying shrinkage

As the name implies, this shrinkage occurs as water is lost from the cement paste.

Illston 1994 :

Hydrated cement paste has a considerable affinity for water and therefore its overall dimensions are water sensitive i.e. loss of water results in shrinkage. The water content also has an effect on porosity, to illustrate this it is useful to look at the way in which water behaves in the paste (see fig.6 below).

- *Water vapour* – largest voids may only be partially filled with water, and remaining space will contain water vapour.
- *Capillary water* – located at the capillary and larger gel pores, it is the bulk of water not influenced by the attractive forces of solid surfaces. Water in voids larger than 50nm is considered free in that it’s removal does not lead to any overall volume change. However, water in pores smaller than about 50nm is subject to capillary tension forces, and its removal may lead to some shrinkage.

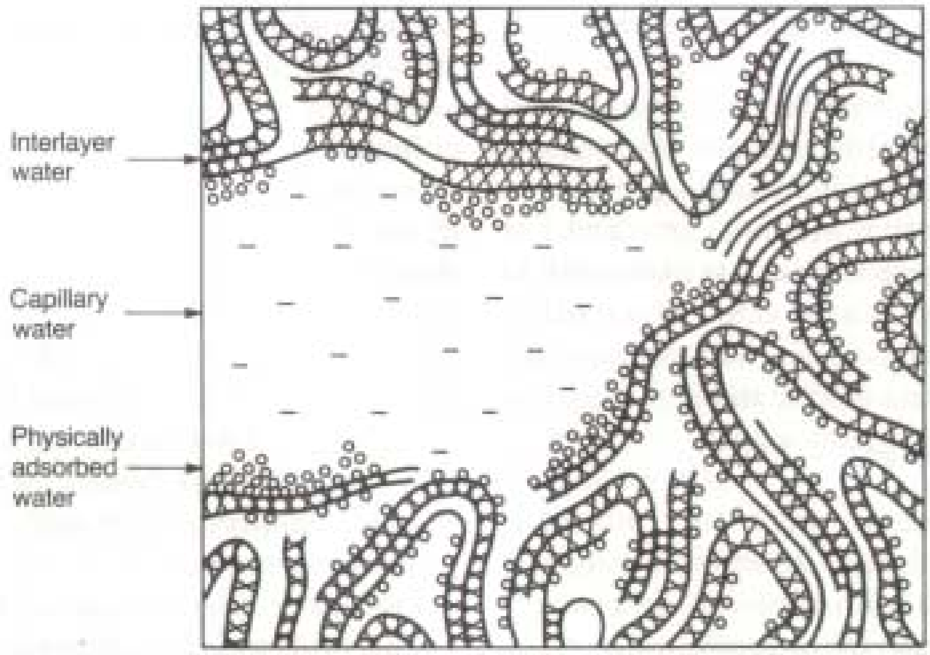


Figure 6: schematic of types of water within hydrated cement paste (from Illston 1994)

- *Adsorbed water* – Close to solid surfaces and under the influence of surface attractive forces. A large proportion of this water can be lost on drying to 30% relative humidity and this loss is the main contributing factor to drying shrinkage.
- *Interlayer water* – This is the water in gel pores narrower than about 2.6nm, this is under the influence of two surfaces and therefore more strongly held. It can only be removed by strong drying – i.e. elevated temperatures and/or relative humidities less than 10%. Its loss results in considerable shrinkage as strong forces pull the solid surfaces closer together.
- *Chemically combined water* – Water that is combined with the fresh cement in hydration reactions. This is not lost on drying.

Figure 7 below illustrates the relationship between water/cement ratio and shrinkage.

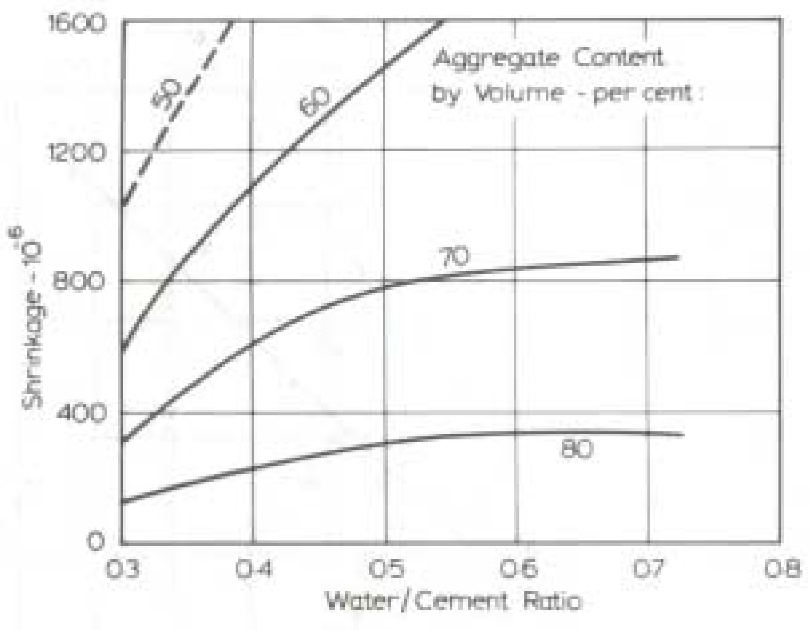

Figure 7: Influence of water/cement ratio and aggregate content on shrinkage (from Neville 1995)

The shrinkage of cement or mortar is larger the higher the water/cement ratio as this determines the amount of evaporable water in the cement paste and the rate at which it can move to the surface. The amount of shrinkage is not equal to the volume of water removed as it is also influenced by other factors such as gel particle size. The affect of aggregate leads to less shrinkage in concrete in comparison with mortar, which does not contain aggregate. Also the type of water removed has an affect as discussed earlier, emptying of the capillaries results in water loss with no shrinkage, but once capillary water is lost, the removal of adsorbed water takes place and causes shrinkage. When no moisture movement to or from the cement paste is permitted, shrinkage occurs due to withdrawal of water from the capillary pores by the hydration of the hitherto unhydrated cement called self desiccation. This shrinkage is restrained by the rigid skeleton of the already hydrated cement paste and also by the aggregate particles.

From a graph of early shrinkage (Figure 1.1., Appendix 1), it can be seen that after 24 hours mortar has shrunk by 0.0045 of its original volume i.e. 0.45%. At this point the graph becomes level, it can therefore be concluded that the majority of shrinkage occurs within the first 24 hours and so the figure of 0.0045 has been taken as the value for shrinkage strain for the plain mortar used in testing.

3.3. Preventing shrinkage and cracking

For a sample of constrained mortar, i.e. in this application mortar is held by the tank walls, improving the mortar strength can reduce cracking. Increasing tensile strength will increase the shrinkage strain that can be tolerated before cracking occurs:

as $\varepsilon_{yield} = \sigma_{yield} / E$

3.3.1. Factors affecting mortar strength

3.3.1.1. Water Content

Illston 1994:

The strength of cement paste is governed by its porosity, which depends on the water cement ratio and degree of hydration. The higher the water content the greater the porosity and volume of voids, which leads to a weak mortar. Figure 8 below shows the effect of age and water content on the strength of the mortar.

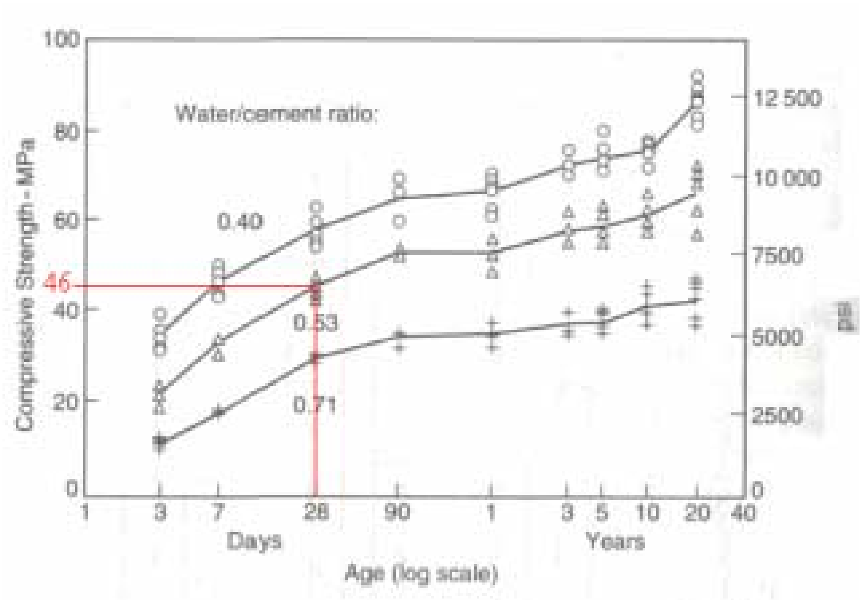

Figure 8: Effect of age and water/cement ratio on concrete strength (Neville 1995)

However, too low a water content will reduce the workability of the mortar and therefore a compromise between strength and workability is required.

3.3.1.2. Effect of age

The degree of hydration increases with age. This leads to an effect on the strength as can be seen in figure 8 above. Hydration reactions are never complete, and in the presence of moisture, concrete will continue to gain strength for many years. The rate of increase, however, will be very small in such situations.

The water/cement ratio used for the mix was 0.5, and each sample was tested once it was 28 days old. The graph in figure 8 indicates a figure of around 46Mpa for the compressive strength of the samples, (in SI units 46×10^{-6} N/m^2). According to British Code of Practice BS 8007:1987, the relationship between the compressive and tensile strength of concrete can be defined by the formula:

$\boldsymbol{f_t = 0.12\,(f_c)^{0.7}}$ (eq. 1)

Where f_t is the tensile strength and f_c is the compressive strength[3].

However, this usually gives an underestimate of tensile strength, presumably to ensure a safety margin in concrete and mortar used for building. A graph showing the relationship between compressive and tensile strength can be seen in figure 1.2. appendix 1, from this graph the best fit overall is given by the expression:

$\boldsymbol{f_t = 0.3(f_c)^{2/3}}$ (eq. 2)[4]

Using this formula with a value of 46 Mpa for compressive strength taken from the graph in figure 8 the tensile strength of the plain mortar samples can be calculated to be 3.85 Mpa (3.85×10^{-6} N/m^2). Values for tensile strength will be used in section 5 in order to calculate an expected relationship between crack width and number of cracks for the purposes of comparing the theoretical predictions with actual results.

3.3.1.3. Effect of curing

Neville 1995 and Illston 1994:

The object of curing is to keep concrete saturated until the originally filled water space in the fresh cement paste has been filled to the desired extent by the products of hydration of cement. Hydration is greatly reduced when the relative humidity in the capillary pores drops below 80%[5]. It therefore follows that for hydration to continue, the relative humidity inside the concrete has to be maintained at a minimum of 80%. Once the concrete or mortar surface is no longer liable to damage, curing can take place. This can be done by covering the surface with wet material, submerging it in

[3] Neville pg.310
[4] Neville pg.310

water completely or leaving it in a sealed environment to reduce evaporation and maintain high humidity in the air surrounding the specimen. Some form of curing i.e. preventing water loss from the concrete surface is not only important to maintain hydration and therefore strength gain, water loss also leads to plastic shrinkage and increased permeability (due to increased porosity) – which is a problem when the material is required for waterproofing. Figure 9 below illustrates the influence of curing on concrete strength.

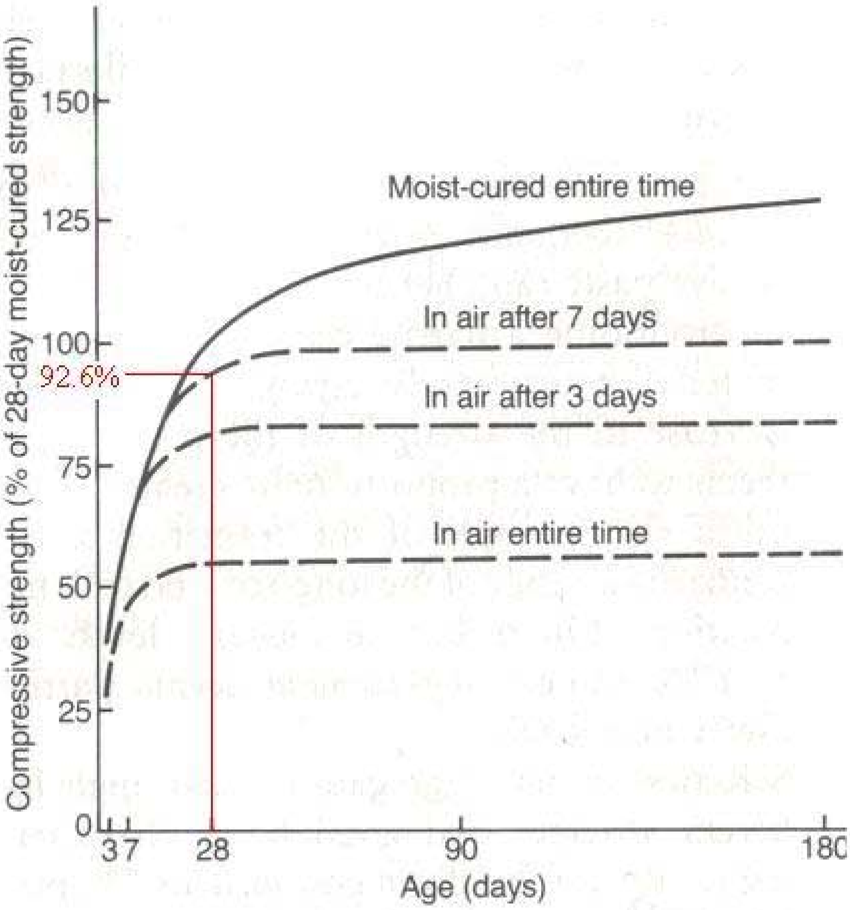

Figure 9: Influence of curing conditions on concrete strength (From Illston 1994)

The data from this graph can be used to make the figures for tensile and compressive strength attained in section 3.3.1.2. more accurate. The graph in figure 8 shows data for samples, which have been moist, cured the entire time. Due to time restrictions the samples used were only cured for seven days and then left to dry in air for another 21

---

[5] Neville pg.318

days before testing was carried out. From the graph above it can be seen that the actual compressive strength is therefore 92.6% of the previous figure, giving a new value of $42.6x10^{-6}$ N/m^2. Using equation 2 defined in section 3.3.1.2. the tensile strength becomes $3.66x10^{-6}$ N/m^2.

3.3.2. Admixtures

Rixom 1978:

These are chemicals that are added to the concrete immediately before or during mixing. They significantly alter its fresh early age or hardened state, to advantage or gain in properties. There are different types of admixtures:

- Water reducing
- Accelerating
- Air entraining
- Retarding
- Superplasticising
- Water-proofing

For the purposes of this report only those that may help reduce shrinkage cracking or leakage are discussed.

- Waterproofing – concrete absorbs water by capillary action. These admixtures aim to prevent penetration of water into concrete, for example vegetable or animal fats.
- Water reducing – in order to reduce the water: cement ratio whilst retaining workability. This will enable the use of a low amount of water thus reducing drying shrinkage and increasing strength. The most effective of water reducing agents are superplasticisers:
- Superplasticisers – Long molecules wrap themselves around cement particles giving them a negative charge so they repel each other, resulting in a dispersion of cement particles improving workability. These can also be used to produce concrete of normal workability but high strength due to reduction in water/cement

ratio. Superplasticisers can reduce water content for a given workability by 25 to 35%.

If the initial water/cement ratio is 0.5, a reduction in water content by 30% would mean a new ratio of 0.35. This corresponds to a compressive strength of 61.3 MPa, (see graph fig.1.3 appendix 1), if 92.6% of this value is used (due to each sample being cured for 7 days) the compressive strength is 56.8 MPa. Using equation 2, as defined in section 3.3.1.2. the tensile strength can be calculated to be 4.43 MPa ($4.43x10^{-6}$ N/m^3).

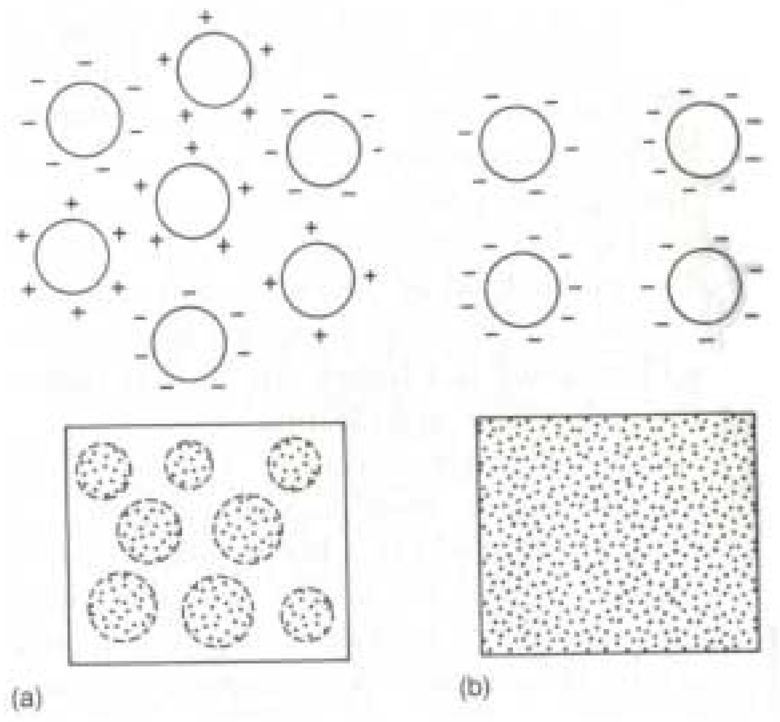

Figure 10: Dispersing action of plasticising admixtures (From Illston 1994)

(a) flocculated particles
(b) dispersed particles after admixture addition

There are also strength increasing admixtures which can have the effect of reducing cracks by producing a mortar with greater tensile strength so there is greater opposition to crack propagation.

3.3.3. Expansive cements

Odler 2000:

Expansive cements are inorganic binders that generate expansive (compressive) stresses in the hardened paste in the course of hydration, counteracting the tensile stresses generated by chemical shrinkage and drying shrinkage. Thus the generation of these expansive stresses may prevent the formation of cracks in concrete in the course of drying. Cements that meet these requirements are called *shrinkage-compensated cements*. The setting and hardening properties of concrete mixes made with shrinkage-compensated cements differ little from those made with ordinary cements, but the impermeability of the hardened concrete increases significantly

3.3.3.1. Expansive cements based on ettringite formation

Odler 2000 and Illston 1995

During hydration reactions, prior to setting, ettringite is regularly formed in ordinary Portland cement. It is the result of the reaction of gypsum with C_3A to form calcium sulphoaluminate (ettringite):

$$C_3A + 3CSH_2 + 26H \rightarrow C_3A \,.\, 3CS \,.\, H_{32}\,.$$

However, this formation of ettringite does not cause expansion as it will crystallise out, this can be seen in figure 4 section 2.4., which details the products of hydration over time. The formation of ettringite will lead to shrinkage compensation if the ettringite is formed after setting, at a stage when the paste has already attained certain rigidity. There are shrinkage-compensated cements available, which will reduce shrinkage in concrete through ettringite formation.

3.3.4. Reinforcing mortar

The reinforcement of mortar aids in increasing mortar strength, as the material used for reinforcement has a greater tensile strength than the mortar itself. Here two types of reinforcement are discussed:

- Fibre reinforcement
- Wire mesh reinforcement

3.3.4.1. Fibre reinforcement

Bentur 1990:

Fibre reinforcement is used in cementitious materials in:

a) Thin sheet materials, in which conventional reinforcing bars cannot be used. In these applications fibres act to increase strength and toughness.

b) Components, which must withstand locally high loads.

c) Components in which fibres are added to control cracking induced by humidity and temperature variations.

In application (b) and (c), the main role of the fibres is to control the cracking of the composite. The effect of fibres in fibre reinforced concrete is illustrated in the schematic (figure 11) below. The fibres improve the 'ductility' of the material, i.e. its energy absorption capacity.

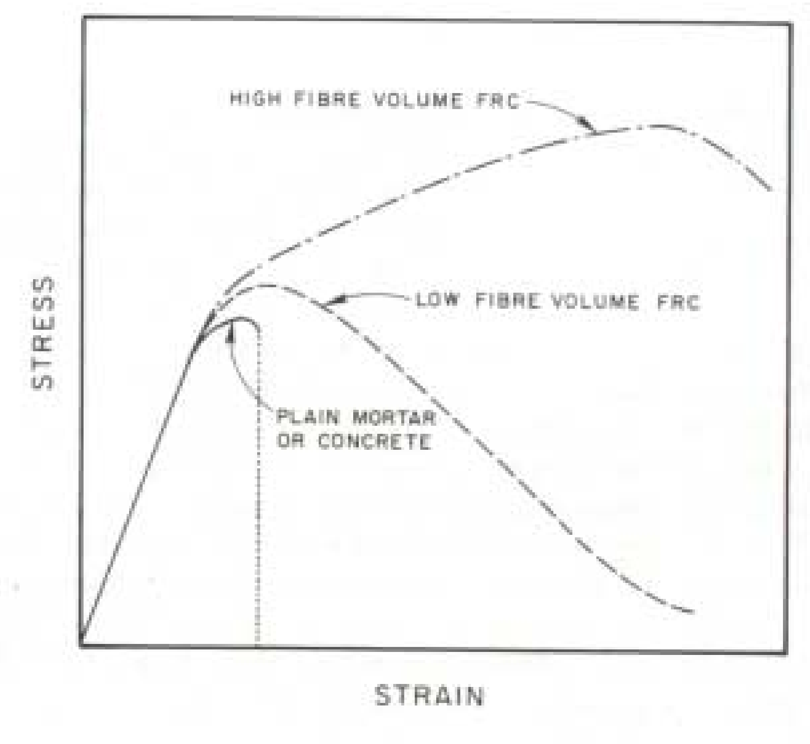

Figure 11: Typical stress-strain curves for low fibre volume and high fibre volume FRC
(From Bentur 1990)

3.3.4.2. Mesh reinforcement

Watt 1978:

The weakness of mortar in tension occurs due to planes of weakness between the edges of discrete lumps that make up the mortar. These are exaggerated by shrinkage during curing and the imperfect bond between each layer of mortar that is trowelled on. In compression these planes of weakness are held together by the load, but under tensile loading they will open up beyond their elastic limit, and cause the mortar to fail. In reinforced mortar, the mortar is assumed to contribute greatly to the tensile strength of the composite layer. This is due to the wire mesh, distributed relatively densely through the mortar, will allow the load to be taken throughout the complete layer and will prevent the early concentration of critical stresses in planes of weakness. Any cracks that do form under moderate loading will not be wide enough to allow water to reach the reinforcing wires and start corrosion.

According to Watt (1978), the maximum tensile stress in a thin walled cylindrical tank, constructed using wire mesh reinforced mortar, is 1.26 Mpa. This figure is given for a tank of wall thickness 0.03m, it can therefore only be used as an approximation as the tank lining of interest should have a thickness of 0.01m.

Reinforcement has the benefit of not only increasing the strength of the mortar but can also enable better crack distribution and the mathematical analysis in section 4 shows that this can lead to a reduced leakage rate.

4. Crack Distribution theory

Flow through a crack can be modelled as laminar flow driven by a pressure gradient between two infinitely wide plates (Plane Poiseuille Flow). This is assuming that the crack length is much greater than the crack width. Figure 12 below shows flow between plates a distance 2R apart, a fluid element of width 2y has been highlighted for analysis.

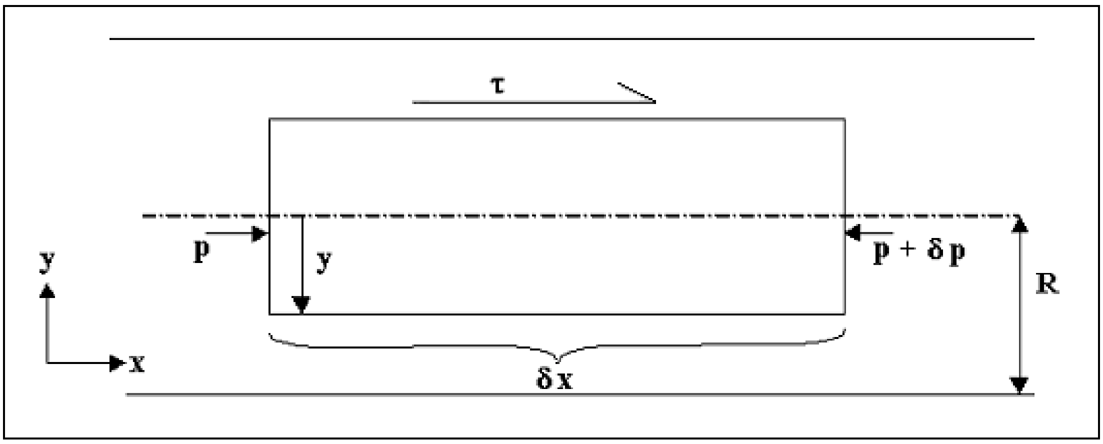

Figure 12: model for crack of width 2R, mortar thickness w (where w is parallel to x axis) and infinite length

y : distance from axis
p : pressure
R : ½ crack width

$$\tau = -\mu \frac{du}{dy}$$

τ : viscous shear stress for a Newtonian fluid

u : velocity parallel to axis shown

μ : viscosity of fluid

Force balance for a unit length into the paper:

$$p2y = -2\tau\delta x + (p + \delta p)2y$$
$$2\tau\delta x = (p + \delta p)2y - p2y$$
$$\tau = \left(\frac{\delta p}{\delta x}\right)y$$

where:

$$\frac{dp}{dx} = \frac{\Delta p}{w}$$

where Δp is pressure drop across a crack through mortar thickness of w

$$\tau = -\mu \frac{du}{dy} = -\frac{\Delta p}{w} \cdot y$$
$$\frac{du}{dy} = -\frac{\tau}{\mu} = -\frac{\Delta p}{w} \cdot y$$

Integrate to get velocity profile:

$$\int du = -\int \frac{1}{u} \cdot \frac{\Delta p}{w} \cdot ydy$$

$$u + c = -\frac{\Delta p}{2\mu w} y^2$$

at

$$u = 0, y = \pm R$$

$$\therefore c = -\frac{\Delta p}{2\mu w} y^2$$

$$u = \frac{\Delta p}{2\mu w}(R^2 - y^2)$$

Volumetric flow rate:

By symmetry:

$$Q = 2\int_0^R u(y)dy$$

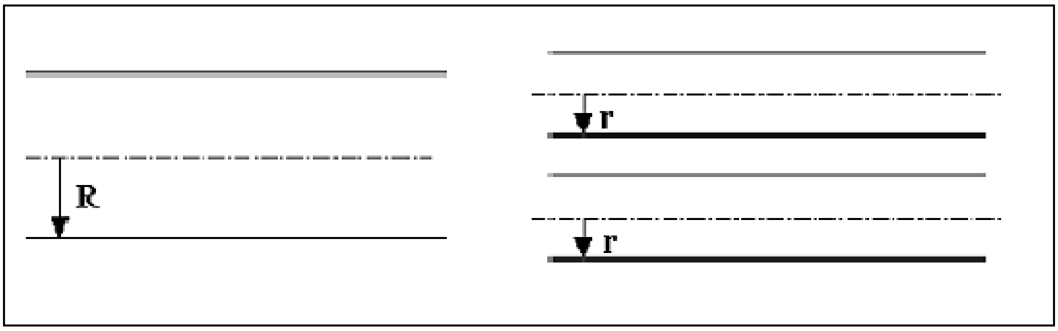
$$Q = \frac{\Delta p}{\mu w}\int_0^R (R^2 - y^2)dy$$

$$Q = \frac{\Delta p}{\mu w}\left[R^2 y - \frac{y^3}{3}\right]_0^R$$

$$Q = \frac{\Delta p}{\mu w}\left[R^3 - \frac{R^3}{3}\right]$$

$$Q = \frac{2\Delta p R^3}{3\mu w} \qquad \text{(eq. 3)}$$

Therefore Q α R^3



If the number of cracks is doubled but surface area remains the same (R=r/2), and if $Q_1 = KR^3$ is the flow through a single crack, then for the two half-sized cracks taken together the flow will be:

$$Q_2 = 2 \times K\left(\frac{R}{2}\right)^3 \qquad Q_2 = K\,\frac{R^3}{4}$$

It can therefore be concluded that distributing cracks in order to achieve twice as many cracks for the same surface are will quarter the flow through the cracks.

This analysis will only apply if the flow through the crack is laminar. The crack has the smallest surface area in comparison with the rest of the rig through which water will flow, therefore flow is least likely to be laminar in the crack.

For an estimated flow of 0.1m/s, and a crack width of 0.001m (a crack width of 1mm is likely to be the largest crack size possible), Reynolds number can be calculated:

$$\text{Re} = \frac{U2R}{\mu}$$

where U: mean velocity = 0.1   2R: Crack width = 0.001 μ : viscosity = 10^{-3}

therefore Re = 0.01

A Reynolds number of less than 1 indicates that the flow is laminar. Therefore the Plane Poiseuille Flow analysis holds.

5. Reducing cracking in constrained mortar

In this section the methods that were tested are discussed in more detail.

5.1 Plain Mortar

Initially four samples of plain mortar were tested. All samples had a sand/mortar ratio of 3 and a water/cement ratio of 0.5, they were cured in a humid environment for seven days and left for cracks to form for a further twenty-one days. Therefore each sample tested was twenty-eight days old. The expected tensile stress for these samples was calculated to be 3.66×10^{-6}N/m^2.

An expression for calculating crack width can be derived using stress, strain and Youngs Modulus for mortar in tension:

For mortar in tension:

$\sigma = \sigma_{UTS}$ where σ_{uts} is the ultimate tensile stress.

Youngs Modulus = stress/strain

$$\therefore \sigma = -E\varepsilon$$

$$\therefore \varepsilon = \frac{\sigma_{UTS}}{E}$$

Crack Width = circumference (-ε) / number of cracks, where –ε is the shrinkage strain less strain accommodated by tension. The shrinkage strain is 0.0045 (shrinkage of plain mortar – see appendix 1). Strain accommodated by tension is σ_{uts}/E.

Therefore:

$$2R = \frac{\pi d}{n} \times \left[0.0045 - \frac{\sigma_{UTS}}{E} \right] \qquad \text{(eq. 4)}$$

Substituting values for plain mortar:

Diameter of rig = 0.165m	$E = 28x10^{-3} N/m^2$ (Illston 1994)
$\sigma_{uts} = 3.66x10^{-6} N/m^2$	*R n = 1.13x10*$^{-3}$

Where *R* is half crack width and *n* is number of cracks. For example if we could expect ten cracks, then the average crack width would be: *0.00023m*, for plain mortar.

Referring to equation 3 in section 5:

$$Q = \frac{2\Delta p R^3}{3\mu w}$$

Substituting values:

In this case *2R = 0.00023*	R = 0.00012 m
$\Delta p = \rho g h$	(in testing a head of 2m is required)
$\rho = 1000\ kgm^{-3+}$	$g = 9.81\ ms^{-2}$
h = 2m	therefore Δp = 19620 Pa
$\mu = 10^{-3}$	*w* (mortar thickness) = 0.01m

Therefore the flow rate through one crack of width 0.00023m is:

$Q = 0.0023\ m^3 s^{-1}$

This is a leakage rate of 2.3 litres/s, in one day a crack of this size will leak 198720 litres, i.e. almost 200,000 litres leakage per day. This is a phenomenal amount, and it must be kept in mind that any measured leakage rate must eventually be projected onto a full size tank with a capacity of $10m^3$ (1000 litres): diameter 2.5m, height 2m. *[Note: at such high flow rates the analytic neglect of the pressure drop (= velocity head) to get the flow into the crack becomes invalid.]*

5.2. Rockfast

Brown 2001:

Rockfast cements are shrinkage-compensated cements based on the incorporation of calcium sulphoaluminate into a Portland cement system to give a composite cement which exhibits rapid setting, high early strength and dependent on proportions either shrinkage compensation or positive expansion. According to the literature by Blue Circle Cements, a 12% Rockfast replacement of Portland cement will lead to an expansion of 0.6% and a compressive strength of 45.2 N/mm² in 28 days. As the shrinkage of mortar is known to be 0.45%, an expansion of this much is required and therefore 9% replacement is required. According to this theory, therefore a 9% Rockfast replacement of Portland cement should lead to no cracking in the mortar.

5.3. Mesh reinforcement

The method of mesh reinforcement is currently being used in DTU rainwater harvesting tanks. For the purposes of testing a thin layer of mortar was plastered onto the rig. The mesh was placed over the first layer and a second thin layer was applied in order to incorporate the mesh into the mortar. In practice the mesh is held by wooden blocks a certain distance away from the tank wall and the mortar pushed through, but this was not seen as convenient or possible for the small scale on which it was being applied.

5.4. Fibre reinforcement

In tank construction fibres commonly used in fibre reinforced concrete (FRC) manufacture such as steel and glass would need to be purchased from a manufacturer, it was therefore decided to use vegetable fibres as these would be cheap, available and possible to process on site.

Property	Jute[3]	Sisal[3]	Coconut[3]	Sugarcane bagasse	
				Ref. 2	Ref. 3
Tensile strength (MPa)	250–350	280–750	120–200	170–290	20
Modulus of elasticity, (GPa)	26–32	13–26	19–26	15–29	1·7
Elongation at break, (%)	1·5–1·9	3–5	10–25	—	—
Fibre diameter, (mm)	0·1–0·2	—	0·1–0·4	0·2–0·4	0·24
Fibre length, (mm)	1800–3000	—	50–350	50–300	—
Water absorption (%)	—	60–70	130–180	70–75	78·5

Table 2: Properties of natural fibres (from Bentur 1990)

Sisal fibres were used as these were readily available, the fibre length was 5-10 mm and its diameter less than 0.2mm. The stress – strain curves of fibres show an ultimate strain in the range of 1 – 5%, which is much greater than that of the matrix (i.e. mortar). Therefore the mixing of 0.5% fibre (by weight to the mix) should have a positive effect on the strength of the mortar and reduce cracking, or distribute cracks.

In mixing technology, the increase in fibre content and length is associated with reduced workability. A fibre length of around 0.01m was used.

5.5. Double layer with nil coat in-between

Plain mortar mixed in the same proportions as before was used for this render. A thin layer of plain mortar was applied. This was cured for seven days and then left for a further week to dry and crack, then a cement-water wash (nil coat) was applied as the next layer. This layer was allowed to dry and crack for two days before the final layer of plain mortar was applied, this was cured for a further seven days and allowed to dry and for cracks to form for 21 days, as with the other renders. The expectation is that the first layer will crack, these cracks are filled by waterproof nil, then the second layer is applied and also shrinks and cracks, but hopefully in different places so the cracks do not overlap.

6. Leakage Testing

6.1. Experimental method

6.1.1. Previous problems

The experimental method used last year was not devised to simulate a water tank, but to create a condition in which the mortar would be constrained to induce cracking. The mortar was therefore set around a mild steel cylindrical pipe (length 140mm, diameter 165mm, wall thickness 5mm), this would ensure maximum constraint and cracking, and therefore give measurable flow rates. The test rig was required to be such that water could flow behind the mortar, i.e. between the outside of the pipe wall and the mortar. This was the area, which had given the most trouble in the previous year. A helical groove was machined into the outside of the pipe with a pitch of 50mm, and a depth of 3mm (this depth was not constant as the cross-section of the pipe was not a perfect circle). The groove was intended to be the channel through which the water would flow, therefore a way of keeping the channel clear was required so that when the mortar was applied it did not block the groove. Two different methods where tried - laying string in the groove and laying wire in the groove. Both were considered unsatisfactory, not allowing the water to flow freely through the channel, and therefore not ensuring all the cracks were fed.

6.1.2. Finding a solution

In order to find the best way of keeping the channel open it was decided to conduct a short test using three different methods.

- Method 1: using a thin length of string in the channel to act like a wick for the water through the channel:

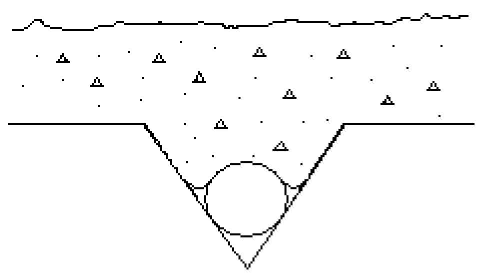


Figure 13: diagram showing string in v-shaped groove, with a layer of mortar on top.

- Method 2: Using a thick length of string to keep mortar from blocking the channel and allow water to flow through it:

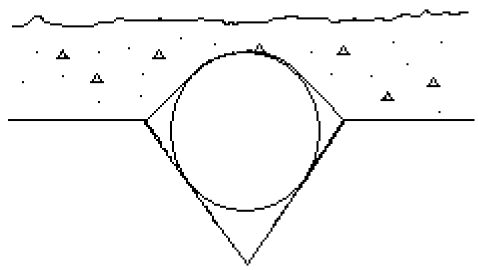

Figure 14: same as figure 13 but with bigger cross-sectional area of string so it acts as a barrier to the mortar entering the groove rather than a wick.

- Method 3: Using a crimped wire on order to keep the channel open and allow water to reach the mortar:

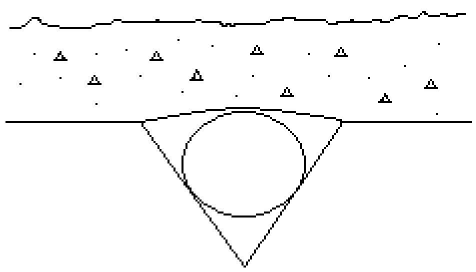

Figure 15: A wire is used instead of the string, the wire cross-sectional area is chosen so that it sits roughly flush with the pipe outside wall.

In order to test these methods each was applied to a rig with a piece of material wrapped tightly round the whole rig to keep the string and wire in place in the channel. It was hoped that the most effective method of keeping the channel open and allowing the water to flow through to the mortar would become apparent by measuring the leakage rate through the material. However, the leakage rate was faster than could be measured and flowed straight through the wrapping material bypassing the channel.

By doing this test it became apparent that a layer of material on the rig in between the mortar and the pipe wall would be very effective in keeping the channel open and would not have the drawbacks of stopping the water reaching the whole channel or slowing flow down significantly as the string did.

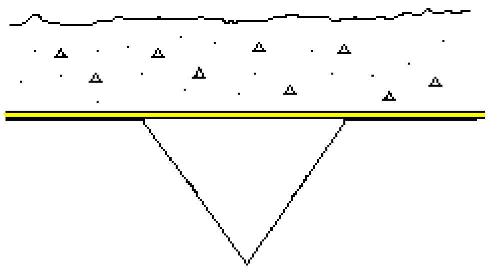

Figure 16: the channel is kept open by a piece of material between the mortar and the pipe.

As the material had to be wrapped tightly around the pipe, calico was chosen, being pure un-shrunk cotton it could therefore be shrunk onto the pipe. The calico was sewn to fit the circumference of the pipe, then shrunk onto the pipe in water.

6.2. Modifying the test rig

There were four existing rigs, which would need to be modified to ensure that the water flowed through the entire channel therefore feeding all the cracks. A manifold to better connect the channel was included, this had to be sawn by hand and filed to a v-shaped groove. A representation of the rig seen from front on (outside pipe wall) is shown in figure five below, originally the rig had only a helical groove (channel) and a hole for feeding water through from the inside at one end:

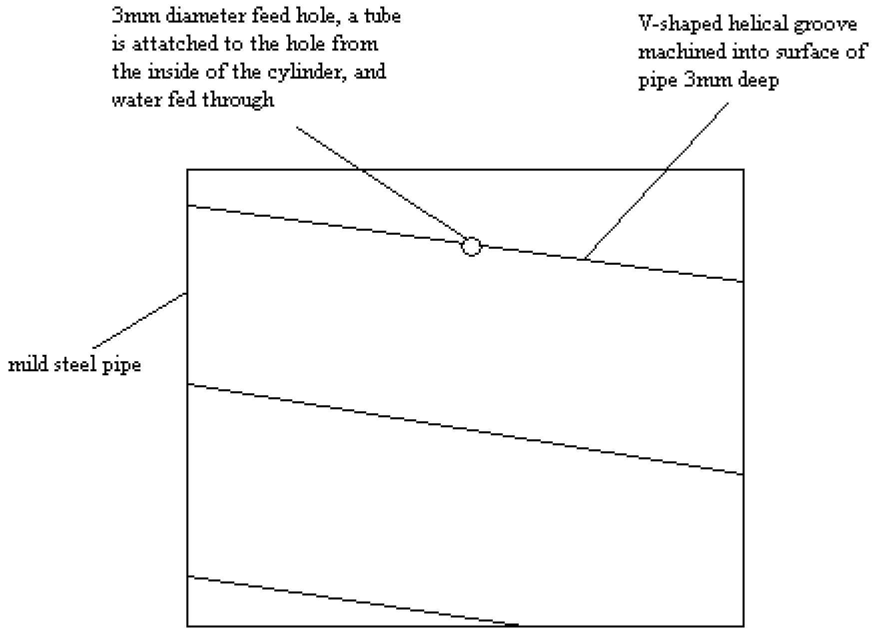

Figure 17: a representation of the front of the test rig (looking at the outside wall) – the original rig used in last year's tests (2001).

Two manifolds diametrically opposite eachother were included to run the whole length of the pipe, the original feed hole was blocked and a new hole drilled in the middle at a point where a manifold intersected the groove. The point at which this manifold intersected the last section of the channel was too near the end of the pipe. This was a problem as the ends were to be sealed due to the likelihood of water leaking from the ends, therefore a connecting channel was also included in the same manner the manifolds had been. Two bleed holes where then drilled into the pipe wall diametrically opposite the feed-hole intersecting the channel (therefore intersecting the second manifold). These were to ensure that air was pushed out of the channel as the water flowed around it, and would be immediately blocked as water came through.

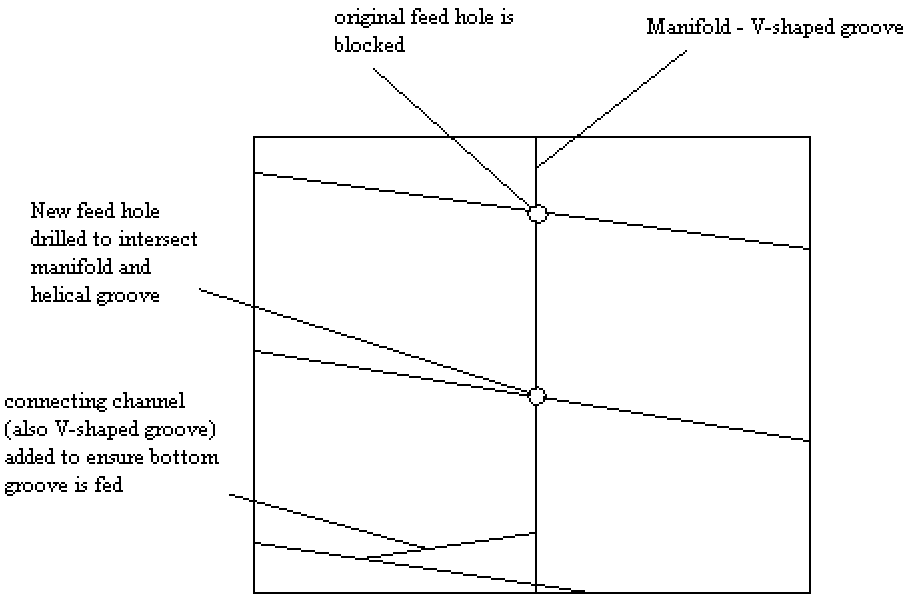

Figure 18: The test rig once modified to improve flow, the two bleed holes are not visible as they are on the other side, they also intersect with the channel.

The test rig was therefore set up as shown below, with a pipe to the feed hole, fed from the bottom to ensure that air was pushed up and out of the channel.

A two meter head was used in order to ensure the water was pushed up the groove and also to be able to compare results with a real tank, which has a height of 2m.

As well as modifying the existing rig, a new rig design was submitted using the same size and material for the pipe but with much closer grooves to ensure that the maximum crack area was fed (see appendix 2 section 2.3). The new design incorporated grooves at 1cm pitch, 2 manifolds diametrically opposite intersecting 2 feed holes at one end of the pipe (one on each manifold), and 2 bleed holes at the other end. This rig was designed so it could be tested upright rather than on its side.

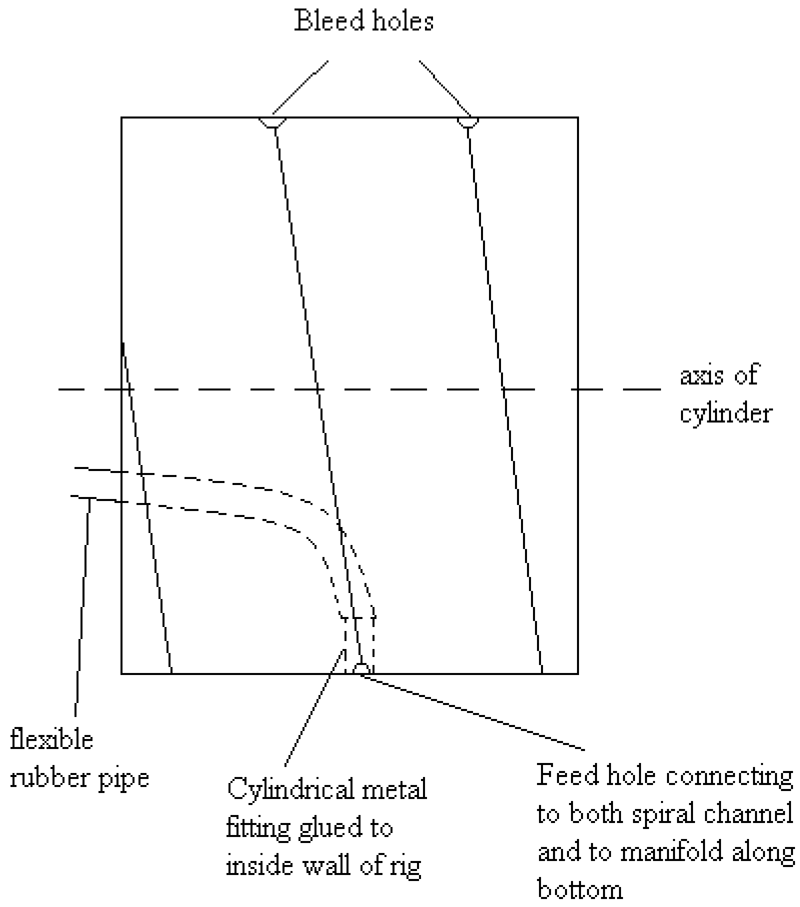

Figure 19: The test rig, as used for testing (looking at the pipe wall but with the rig on its side).

6.3. Constructing render samples

A 0.01m thick layer of mortar was initially applied to two rings, the cement : sand ratio used was 1:3. The water to cement ratio was 0.5. This formed a very thick paste, which was difficult to apply to the pipe wall (now covered in calico), as due to the dryness of the mix it had a tendency not to stick. However, it was decided to keep with a dry mix as more water in the mix the compromises on strength in the mortar. The rigs were left to cure in a bag for seven days before drying outside the bag for a further 21 days. This was done as in the last project it had been noted that it took 28 days for the cracks to form.

The mortar was then applied to the two remaining rings with the same ratios as used before of cement, sand and water. Due to concerns of leakage from the edges it was decided to modify the rings slightly by applying the calico so that roughly 2cm of the rings were left exposed at either end, these ends were roughened using a file. This was to ensure the mortar would stick to the pipe ends and reduce any leakage or seepage through the material if it protruded from the ends. Silicone sealant was also applied to the ends of all four rigs.

The last two of the four rigs were expected to yield better results as the plastering was of a better quality, with a constant thickness throughout. Also there had been more measures taken to prevent end leakage.

After these rigs had been tested the mortar was chipped off, at this point the newly designed rigs had also become available. With eight rigs, it was possible to test four variations of render with two rigs to each render. The renders were applied as described in section 5, the most difficult to apply being the wire mesh as it had to be held onto the outside of wet mortar ensuring no gaps between mesh and mortar:

Figure 20: making a wire mesh reinforced render, (on right – applying mesh into wet mortar, on left – mortar chipped away after testing to reveal mesh).

7. Testing

The rigs were set up so that a 2m head could be obtained. A pipette was attached to the top end of the pipe and water poured through a funnel into the pipette. Two people were required to conduct the testing, as a person was needed at the bottom end to block the bleed holes the moment water poured through them.

Initially testing went to plan as the water first emerged from the bleed holes before the cracks so it could be assumed that there was no air in the channel interfering with the flow. However, once the bleed holes were blocked it soon became apparent that water was flowing through the cracks faster than it could be poured through the pipette, therefore it was not possible to measure the leakage rate.

This proved that the testing method had been improved in the sense that flow was most definitely not inhibited in the channel. However, the leakage rate needed to be measured and so the set up of the experiment was altered. A wider pipette and pipe were used, initially the pipette had a diameter of 7mm, it was now 11mm. Also the pipette was moved down to the bottom so that the water level was not falling immediately at the point it needed to be measured, i.e. the person at the top could stop pouring when the person at the bottom had blocked off the bleed holes and ensured that the water was flowing through the cracks, and then after a few seconds the top of the water level would reach the pipette so the person at the bottom could time the drop. This worked well and a leakage rate was recorded.

Figure 21: set up of the rig showing pipe connecting to channel and pipette

Figure 22: Leakage through a crack

For later tests a reservoir was introduced so that testing only required one person. Water was held in a container 2m high, with a tap, which was attached to the rubber pipe. There was also a valve on the rubber pipe, positioned just above the pipette so one person could control the flow from the bottom (see figure 5 section 3.1 for a rough schematic of how the test was set up).

Crack measurement was done using a microscope with a graticule that measured to 1/20 of a millimetre.

7.1. Problems encountered during testing

As the leakage rate was high due to low resistance in the rig (see appendix 2 section 2.2.), ensuring accurate results was difficult as the water level in the pipette tended to drop very quickly. This was a problem, which could only be overcome by repeating tests and obtaining an average.

A major problem encountered was leakage from the ends, as can be seen below in figure 23. The mortar is wet along the edge below the silicone sealant, indicating water is leaking from the sealed edges:

This had to be overcome by observing leaks, marking them and applying greater quantities of sealant. In the case of the wire mesh samples this was done twice as the end leakage was excessive in these samples. Therefore, in the results there are three different flow rates for the mesh samples, the smallest being that with all end effects removed. This was also done once for the Rockfast sample, giving two flow rates for Rockfast.

Figure 23: A sample with end leakage

8. Results

8.1 Crack measurement results

Two different types of rig were used, the *original rig* used in last years experiments by Tom Constantine and the *new design* of rig detailed in section 6.2.

The plain mortar samples were both set on original rigs, as these were the first samples to be made and the rigs made to the new specification were not available at that time. There are no crack measurement results for the samples made with two layers of mortar with a cement-water wash, as no cracks were visible on these samples. The results are detailed in appendix 3 tables 3.1. to 3.8., and summarised in section 9.1 to enable analysis.

8.2. Leakage results

For the Rockfast tests there is only one leakage result, due to the failure of one rig (the original design), there was a blockage at some point in the groove and not all cracks were being fed also one of the bleed holes did not leak which implies air was trapped inside the channel.

As the results are different for the new rig and old rig, there are two tables – one showing the raw data as measured (appendix 3 table 3.9.) and table 3 below with the results for the new rig normalised so they can be compared with the old rig results.

Table 3: Normalised data for leakage rates

Rig	Type	Test number	Flow rate (m^3s^{-1} E-06)
Original	1) Plain	1	6.2
Original	2) Plain	1	7.6
Original	3) Plain	1	4.6
Original	4) Plain	1	3.7
Original	Mesh	1	0.51
New design	Mesh	1	0.43

New design	Double layer	1	2.7

9. Analysis

9.1. Analysis of cracking results

Table 4: Crack measurement results and projected expectations of flow

Sample	Number of cracks	Average crack width (E-03m)	Average crack surface area (E-03m^2)	Total crack surface area (E-03m^2)	Shrinkage	Expected flow rate (E-03m^3s^{-1}
Plain mortar 1	9	0.089	0.0075	0.067	0.00089	1.037
Plain mortar 2	8	0.093	0.0069	0.056	0.00075	1.04
Mesh 1	9	0.036	0.0012	0.01	0.00013	0.08
Mesh 2	9	0.034	0.001	0.0092	0.00012	0.06
Rockfast 1	7	0.100	0.0093	0.065	0.00087	1.31
Rockfast 2	9	0.088	0.0077	0.07	0.00093	1.01
Fibre 1	9	0.130	0.010	0.09	0.0012	3.16
Fibre 2	5	0.120	0.013	0.065	0.00087	1.56

9.1.1. Shrinkage

The shrinkage of the samples was calculated by dividing the total crack surface area by the actual surface area of the mortar on the rig. Analysis of these results reveals that the only effective method of reducing shrinkage was the wire mesh reinforced mortar. The addition of Rockfast made no difference to the shrinkage or crack distribution as the figures for shrinkage are similar to the figures for the shrinkage of plain mortar. Fibre reinforcement also made no difference, having one of the highest shrinkage values. The expected shrinkage for plain mortar, *0.0045*[6], is not reflected in the results, the highest shrinkage being 0.0012, almost a quarter of the expected value. The expected average crack width calculated in section 5.1., for an estimated 10 cracks around the set diameter of the test rig was 0.00023m, in reality the highest average crack width found in the fibre reinforced samples was 0.00013m, almost half the expected width.

9.1.2. Expected flow rate

The expected flow rate through each mortar lining was calculated using the value for average crack width substituted into equation 3 defined in section 5:

$$Q = \frac{2\Delta p R^3}{3\mu w} \qquad \text{eq. 3}$$

Where R is half the crack width. The figure obtained from this calculation was then multiplied by the number of cracks in each rig in order to give a total leakage value for the whole section of mortar. These flow rates will be used in the leakage results analysis below.

9.2. Analysis of leakage results

Table 5: Comparison of expected flow rate with actual

	Theoretical flow rate ($E\text{-}03 m^3s^{-1}$)	**Measured flow rate ($E\text{-}03 m^3s^{-1}$)**
Plain mortar 1	1.037	0.00463
Plain mortar 2	1.04	0.00371
Mesh 1	0.08	0.00051
Mesh 2	0.06	0.00043
		0.00027
		0.00023
Rockfast 1	1.31	
Rockfast 2	1.01	0.01056
		0.00560
Fibre 1	3.16	0.00480
Fibre 2	1.56	0.00474
Double layer 1		0.0022
Double layer 2		0.0027

The table above shows a comparison of the expected flow results according to the theory modelling a crack as laminar flow between parallel planes, and the actual flow rates obtained through measurement. The theory predicts a much higher flow through the cracks measured, in comparison with the actual flow, which in most cases is more

[6] Neville 1995

than 100 times smaller. As well as comparison with the theory it is important to realise findings must be projected onto a much larger tank, which will hold $10m^3$ of water (10,000 litres). The leakage rate for the area of mortar on the test rig was projected onto the larger area of a tank with a height of 2m and a diameter of 2.5m (see table 3.10. appendix 3). The calculation was done for the expected leakage rates and the actual leakage rates measured.

Table 6: results projected for leakage in one day in a tank of volume$10m^3$

	Expected leakage in full sized tank in one day (litres)	Projected leakage (from experimental results) in full sized tank in one day (litres)
Plain mortar 1	18755597	83758
Plain mortar 2	18809856	67010
Mesh 1	1446912	9188
Mesh 2	1085184	7808
		4909
		4091
Rockfast 1	23693184	
Rockfast 2	18267264	190979
		101202
Fibre 1	57153024	86869
Fibre 2	28214784	85806
Double layer 1		39718
Double layer 2		48869

In a 10,000 litre tank, ideally a leakage of more than 10litres a day is unacceptable. Therefore projecting the figures to a full size tank has produced leakage rates, which are far too high and seem unrealistic. Even using the values for mortar reinforced with chicken mesh, which give the lowest leakage, a full tank would be empty in two days.

10. Discussion

In section 1.4 two objectives were outlined:

- To improve on the experimental method used in the previous year to yield more credible results.
- To measure leakage flow through renders in order to recommend methods of effective waterproofing for water tank construction.

10.1. Experimental procedure

The problem encountered by Tom Constantine last year was too large a resistance in the channel, which therefore bought into question whether water was allowed to flow freely and feed all the cracks. The resistance in the rig was greatly reduced by removing all obstructions in the channel, however this then led to the problem of a leakage rate so fast it was difficult to measure. With such low resistance in the channel end leakage also became a problem and some results should have been repeated but could not be due to lack of time.

The rig produced a totally constrained state for the mortar and leakage was also made higher by the large pressure difference between inside the channel and the outside wall. In practice the mortar is backed by earth or bricks, which would serve to reduce the leakage rate. Therefore, with all these factors taken into account the rig is not an ideal approximation of real life. Projecting the leakage rates onto a tank with a 10,000 litre capacity does not yield accurate results for leakage in large tanks, as such tanks are in use and leakage rates are not as high as those calculated in this report. However, the test rigs give a good method of measuring leakage rate through mortar, if all unwanted leaks can be overcome. The rig can provide a controlled system, which allows water to flow freely behind mortar and a reliable method of testing flow rate through cracks. Therefore it is a good method for comparison between different measures to reduce cracking. From the results obtained in this report, wire mesh had the best performance in comparison with the other techniques tested.

10.2. Methods of waterproofing

Rockfast

Although expected to eliminate cracking in the mortar due to shrinkage compensation, the addition of Rockfast produced the same results as plain mortar, if not fairing slightly worse. The shrinkage of plain mortar was in fact less than that predicted by the theory, according to Neville plain mortar shrinks by 0.45%, in tests it was found to average at 0.082%. It is therefore possible that the amount of Rockfast used was too much and instead of shrinkage compensation, encouraged further expansion. Due to the constrained nature of the samples this may have led to internal stresses developing which would have caused cracking.

Fibre

The fibre-reinforced mortar also performed very badly, again giving no real difference from plain mortar. As fibres make mixing difficult, it is possible that this led to a poor quality mortar. During plastering, it was necessary to plaster from the bottom of the rig to the top (along the length of the cylinder) as any other way resulted in the mortar falling off. It is therefore also possible that this plastering action aligned many of the fibres in the wrong direction, as cracks propagated along the length of the cylinder and therefore the fibres would be required to be perpendicular to the cracks, rather than along the same line.

Double layer

The rigs coated with two layers of mortar and a cement-water wash between the layers, performed fairly well. It was harder to seal the ends of these rigs as the layer of render was much thicker than on the other rigs. This may explain why the leakage rate is higher than expected, seeing as no cracks could be identified on the mortar surface. Despite this, the leakage rate with this method of rendering was half that of the three previously discussed. In the building of a real tank using this method is inconvenient as the site will need to be visited at least three times for the application of each layer, and both mortar layers have to be allowed to cure and dry. This also increases expense.

Wire mesh reinforcement

This performed the best of all four methods, reducing the leakage rate from plain mortar by a factor of 10. However, there is a possibility that carbonation will occur with chicken mesh in mortar, particularly in hot countries. Carbon dioxide reacts with alkalis stripping the protective layer on steel, especially in hot countries with poorly made mortar. The mesh will rust in the mortar, leaving the mortar weak and prone to cracking. However, on the basis of the tests performed, wire mesh is most effective in preventing cracking.

10.3. Mortar Quality

Mortar quality is an important factor affecting mortar strength and cracking, that has not been addressed in this investigation. Implementing a rainwater harvesting project in a developing country involves teaching local workers the necessary skills required to build tanks.

The mortar needs to be as dry as possible, however, this makes the plastering job slightly harder and therefore, if emphasis in not placed on the correct water content plasterers may add more water to increase workability. Watt describes the problem of too much mortar being mixed in one go, which leads to a large amount becoming stiff as it is left out in the sun. In this situation it is not uncommon for the person plastering to add a little more water to make it workable again – this will also compromise mortar strength and quality. There also needs to be a great emphasis placed on proper curing, as this increases mortar strength. Without these measures being taken cracking will occur in mortar.

11. Conclusions

The use of test rigs with the channel kept open by a layer of material between the channel and the mortar worked well in reducing resistance in the water-feed path. The test rigs provide a method of comparing renders, however they do not provide a good approximation to a real size tank.

A better method of sealing the ends is required, as in some cases silicone sealant was not sufficient to stop end leakage. For this reason the tests in this report need, ideally, to be repeated.

The best render was the wire mesh reinforced mortar. Although it produced the same number of cracks, the crack sizes were greatly reduced. In plain mortar the average crack width was almost 0.1mm, for mesh the average crack width was 0.035mm, a reduction of almost two thirds. The leakage was reduced by more than a factor of 10.

11.1. Further work

The method of testing needs to be further improved so it can be used to better approximate real size tanks. The use of better seals at the ends of the rigs should reduce the leakage rate to reflect only the leakage from the cracks. One possibility is the combined use of silicone sealant and fix clips (used by Tom Constantine in 2001). If the flow can be reduced, it would make the leakage rate easier to measure and leave fewer margins for error in the timing of the drop in water level through the pipette.

There were many methods of waterproofing renders that were not tested in this report, for example the use of a waterproofing paint, the use of superplasticisers and other chemical admixtures. Also the methods tested need further development,

- testing with different amounts of Rockfast to obtain the right shrinkage compensation
- testing with different types of fibres
- longer term tests with wire mesh to study the effects of carbonation
- repeating tests with an improved end sealing technique

The tests also need to be repeated as two samples of each render are not enough to give conclusive results. The main recommendation that can be made is greater research into wire mesh reinforcement.

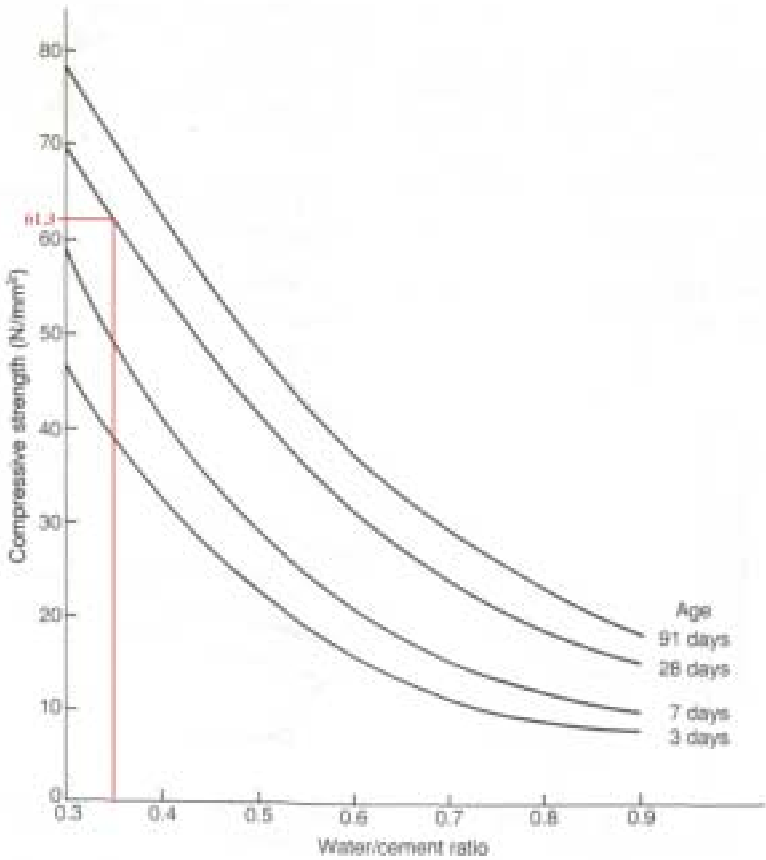

Figure A1.4 Relationship between water/cement ratio and strength (Illston 1994)

Appendix 2 – experimental procedure

A2.1. Calculations carried out before testing began

To ensure a measurable leakage rate through the rig:

Suppose threshold of interest is 1litre/day

Suppose tank is 1m diameter x 2m high

Mean pressure head 1m – (similar to experiment)

1litre/day loss = q Area secs/day

q = 0.001/6.3*86000 = $1.84 \times 10^{-9} m^3/s$ per m^2

Test rig:- Mortar area = $\pi \times 0.165 \times 0.14 = 0.0725 m^2$

Therefore leakage rate per hour = $0.0725 \times 1.84 \times 10^{-9} \times 3600$

= $0.48 \times 10^{-6} m^3/hr$

= 0.48 ml/h ← just about observable

Check that surface tension of water does not prevent flow:

Surface tension of water at 20°C = 72×10^{-3} N/m

Force per metre on film acting downwards is: $72 \times 10^{-3} \times 2 \times \cos\theta$

Assume $\cos \theta = 1$

$F = 1pw$, so $pw = 1.44 \times 10^{-3}$, and $p = 1.44 \times 10^{-3}/w$

If crack width w = 0.0001m (0.1mm), then p = 1440 Pa, i.e. 14 cm of water

A2.2. Resistance in rig

The flow rate through the bleed holes was measured i.e. water flowing straight through rig, bypassing cracks. This rate was 6 litres/second ($0.006 m^3 s^{-1}$ → 10^3 times faster than the flow rate through plain mortar), therefore resistance is negligible in the channel.

A2.3. Comparison of feeding cracks through channel and feeding cracks in an actual tank

In the test rig cracks are fed primarily at points where they are intersected by the channel, figure 2.1. below shows a schematic of the water distribution in a crack as fed by the channel:

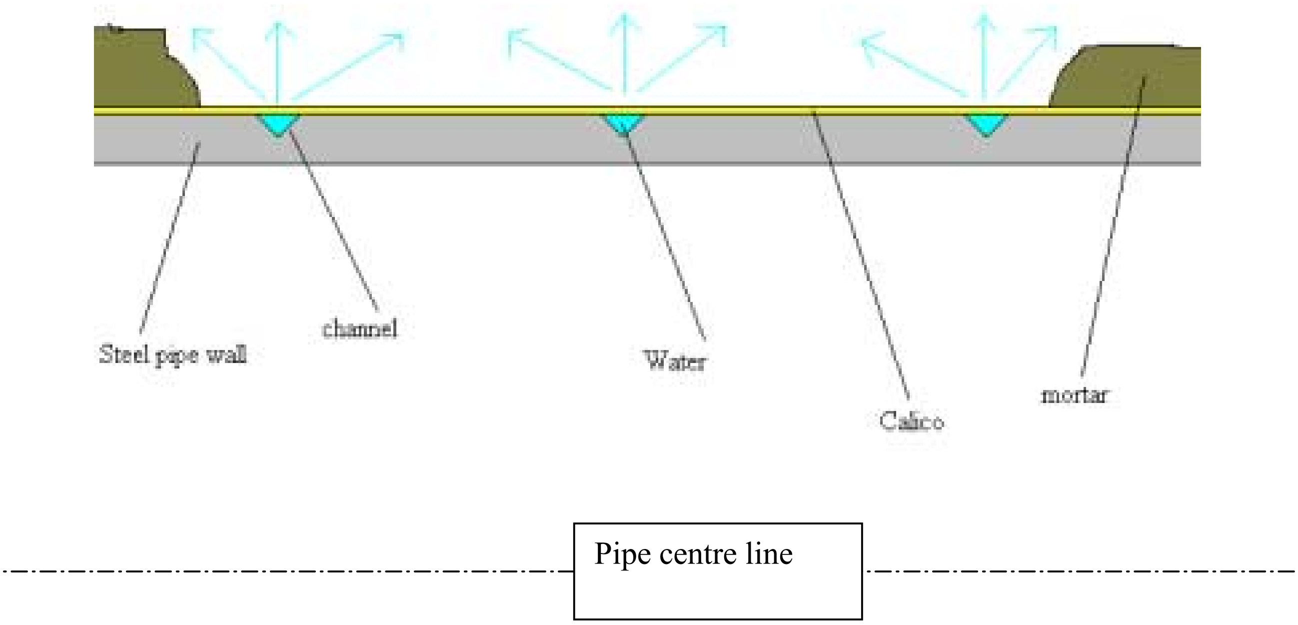

Figure 2.1.: Cross section of mortar and rig, at a point where there is a crack. Water is not evenly distributed through crack

If this is compared with the same situation in a real tank:

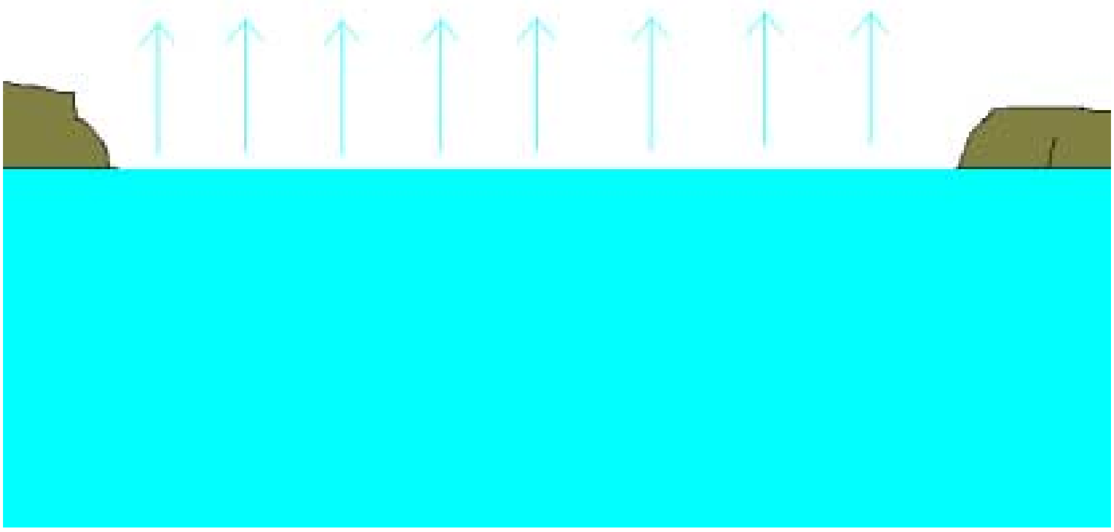

Figure 2.2: in a real tank water distribution is constant

This implies the measured leakage rate from the rig is an underestimate. However, it should also be taken into account that the rig provides the most severely constrained state to ensure maximum cracking. Also mortar lining in real tanks is backed by earth or bricks, whereas in the tests there is only air on the other side of the mortar, so the pressure difference is far greater which will lead to increased flow. Therefore it can be assumed that these factors will have a cancelling effect.

1. INTRODUCTION

The intensification of agriculture in African countries, especially in the traditional sector of their rural economies, is receiving much attention today. This escalation of agricultural activity is seen as an essential means of achieving self- sufficiency in food production (despite rising populations). It is also seen as a way to increasing rural income generation, which would have the valuable effect of removing a prime cause behind over-rapid urbanisation. However, unless considerable care is taken, the intensification of land-use can lead to irreversible degradation of soils. Whilst simply improved farming techniques can do much to increase yields, a substantial improvement in agricultural production usually also entails increasing such inputs as the water, fertiliser and energy used in cultivation.

In Zimbabwe the productivity of most land is water limited. In very few areas can more than one rain-fed crop be harvested each year, and in much of southern and western Zimbabwe even that one crop is often lost in a dry year. Drought relief programmes are then operated. Seasonal malnutrition is also a concern. On large commercial farms, irrigation using water reservoirs or boreholes is widely practised with good results: the hectarage so irrigated has grown rapidly in the last 30 years. On small- holdings in the less fertile land of the Communal Areas, irrigation is, by contrast, quite rare despite being under- estimated in official surveys. The farmers (often women) have little capital, electricity for pumping is not available, the plots are too small or steep for commercial irrigation equipment to be economic and its maintenance can be a problem. For example a petrol-driven pumpset is too powerful, costly and complex for a farmer of 2 hectares and yet is not easily shared. Irrigation often conflicts with farmers' "minimum risk" strategies.

Part of Manicaland is mountainous and has the best rainfall in Zimbabwe. Much of the North and East of the Province is classed as "Agroecological Zone I" on the national map of "Natural Regions and Farming Areas", (a climate advantage which is offset by the steep and rocky nature of much of the land). Many of the streams are perennial. Despite this there is still a long dry season in winter when little rain falls and most cropland lies idle. Besides the three relatively large irrigation schemes operated by DERUDE, a little gravity-fed irrigation is practised in the Communal Areas, but there are very few pumps, long furrows or dams for seasonal water storage. Within the constraints of dry-season stream flows and other demands on surface waters, a substantial expansion of small-holder irrigation seems possible using stream water. Only at a later date will it be necessary to tap underground water, which is generally more costly to access and has special problems (like salination and depletion) in use.

The Manicaland Development Association (MDA) was formed in 1980 to assist rural grassroot communities with their social, economic and agricultural development. MDA has two Training Centres and District Development Committees in seven districts of Manicaland Province. It undertakes agricultural training and extension, it employs domestic technology instructors to improve nutrition and women's welfare and it promotes rural income-generation using appropriate technologies. Its main focus is upon the needs of those living in Communal

Areas. In relation to irrigation, its northern Herbert Chitepo Training Centre (HCTC) at Bonda is well placed for both demonstrations and extension work.

Warwick University has had connections with HCTC since its early days. The University has within its Engineering Department a Development Technology Unit (DTU) that specialises in rural industrialisation and the design of technologies for rural development in Asia and (especially) Africa. One device it has been researching slowly for some years is the water-powered "hydraulic ram pump" pump, seeking to modify traditional designs so that they might be made in small workshops at a cost that would permit their use for irrigation. Early prototypes were build at HCTC in 1986 and 1988. Recently the DTU has obtained British Government funding to accelerate its research into these pumps. The DTU has links with programmes using ram pumps in Zambia and Zaire.

The development of appropriate pumps is only one part of any programme to promote irrigation on smallholdings. There are many possible irrigation techniques (not all using pumps) and many factors affecting the viability of any one method in a particular area. A nine month period of pump testing and improvement at HCTC, involving the placement of a DTU representative there to work with HCTC's Appropriate Technology Section, was started in August 1989. It was decided to attach to this a short study of the relevance of non-motorised smallholder irrigation in Manicaland. The aims of the study carried out between mid-August and mid-September 1989 were:

- to identify major social, economic or geographical constraints on the expansion of irrigation of small plots in Communal Areas
- to develop a better specification for water-lifting devices
- to examine the agricultural options available for the use of extra water.

A further field study was undertaken in December 1990, mainly to clarify the likely area of irrigable land. By this time one of the pumps being tested at Bonda had run continuously for 9 months giving greater confidence in its suitability for irrigation applications.

The Working Paper describes the findings of two studies and records the initial test performance of two pumps (one water- powered, the other human-powered) installed near the Model Farm of CATC. The Paper is necessarily brief and simple, reflecting the brevity and simplicity of the studies. It has been written partly to give a framework to more detailed evaluation in the future, and partly to back up a request for irrigation programme funding that MDA is making.

2. IRRIGATION TECHNOLOGY

2.1 Choice of technology for smallholder irrigation in Manicaland

There are very many ways of supplementing rainfall to increase agricultural yields; irrigation is a well developed art. We are concerned here with a specific group of farmers in a specific area. Namely those living in Communal Areas of the moister parts of Manicaland. Existing irrigation of their dry season gardens is by gravity feed from streams, or is a secondary use of water primarily provided for domestic purposes. In this context it has been already argued that the expansion of irrigation using surface waters should take precedence over the introduction of irrigation using underground water from aquifers.

Of the various methods of applying water to a plot, those that are most efficient in water use - for example sprinkler and drip irrigation - are also those that need the most expensive equipment and highest water pressures. For both reasons they are not suitable primary techniques for the target group. Application by furrow, hosepipe or bucket has therefore been assumed, although in some places particularly permeable soils may require other treatment. Furrow irrigation needs considerable land preparation (of the same sort as erosion limitation on steep plots); a variant is free flooding from a top furrow, which however is inefficient in water use and can cause soil erosion.

Since dry season river flows are only a small fraction of Summer flows, seasonal storage behind small dams is common on large commercial farms. There are few examples of such reservoirs in Communal Lands, and in some parts of Manicaland suitable sites would be hard to find. The cost and degree of cooperation between individual smallholders necessary to construct and safely maintain dams is quite high: dam construction should not normally be a part of any self-managed irrigation schemes for small-scale farmers. There is a number of government-administered smallholder irrigation schemes in Zimbabwe where expensive shared facilities (dams, boreholes) are employed; however these schemes are usually subsidised to a degree that makes them poor models for copying.

Movement of water from source to plot can be by gravity or by pumping. Existing smallholder irrigation uses gravity, but there are many sites where the furrow leading from an abstraction point on a stream to irrigable land would be very costly to create and difficult to maintain. Long furrows, furrows through permeable soils (needing lining) and furrows through rocky terrain (needing blasting) are all likely to be too expensive. Contour furrows need protecting from damage or siltation by cross flows during rains. There is no doubt scope for increasing gravity-fed irrigation in Manicaland, sometimes in conjunction with the creation of very small (even temporary) dams to act both as diversion structures and as overnight water stores. Some of the gravity-fed sites now in use contravene the Stream Bank Protection Regulations, being within 30 metres of a watercourse: enforcement of these regulations is expected to tighten in future.

For a majority of new sites some form of water lifting will be required or will be preferable to the alternative of using a long furrow; it is specifically pumped irrigation that is considered in the rest of this report. In commercial irrigation, engine- driven pumps (the cheapest cost around Z$4000) or electric pumps are invariably used. These are usually uneconomic when irrigating less that 2 hectares. Mains electricity is rarely available at streamsides and photo-voltaic electricity is far too costly. Windpumping also has far too high a capital cost for irrigation pumping in Zimbabawe, even on sites with especially favourable wind regimes.

Three water-lifting techniques meet the requirement for low capital cost, low running cost and simplicity, namely human- powered, animal-powered and water-powered pumping. Animal-driven devices are not known or available in Zimbabwe, although they have been used in Asia for many centuries. They may become of more interest if there is an increase in the use of draught animals in Manicaland, but do not constitute a good option today.

Human-powered irrigation, at least of small plots, is widely practised. Applied to plots of even 0.2 hectares it becomes very arduous. Such a plot requires about 1000 large buckets (10000 litres) of water per day, about 4.5 buckets per minute for 4 hours per day. Even with 3 carriers, such a rate could only be maintained if the distance carried were less than 30 metres and the lift less than say 2.5 metres. Pumping is much preferable to carrying, as it employs energy far more efficiently. Of the many types of "hand" pump, those that make good use of back and leg muscles are superior to those only using arm muscles. It should be possible for a team of two people to raise 10000 litres per day through 5 metres using a human powered pump. In countries where human-powered irrigation is widely used, a lift of about 3 metres is regarded as a limit to viability. Higher lifts are however used in Bangladesh.

The last technique listed above is water-powered pumping. This is only feasible for lifting water from streams in hilly areas as it uses energy extracted from the small fall of a large flow to lift a small flow to a height. There are few water-powered pumps available. In China water turbine-pumpsets are manufactured, and a few other devices exist in particular countries, but the only widely used water-driven pump is the hydraulic ram pump. Even this is unsuitable for irrigation in its usual high-cost, high-lift, low- capacity form; however a variant designed specifically for low- lift irrigation in Africa is becoming available and is described below.

2.2 The hydraulic ram pump

Background.

The automatic hydraulic ram has been used successfully in rural areas for lifting water for nearly two hundred years. The hydraulic ram is a pumping device which utilises energy from the fall of a flow of water to lift a fraction of the supply to a much greater height. Because it has only 2 moving parts and no bearings, it has a reputation for reliability and low maintenance. By its very nature it cannot be used to pump "static" water from ponds or wells: it is restricted to hilly area where stream gradients are relatively steep.

Existing designs

Commercially manufactured ram pumps are usually made from steel castings and have to be imported to Zimbabwe. These are rarely used for irrigation because of:

- the high cost of the rams and large diameter pipe networks needed for irrigation
- the lack of experienced technical back-up to assist system design on site
- the unreliability of spares supply and access to maintenance.

The reasons are particularly true for small farms in remote areas. Secondhand Blakes ram pumps command high prices (Z$4000 upwards) in Zimbabwe today.

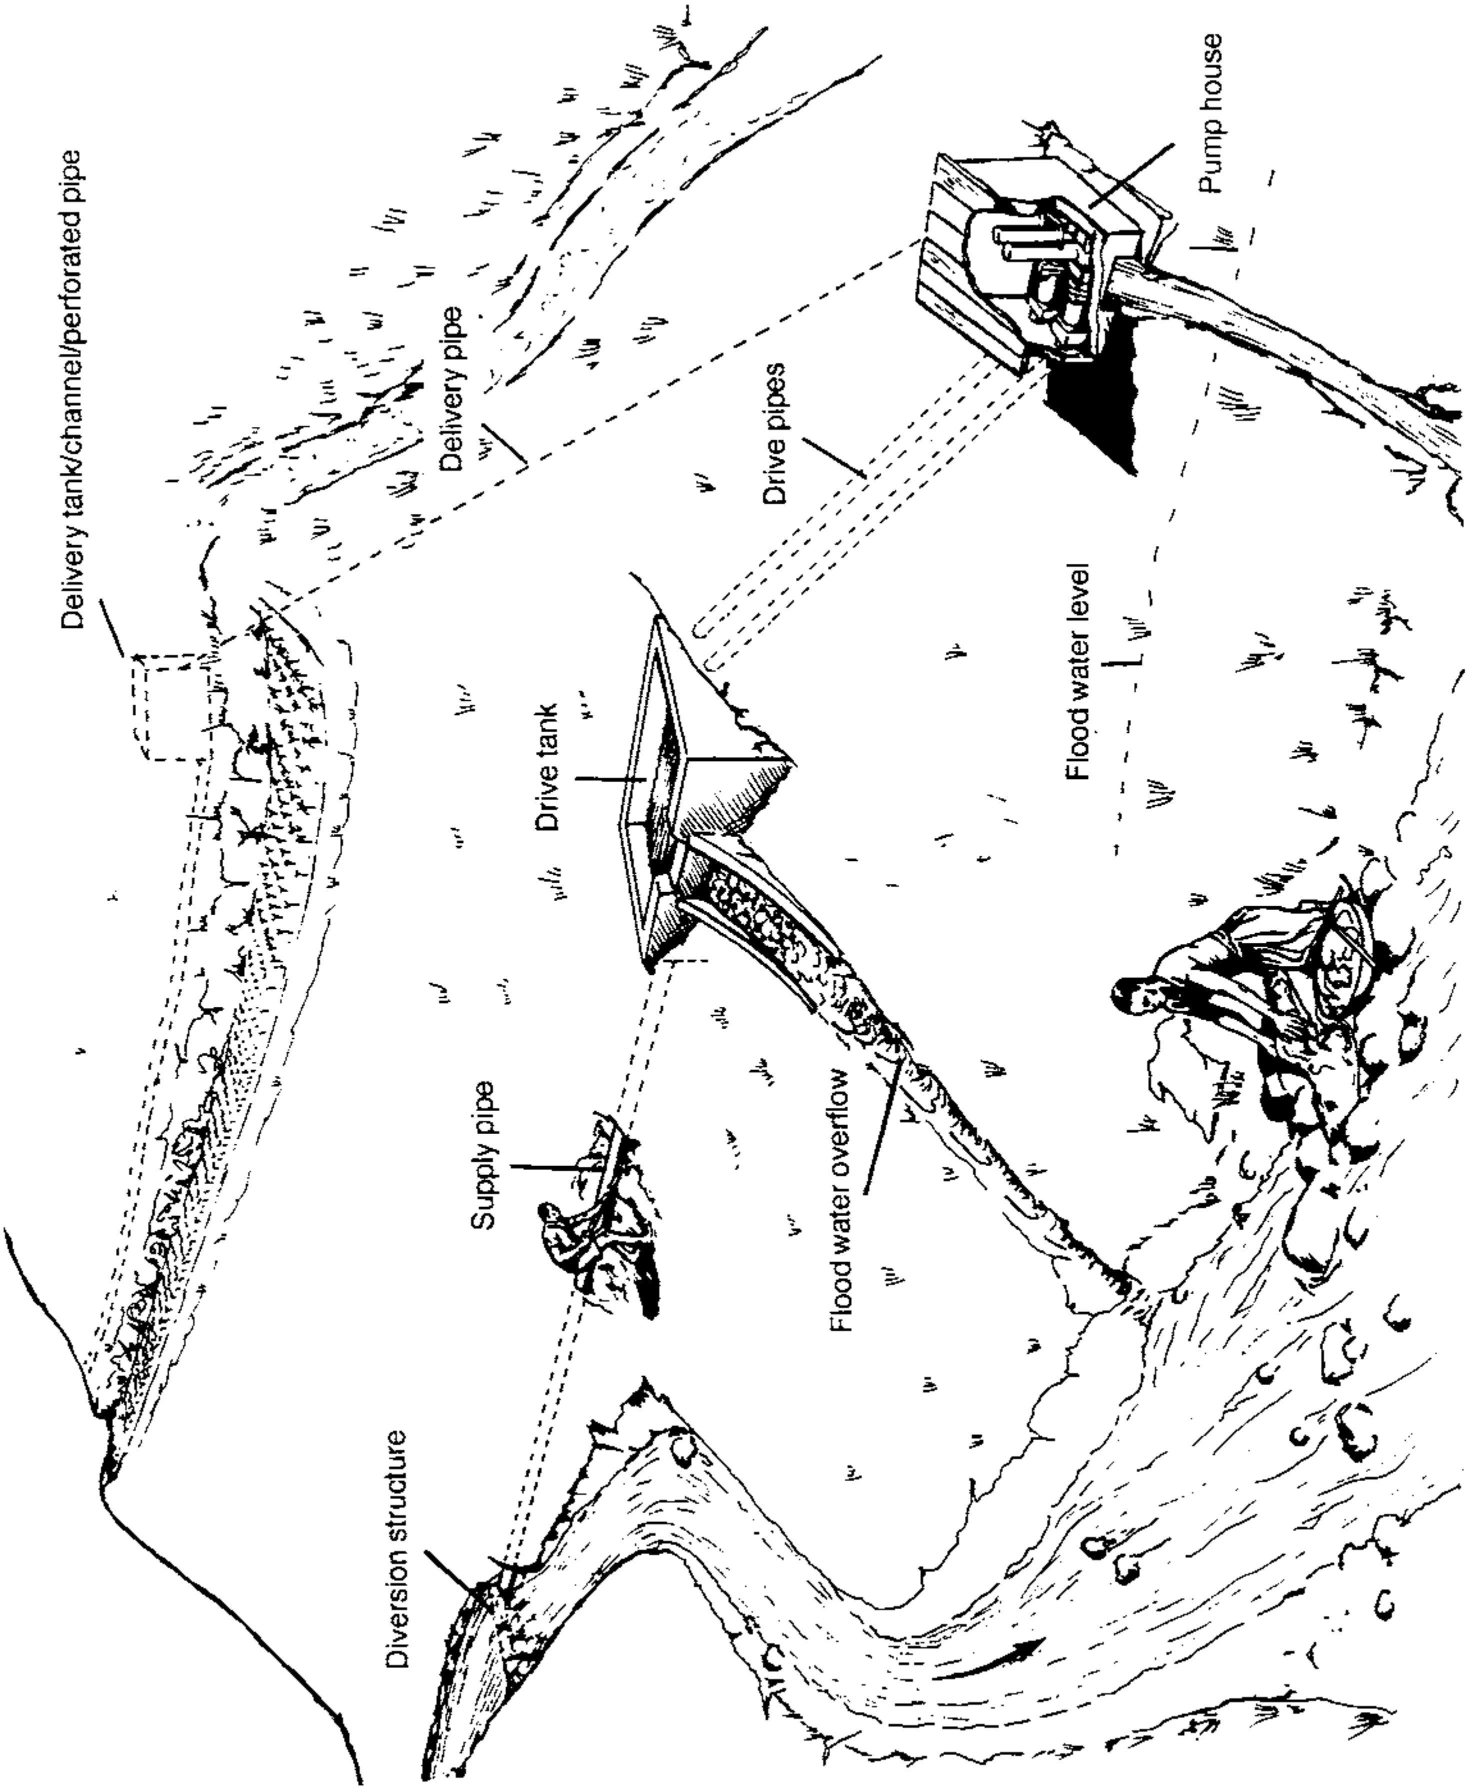
Warwick Design

The low-lift plastic ram pumps developed by the DTU are aimed at small-scale irrigation in Africa. The main design objectives are:

- to produce a pump which can irrigate, reliably, small farms at a height of 12m above a water course
- to make it possible to manufacture within the country of use, preferably in rural areas, using components and tooling techniques widely available
- to create employment in workshops with both manufacture and maintenance.

A hydraulic ram pump system (refer to diagram on the next page.)

The diversion structure channels water flow into a pipe or conduit which follows the contour (with a slight slope) away from the stream to the drive tank. The drive tank is at a point about 2m above the stream. Separate drive pipes bring the flow down the 2m "head" to drive the parallel pumps (between 1 and 4 pumps). A common delivery pipe takes the pumped water up to a delivery tank. The system can deliver about 7% of a stream flow at any single location. Another set of pumps at another location down stream could lift another 7% of the stream flow remaining and so on. This 7% maximum could be increased if the drive head were greater than 2m or the delivery head less than 12m.



Delivery tank/channel/perforated pipe
Delivery pipe
Drive pipes
Pump house
Drive tank
Flood water level
Supply pipe
Flood water overflow
Diversion structure

Performance
The characteristic of a particular (DTU) ram pump was found to be:

Delivery Head (m)	6.2	6.7	9.6	10.0	15.5	16.0	20.3	21.5
Delivery Flow (l/min)	17.0	15.5	12.0	11.3	7.0	6.8	4.6	4.2

The figures in the above table were taken from tests taken with a prototype plastic pump at HCTC, Bonda in September 1989 and are also plotted on the next page. The pump drive head was 1.2m and the delivery pipe had negligible friction. The pump was tuned for maximum delivery, not maximum efficiency, and so the average efficiency was only 23%, which is pretty low. Note how the delivery flow falls as the delivery head is increased. In practice, with the losses in 100m of 25mm delivery pipe, and 30m of conduit, these results would be more representative of a system drive head of 1.5m. From these figures it was predicted that in a standard configuration (2m system drive head and 12m delivery head with a single pump), about 17500 litres per day would be delivered, capable of irrigating about one third of a hectare in the dry season. Reconstruction of the demonstration system at HCTC in 1990 to fit these conditions has confirmed the prediction.

Siting
The siting of a ram pump is a very important part of the system design, affecting both the cost and performance. Some guidelines are:

- choice of a site where the water course falls reasonably rapidly - this will reduce the length of the conduit and make a larger drive head possible
- the flow through each pump should be at least 3 litres/sec (and preferably 6 litres/sec)
- the land for irrigation should not be more than 12m above the pump(s) and as close as possible to the pump system - reducing cost and headloss in the delivery pipe
- there should be some way of protecting the system from flood damage and/or theft - possibly by siting above the high water level, having capabilities for removal, or enclosing in some protective chamber.

Manufacture
Assistance will be required with site selection and installation by trained personnel whose travel would prove costly if they were not locally based. The pumps and spares should be made in- country to ensure the reliability of supply. There are advantages in integrating manufacture with installation because it allows for feedback from the user and a quick, reliable maintenance service. Further, it would be a form of rural employment generation outside agriculture which is greatly needed in Zimbabwe. So, if possible, the pumps should be manufactured locally.

This, however, has implications for the manufacturing techniques used because the numbers of pumps required are unlikely to warrant the purchase of expensive machinery. The system is therefore designed so that it could be manufactured using:

Materials

plastic (PVC) extruded pressure and drain pipe, and standard pipe fittings
standard steel bolts, rods and sheets
concrete

Techniques

use of basic metal and plastic cutting tools
use of a drill and thread cutting dies and taps
use of solvents
basic building skills

Cost

The components to produce one plastic ram pump (including foundations, drive pipe and drive tank) cost about Z$600 and 100m of 25mm diameter delivery pipe costs another Z$400. Allowing a further Z$500 for labour and for the (say 30m) conduit gives an estimated price of Z$1500 for a single pump installation. This includes no provision for storage of the 8 cubic metres of water pumped at night: a concrete tank this size might cost Z$3000 but a pond of this size much less. If several pumps are operated at one site, the cost per pump will be much lower: a 4-ram pump system irrigating 1.2 hectares might cost Z$4000 excluding water storage. Costs are somewhat site specific.

Development status

There are a number of test sites in UK run by the DTU, as well as the one at the Chitepo Training Centre. A workable design is at present being tested, however there is need for improvement and the design features to be improved are:

- durability
- simplicity of manufacture and use of alternatives to components scarce or unavailable in Zimbabwe (for example pressure elbows which have disappeared from the local market)
- overall pump system costs.
- Further areas of development will be:
- increased pump efficiency and performance
- wider sharing of expertise.

2.3 The treadle pump

Background

Broadly speaking, the treadle pump uses foot power through one or two rocking foot bars (or boards) to produce pumping power. The use of feet as the propeller means that the strong leg and back muscles are employed as well as the operator's body weight. Ergonomic research shows that the mechanical advantage over hand pumps can be up to 3 times. Because the treadle pump is human powered, it can of course lift from both static and running water sources.

Harare design

Following research into human-powered pumping by Loughborough University (WEDC) jointly with the University of Zimbabwe (Civil Eng), there have been demonstrations in Harare of both a treadle pump and hand powered "rope and washer" pump. For the reason outlined above the treadle pump is likely to be more appropriate for the large water needs of irrigation.

The Harare design:

- will pump to a maximum of over 15m, but only about 6m is suitable
- has adjustable mechanical advantage - allowing for the different size and strength of the operators and for different lifts
- is made of component easy to fabricate and so replace if needed is manufactured in country.

The pump works by the operator standing on 2 foot bars attached to 2 parallel piston-pumps which are operated by each leg alternately in a walking motion. There is a common suction pipe leading from the water and a common delivery pipe which would be used for direct irrigation, without storage.

Performance

In a test carried out to evaluate the usefulness of a treadle pump, compared to the traditional method of carrying a bucket, we obtained the following results.

	Treadle	Bucket
Man A	30.0 litres/min	9.6 litres/min
Man B	30.0 litres/min	12.0 litres/min
Average	30.0 litres/min	10.8 litres/min

This was for a lift of 6m and a carry distance of 40m, working for half hour periods and using 25mm delivery pipe and a 20 litre bucket respectively.

The ratio of efficiencies is 2.8 to 1 in favour of the treadle which (if it was operated for 4 hours in a day) would deliver 7,200 litres. The men involved in the test commented that the treadle was much easier to sustain, and once they were adapted to its motion, they could keep up say 50 minutes pumping in each hour. By contrast, they felt that they needed more frequent rests when carrying buckets. However it must be noted that in contrast to pumping, the effort to carry buckets depends more on distance than on height lifted. Thus the comparative advantage of the pump would decrease with shorter distances carried and increase with longer ones. The distance used in the experiment was only slightly greater than the 30 metres from a stream prohibited from cultivation by law.

Manufacture
The prototype used was manufactured in an informal sector fabrication workshop in Mbare, Harare, where they are in serial production. The sale price for a single pump is about Z$800 to which must be added the cost of a delivery pipe at about Z$4 per metre. No water storage tanks are required. The leather piston cups are bought in, being available on the market.

Development status
The pump is a working product, and a number have been produced in recent months. However it has not experienced extended field use and there is some scope for further improvement. Areas deserving attention include cost reduction, better piston sealing, reduction in the number of welds required for manufacture, addition of an intake filter and simplification of the method of adjusting the machine to users of different physical size (indeed the ergonomics of the pump merit further study and redesign). Research into these issues is under way at Warwick University.

3. AREA IRRIGABLE BY LOW LIFTS FROM STREAMS

Stream water, especially in the dry season, is a scarce resource; existing downstream users will not permit the emptying of streams for irrigation in upstream Communal Areas. An abstraction of 25% of dry-season flows might be an acceptable target for an irrigation programme, after which seasonal storage must be used.

Extensive hydrological records, extending over two or more decades, are available from the Ministry of Water Development which maintains over 20 gauging stations in Manicaland. The rainfall, and the dry season runoff per unit area, vary widely across the Province and even within a given agroeconomic zone. Peak monthly flows vary widely from year to year (although most gauging stations cannot record flows in major floods), but minimum monthly flows are more stable. At one site (Tindini Rodel Township) in 1982-4 for example, peak (February) flows were below 10% of their 10-year average but minimum (September) flows were 40% of their 10-year average. At this location, the September flow exceeded for 9 years out of 10 was about 2.2 l/s for each square km of stream catchment area. By contrast the Mare River near its mouth in Nyanga National Park has a September 90%-exceedance flow of 5.5 l/s per square km of catchment. This latter figure is untypically high, since the Mare River drains Zimbabwe's highest mountain, and its flow is regulated by three dams. We may assume that over the whole of the highland parts of Manicaland (including the Honde Valley) there is about 3 l/s of reliable dry-season flow per square km of catchment.

Using 25% of this 3 l/s yields a flow of 65000 l/day/sq. km, capable of irrigating about 1.3 hectares of land in Winter if applied carefully. On this basis, water availability would appear to limit irrigation to about 1.3% of the land surface. The fraction of the land which is cultivable is not know but is probably around 25%, on which basis some 5% of cultivable land might be irrigated.

In May, rather than September, this fraction might be doubled as mean river flows are about twice those in September.

Table of Mean Monthly Flows over 10 Years at Rodel Township
(Gauging Station DGP 27), expressed as l/s/sq.km of catchment

Month	Oct	Nov	Dec	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep
Flow	4.0	4.2	7.2	12.7	20.5	15.8	8.9	7.0	5.8	4.7	3.9	3.4

(Minimum flow recorded in 10 years = 1.2 l/s/sq. km Maximum flow recorded in 10 years = 67 l/s/sq. km)

A more difficult question to answer is "*is 1.3% of the land area topologically suitable for irrigation?*" Suitability requires adequate depth of soil, modest slope (under 8%?) and elevation not more than say 10m above an adjacent stream bed. Subtracting "forbidden" land (within 30m of a stream) from the total, and acknowledging that many of the saddles and outwash aprons surrounding the granite massifs are too high, it seems that in much of highland Manicaland the availability of suitable plots may be as severe a constraint on irrigation as that caused by water shortage.

On a 1:50000 map with 20m contour spacing, a slope of 5% requires contours to be 400m apart, which is 8mm on the map; a slope of under 2% gives contours over 20mm apart. Examinations of map sheets 1832 B3 and B4, 1832 D1 and D2, covering in all about 3000 sq.km of North Manicaland, indicates very little land of under 2% slope. Less than 30% of the land is under cultivation perhaps half of which is slope 5% or more. This scale of map is rather small for such estimates and their confirmation requires more careful work on larger scale maps.

Stream gradients, even in the lower reaches of the Odzi, Pangwe, Honde and Nyadiri Rivers, generally exceed 1% (with valley side 4 to 10 times steeper). Thus conduits (furrows) to attain a height of 10m would be typically 400-800m long. By prudent choice of sites that correspond to rapids, feed pipes to give 2m head to a ram pump would be about 30m long. In general a lift of 5m is required to raise water clear of the immediate stream gorge.

A more detailed study of a particular Communal Area, namely the Honde Valley was made in December 1990. That part of the Honde basin that lies within Zimbabwe has an area of around 500 square kilometres. The valley is extensively cultivated except where slopes exceed 15%: there is little terracing. About half of the Valley is within five kilometres of a metalled road, however the nearest urban market is Mutare, some 70 kilometres from the centre of the area.

The Honde River is, along much of its length, too large and therefore costly to dam, so low-cost irrigation must make use of the water only in tributary streams. Irrigation using manual pumping (and hence no dam) is not generally feasible from this river, given the lift needed from its dry season level to any legally irrigable land. By matching observation (shortly after the first rains of the 1990/91 summer), resident's comments and map studies, it was concluded that only at about four kilometres from its source was any tributary likely to have a usable perennial flow. As a general rule, therefore, water is both available and economically extractable from those parts of streams between 4 kilometres and 15 kilometres from their sources: there is a total length of 40 kilometres of streams satisfying this condition in the Honde Valley.

A head of two metres to drive a ram pump is obtained in part (say 0.6 metres) by constructing a small dam and in part by taking advantage of the natural fall of a stream. Assuming an economic ceiling of 35 metres on drive pipe/feed pipe length, and a local slope at the pump site of three times the average stream slope, gives a minimum "average stream slope" of 1.3% for the installation of water-powered pumps. All the 40 kilometres of stream already shortlisted has a slope exceeding this value.

A stream can also be too steep for water-powered irrigation in that a high slope favours irrigation by gravity via a contour canal. Taking 10 metres as the height above the stream bed to command a useful amount of land that is both above the stream's immediate gorge (typically 5 metres deep) and a legally adequate distance from the water (30 metres), the length of an irrigation canal must exceed 10 metres/streamslope. At stream slopes exceeding 4% (14 kilometres out of the 40 kilometres identified) such a canal would be only 250 metres long and would probably be cheaper to build than an equivalent hydraulic ram pumping station.

There are already a few irrigation canals fed by tributaries on the north side of the Honde River. These tributaries descend a high escarpment, two of them having dramatic waterfalls visible from 10 kilometres away. The one canal investigated (Makanga Valley) carried 1.3 litres per second - enough to irrigate about two hectares. Another canal is reported to be considerably larger. Canal building is not however a common skill and on many otherwise favourable sites hard rock requires blasting or cutting if contour channels are to be created. Once clear of the immediate stream gorge channels can run in softer ground but these suffer from considerable seepage. The present few channels are unlined, but using fibre-cement techniques now being employed for roofing in Manicaland, lining might be economically achievable.

On the south side of the Honde River there is at least one example of irrigation water being piped from a spring. Suitable pipe is now very expensive in Zimbabwe (eg. Z$1600 for 400 metres of 40 mm outside diameter) and such irrigation is only likely to be economic on especially favourable sites where the pipe slope can be maintained at over, say, 8%.

Valley sites in the study area are very variable in terms of stream slope, the depth of the flood gorge and the slope of cultivable land above the flood gorge. About 3% of valley sides are suitable for manual irrigation having shallow gorges and cross slopes under 5%. Another 30% of valley sides appear suitable for ram pump or contour canal irrigation, having gorges not over 5 metres deep and subsequent slopes of 5 to 10%. For both cases each irrigable slope above a gorge is likely to be about 60 metres wide. In total therefore, there are about 4 irrigable hectares per kilometre of suitable river, giving a Honde Valley total of 160 hectares, which is 0.3% of the Valley's area.

River flow records are not available in the Valley, but using the flows derived earlier for adjacent areas, there is ample water for 1.3% of land to be irrigated. This compares with the figure of 0.3% apparently suitable terrain in the Honde Valley. Choosing the lower of these figures and applying it to the total area of Communal Lands in Manicaland lying in Natural Regions I or II (high rainfall) yields a total of about 1,000 hectares of irrigable land, or ten times that number of typical 0.1 hectare gardens. In the short term various factors may reduce this figure by up to 60% and a range of 400 to 1,000 hectares potential may be used. In the long term extensive construction of contour canals could double or treble the irrigable areas.

4. PATTERNS OF IRRIGATED AGRICULTURE

4.1 Dry Versus Wet Season Agriculture

This part of the study attempted to find out how small-scale irrigation usage would effect agricultural practices within the villages visited in N.E. Manicaland. A total of 5 villages were visited all within the Honde Valley region on the 29th August 1989 and 30th August 1989: Hambira, Matingo, Gatsi, Dombomupunga and Nyanguzu. Hambira, Matingo and Gatsi are in the Samaringa Area. Dombomupunga is the Sahumani Area. Nyanguzu is in the Nyasanza Area.

From the information collected it would appear that dry-season irrigation would be the most desirable. This period extends from April to October which is also the winter period. From an irrigation viewpoint this seasonality is quite convenient as it means that irrigation water is required when the evaporative demand from the crops is comparatively low.

There are 3 constraints effecting land which can be irrigated by the hydraulic ram pump or other non-motorised pumps. These are water availability from rivers, the height of land above the river and the economical return that can be obtained from the crops grown on the land. Since the amount of irrigation water made available by each pump is relatively small, enough to irrigate approximately 1/3 ha of land at a height of 10m depending upon the evapotranspiration rate, valuable cash crops would be most appropriate to grow. The Gatsi farmers quoted in 1989 that Z$2000 gross income could be earned per hectare of land if vegetables are grown. The farm manager at CATC observed that at 12 tonnes per ha per crop and prices of 35-40c per kg, for tomatoes or cabbages, 1 hectare could gross Z$4800 per crop of Z$14400 per year. These very different 1989 figures may reflect differences in access to markets. In 1990 a group of women in the Honde Valley (which is warm in winter) estimated the dry season income from a small (20 metres x 20 metres) garden as over Z$5 per day, corresponding to Z$25,000 per hectare per season. These figures are affected by 50% inflation over 16 months. A late 1990 gross additional income of at least Z$16,000 per hectare per year seems obtainable if irrigation is introduced.

Besides the possibility of dry-season cultivation there are three options for wet-season cultivation:

> **Option A** would be to increase cotton or maize crop yields by planting seeds just before the wet season started. Compared to dry season irrigation, under option A it may be possible to irrigate a larger area of land, say 1/2 ha. per pump since seeds for the first 30 days after germination require smaller amounts of water. There is evidence that irrigation in October just before the rains could almost double maize yields, earning Z$400 extra per hectare. Both dry-season irrigation and option A have limits upon the amounts of land which can be irrigated because of low flows in rivers before the rains.
>
> **Option B** is to extend the wet-season cultivation of lower value staple/cash crops. This is possible because in April and May, immediately after the rains, water in the rivers is still fairly plentiful. This option would be more costly since more pumps would need to be installed to meet the water demands, however larger areas can be irrigated than under the other options.

Option C is using the pumps as an insurance policy for the cultivation of staple crops during drought years. Possibly 1 year out of 10 does not receive enough wet-season rainfall for crop survival. Installing costly facilities for use only once or twice a decade is rarely cost effective compared with other forms of drought insurance.

Generally speaking it would not seem viable to install a pump for maize or cotton crop use alone, as assumed in options A, B, and C. This is partly because these crops are of much lower value than vegetables. Also these crops are usually grown some distance away from the rivers at a height greater than 10m. Once a pump was installed however its usage could be extended to options A, B, or C, providing all constraints were met.

4.2 Nutrition and Food Security

Since maize is the only storable crop, in the absence of either irrigation or purchasing power, diet would be restricted to sadza, although there is some tradition of boiling and drying of vegetables. In discussions most families said that they do purchase vegetables to improve their diet during the dry season and their interest in irrigation was in significant part to replace these purchases with their own produce.

In N.E. Manicaland serious drought resulting in loss of crops is fairly rare. It seems unlikely a significant area could be irrigated in a drought year when rivers are particularly low. As discussed earlier the economics of irrigation only used in occasional years are particularly poor and other forms of drought relief in these areas would generally be cheaper. Of course in S.W. Manicaland the situation is quite different and drought relief irrigation systems might be used one year in two.

4.3 Maintaining Fertility

All the farmers visited used artificial fertilisers. This was because on average each household owned only 5 cattle, whilst some owned none. Bags of fertilisers were bought from MDA in 1989 at approximately Z$26 per 50 kg bag however subsequent inflation has been substantial. Normally 5 bags of fertiliser are used for 1 hectare of maize - 3 bags of compound D containing amino- nitrate, potash and potassium nitrate and 2 bags of amino- nitrates. An increase in crop production would mean that a) more nutrients would be taken from the soil and b) the land would not be left fallow for the soil to replenish itself. The common answer to the problem appears to be "add more fertiliser".

There is concern that pumping so much fertiliser into the soil is reducing the organic component of the soil which in turn endangers the soil structure. Environment and Development Organisation in Africa (ENDA) is presently researching methods to increase the organic element. Organic matter other than manures are crop residues, specifically grown compost and soil from elsewhere (eg. anthills). At present the management of dung and crop residues is rather poor. In other parts of Africa where land pressures are higher, composting, zero grazing of animals etc. are used to supplement or replace artificial fertilisers. It would be unwise to rely wholly on artificial fertiliser to provide the extra fertility required when irrigation and multi- cropping is extended. Pesticides are not generally used in Communal Areas because they are both hazardous to health and expensive.

4.4 Soil Erosion

On several of the sites visited, cultivation was being carried out within 30m of the river bed on slopes. Under the "Streambank Protection Regulation" this action is illegal. This Regulation is particularly concerned with reducing siltation in rivers which makes water unavailable to households downstream. Elsewhere, the problems of soil erosion on steep slopes is more a concern of top soil fertility loss which the Regulation does not cover.

From 1989 we were told that the law would be enforced more strictly; the penalties are a Z$25 fine plus the destruction of the crops grown. Farmers are reluctant to give this land up from cultivation, partly because it is an important source of their income, partly because it is so entrenched in their culture and partly because of a lack of realisation of the destruction it causes downstream. However agricultural extension workers have been informing communities of how to prevent unnecessary soil loss. We saw several examples of terracing on the steepest slopes which indicates people's efforts.

Grass leys and furrow ridges were other methods used on more gentle slopes. Grass leys which are grown in contour sections are adequate barriers to soil movement on a slope of 2%. On steeper slopes of 3%, 4% and 5% furrow ridges are needed.

For a 10m lift of water, it seems likely that the land at this height will still be part of the steep valley sides assuming that most river valleys are "V" shaped which is indicated on the survey maps of N.E. Manicaland. If this is the case, soil erosion protection will need to be applied. Agricultural experts are available to mark out the contour lines, but then much person power would be needed to build the furrow ridges. Wild flooding appears to be the type of irrigation known and used in N.E. Manicaland. Water is delivered at several points from a supply channel running along the upper edge of a sloping plot or field and is allowed to move freely down the slope. Its popularity is no doubt due to its simplicity. It is a system involving a minimum amount of land preparation and does not require much labour in operation. However it is dangerous to use it on light soils that are prone to erosion. Also it does not distribute water uniformly, which means extra water is required to ensure that all points receive the necessary amount.

The best way to apply water, especially in situations where the water supply rate is low, for example 20 litres per minute, needs further thought and experimentation. Very careful application of suitable irrigation methods is required on sloping plots.

4.5 Economics and Evidence of User Interest

The foregoing discussion has indicated an extra gross income per hectare, attributable to irrigation of some Z$16000 (in the form of produce sold or in food retained by the cultivator's family). This income has to pay for the irrigation itself, for other inputs and to provide a recompense for the farmers' extra labour. It seems acceptable to assign 50% of this income to payment for the water supplied - Z$8000 per hectare per year. As non- motorised irrigation costs are dominated by the capital costs of initial provision rather than running costs, and as the different components of a pumped irrigation system have a life of between 3 and 15 years, a simple payback period of 3 years has been assumed.

Combining these assumptions yields a ceiling for the capital cost of creating an irrigation system of Z$24000 per hectare. Estimates in section 2.2 and 2.3 suggest that for favourable sites it should be possible to keep well below this ceiling. Overnight storage of irrigation water may create a greater income by using it for fish farming.

According to local farmers there was very strong interest in irrigation being applied on their land. In those places in the Honde Valley, eg. Hambira Village, where gravitational systems were already installed, peoples' initial interest was to expand these. Concerning pumps, they wanted assurances that they would do their job, could be maintained and repaired when they failed and that they would be able to pay back a loan borrowed for their initial purchase over several years. In 1989 the Agricultural Finance Corporation lent money at an interest of 13%. Because this rate was seen as high, farmers were reluctant to take up loans. Interest in irrigation is stronger in 1990 than a year earlier due to most farmers being under greater pressure to generate new income.

5. LEGAL AND SOCIAL IMPLICATIONS

The re-use of domestic water for small gardens is regarded as "Primary" water use. In practice very small-scale irrigation is also unofficially treated as primary water use. Licences are effectively not required for scattered small-scale irrigation of gardens. Different unofficial opinions suggested a ceiling of 1/2 ha. on unlicensed irrigation. In terms of an irrigation programme for Communal Areas, there will come a stage when water abstraction is significant, eg. 10% of flows, at which point licensing probably will be required. Although small farmers no doubt have the political sympathy of the licensing authorities it will be important that they are not thought to use water wastefully.

Income for a typical farmer varies. At present in a good year, she could earn Z$1000 from her farm plus a little more from craft work (eg. crocheting) in Winter. Many of the men work in the towns and can earn Z$2000 per year. However because they require lodgings in the city they may send back only Z$700 per year. The cost of living is going up dramatically, without a corresponding income rise. Because primary education is free, children still go to school, but not all go to secondary school which costs about Z$200 per year per child and is about to rise sharply. Secondary schooling lasts for 4 years from age 14 to 18 and most families can only afford secondary education for 2-4 children.

In all the villages we visited, we spoke only to the women, because they are the farmers. They were all keen to grow another crop during the dry season. The women at Hambira mentioned that there was usually less work to do at this period. This was despite the fact that many had small winter gardens close to their houses, watered by gravity or by bucket. Time is spent collecting firewood and doing limited amounts of gardening. An extra crop would increase their workload but also time would be saved for those who now have to carry buckets of water from the river. They did not see the extra workload as a limiting factor because they would simply employ their family in the fields. A typical family has 7 children, which is beneficial in terms of labour supply. The main ambition of most farmers is to be able to send more of their children to school. Since agriculture is their primary source of income, this indicates the importance of creating more income form irrigated crop production. The women said that they would sell extra crops within the local community since there is no transport to take produce to a bigger market. The local market is best when the schools are open because farmers can sell their produce to the schools and to the school teachers.

For a modest increase in smallholder irrigation neither legalities nor work loads appear to be major constraints. Improvements in marketing, especially in terms of transport, will be required if there is a substantial increase in the production of Winter vegetables.

6. SMALLHOLDER IRRIGATION DEVELOPMENT PROGRAMME

The Manicaland Development Association has for some time wished to respond to the requests of its member groups for help with irrigation. Small-holder irrigation is a specialism in which few are expert, and techniques need careful adaptation to local conditions. If MDA is to mount a major irrigation promotion programme, probably lasting 5 years, that programme is likely to require the following components:

a) The identification and refinement of suitable irrigation water-supply techniques for use in Communal Areas.

b) The identification and refinement of agricultural techniques to make the best use of irrigation water.

c) The identification, in much greater detail than in this study, of user priorities, of physical and legal constraints, of markets for dry-season produce and of favourable specific locations.

d) The creation of an irrigation construction team able to survey, assess, design, procure parts for and oversee the construction of small irrigation schemes by MDA member groups. This may be backed by a workshop making pumps, assistance in marketing and help in obtaining water licences.

e) The establishment of a training and extension programme to disseminate the findings of the research components above, especially with respect to:

- agriculture
- maintenance and operation of irrigation schemes
- (later) construction of new systems.

A good case can be made for incorporating into the irrigation programme a fish-farming component. The two activities can often be profitably combined, sharing some common facilities. Increasing the production of fish protein for sale or local consumption is another of MDA's long term interests.

7. CONCLUSIONS

Within the limitations of a brief study it appears that there is considerable scope for the expansion of dry-season (Winter) irrigation of small plots in the Communal Areas of Manicaland using water from small rivers. It is likely that similar conclusions hold for the eastern side of south Manicaland. Using a variety of assumptions it appears that there is enough water to irrigate about 1.5% of the land without requiring seasonal storage of water behind dams. However only 0.3% of land is topologically suitable, which gives a figure of around 1000 hectares in the Communal Areas of Manicaland having good rainfall.

Economically a ceiling of about Z$24000 per hectare has been identified on the capital cost of water provision. Dry-season irrigation appears economically superior to supplementary irrigation just before or after the rains, or to "insurance" irrigation for drought years.

Two suitable pumps have been tested in prototype form. A ram pump system, possible cost Z$1500, lifted enough water in 24 hours to apply 5mm of water to 0.35 hectares of land 10 metres above the headworks, providing a drop of 2 metres was available to drive it. In commercial form, with overnight water storage for each 0.1 hectare garden, multiple-ram pump systems would cost some Z$8000 per hectare. A treadle pump system tested against a lift of 6 metres and a distance carried of 40 metres raised 72000 litres in four hours, enough to irrigate 0.15 hectares: this was 2.8 times greater than raised by the same people in the same time using buckets.

No major legal or social barriers to expanding irrigated gardens were identified and farmers interviewed expressed considerable enthusiasm to expand their incomes in the way. Changes in marketing facilities, especially transport, will probably be needed if dry-season vegetable production is much expanded.

A 5 year programme for MDA to help its member groups expand irrigated agriculture has been outlined.

APPENDIX A:

HYDRAULIC RAM PUMP PERFORMANCE ANALYSIS

In section 2.2 some hydraulic ram pump test results were given. These were obtained in 1989 from the prototype at HCTC. Facilities for the measurement of input water flows (and hence input power) at the test site were very crude, but indicated a drive flow of 6.3 l/s or a little less. Combined with a system drive head of 1.42m, this corresponds to an input power of 88W. On this basis, the results can be restated as follows:

Viable	**Units**								
Lift	m	6.2	6.7	9.6	10.0	15.5	16.0	20.3	21.5
Flow	1/min	17.0	15.5	12.0	11.3	7.0	6.8	4.6	4.2
Flow	1000 l/day	24.5	22.3	17.3	16.3	10.1	9.8	6.6	6.1
Output power	W	17.2	16.9	18.8	18.5	17.8	17.9	15.3	14.7
Efficiency	%	20	19	21	21	20	20	17	17
Pressure swing	%	16	20	13	10	6.5	6	3	3.5

From these figures, the following conclusions may be drawn:

a) The efficiency is very low but fairly constant; the pump adapts to changes in delivery head such that output power is inversely proportional to head.
b) At output heads greater than 20m (corresponding to pressures over 2 bars) performance falls off. In fact the pump durability is unacceptably low at such high pressures.
c) Extrapolating from the test results, a pump lifting water 12m via a delivery pipe having a 1m friction loss should deliver 12500 l/day, or 17500 l/day if the system drive head were increased from 1.42 to 2.0m.
d) The pressure swing figures indicate that for large-flow, low-head applications the pressure vessel is too small.

The low efficiency could be significantly improved, at the cost of a small loss in output, if the pump were retuned to run faster, eg. at 60 rather than 30 strokes per minute.

A separate analysis of individual losses indicated:

the exhaust flow kinetic energy accounts for 21% energy losses
the drive pipe friction " " " " 6% " "
the conduit friction (30m x 110mm pipe) " 15% " "
back-leakage through the delivery valve " 4% " "

This leaves 35% losses to be attributed to impulse-valve leakage, to hydraulic friction in valves and other causes. The percentages above apply to a delivery head of 10m, however only the back-leakage component would be greater at higher heads. Loss reduction requires either better fitting parts or the use of a larger ram pump; it is of importance only where it is desired to abstract a significant proportion (say over 5%) of total stream flow at a single site.

Concerning durability, tests indicate that when delivery heads exceed 15m, the pump is very vulnerable to loss of air in its pressure vessel. Absence of this air results in hammering and the fatigue of components within a few hours. An overpressure relief valve is clearly necessary to protect against this.

Tests also showed that air-control needs further attention. Too much air (gulping) reduces output, whereas failure to draw in any air at all results in the gradual depletion of air in the pressure vessel. Provided the pressure-vessel air is periodically replenished, the pump will operate satisfactorily under water.

Further tests with a modified design in 1990 indicated similar power outputs despite much smaller drive flows. System efficiencies of 40% were obtained, corresponding to pump efficiencies of over 60%.

Comparison between DTU and Commercial Ram Hydraulic Ram Pump Performances

UPDATE AND COMMENTS, APRIL 1996

Since this paper was written, the DTU Mark 6.4 pump has been phased out, to be replaced by first the M8.4 and more recently the S2. All these are pumps normally run with a 2" G.I. drivepipe and delivering to up to 100m using a drive flow of 40 to 120 litres/min. Preliminary results for the M8/S2 on a single setting are given at the end of this paper, indicating that, setting for setting, the M8 is superior to its predecessors. Generally the DTU later models are more efficient than the M6. Of course performance as measured in this paper is only part of the story. The DTU pumps are made largely of mild steel and are therefore more subject to corrosion than most 'commercial' machines. In recent years there has been a trend towards use of plastics in ram pumps as pvc or ABS piping replaces galvanised iron. However plastic pumps can rarely operate reliably at delivery heads exceeding 40 meters. There is also a growing interest in providing the air-cushioning of the output via an enclosed air packet (for example closed cell foam) instead of an air vessel with a free air-water surface. This arrangement can effectively increase the usable drive head by allowing the impulse valve exhaust to emerge under water.

In the paper, the early comparisons with commercial pumps use data from a study by T H Delft which were obtained from slightly larger models (from the respective manufacturers' ranges), and with a much higher drivehead, than the comparisons in the rest of the paper.

Details of the current (1996) DTU designs, namely S1 (for use with a 1" steel drivepipe), S2 (2" steel) and P90 (90 mm. pvc) are given in DTU Technical Releases TR11, TR14 and TR12 respectively.

1. INTRODUCTION

This paper details the performance of the DTU Mark 6.4 hydraulic ram pump in comparison to commercial models run under similar conditions. Details of the performance of a number of commercial pumps tested at Delft University, Netherlands are used for comparison.

1.1 Delft University

Between 1982 and 1984 J. Tacke of Delft University of Technology carried out tests on a number of commercially available hydraulic ram pumps. These were published in 1988 with comprehensive details of all results obtained and the development of a mathematical model for prediction of ram performance. As part of this programme field tests were conducted by the Foundation of Dutch Volunteers in Rwanda. These aimed to investigate the technical performance and durability under operating conditions in a community setting, social acceptance and community participation in installing, operating and maintaining a hydraulic ram system.

The presentation by Delft of all laboratory test results is excellent and allows a good level of comparison for tests on subsequent designs. Unfortunately no details of the findings or conclusions resulting from the field trials in Rwanda are made available. However the DTU are greatly indebted to Delft for their provision of such a useful resouce.

1.2 DTU, University of Warwick

The Development Technology Unit has been investigating hydraulic ram pump design, performance and manufacture since 1985. This began with student projects and has grown into a full-time research programme largely funded by the Overseas Development Administration. The aims of the programme are:

a) to analyse in detail the operation of the ram pump gaining a comprehensive understanding of the operating principles and complex hydraulic interactions occuring within the pump.

b) to produce pump designs suitable for manufacture in developing countries using available materials and production processes.

c) to thoroughly test such designs for their performance and endurance (including extensive field trials) and offer findings for widespread dissemination.

d) to develop and prove methods for surveying and design of complete water supply installations.

e) to produce design charts and computer based tools to enable design and field engineers to confidently include hydraulic ram pumps as an option in their water supply schemes.

f) to provide technical expertise and training for two African based programmes installing ram pumps for village water supply and irrigation.

In terms of hardware development the DTU has two distinct working areas. The first is the development of designs of steel hydraulic ram pumps based on the 2" diameter BSP pipe that has been found to be widely available in developing countries and is of an appropriate capacity for small village water supply schemes. The second area of hardware development is the production of plastic hydraulic ram pumps based on widely available 110mm plastic pipe and especially suitable for irrigation close to water courses. Rough specifications and performance indications are given below.

	Steel	Plastic
Materials required		
	2" Galvanised pipe	110mm PVC pipe
	2" Fittings	Small amount of
	Mild steel bar	mild steel parts
Manufacturing process		
	Welding	Hand tools
	Drilling	
	Turning	
Typical performance ranges		
	40-140	
Drive flow	40/140 l/min	200-350 l/min
Drive head	2-25m	0.5-2.5m
Delivery flow	2-12 l/min	2-25 l/min
Delivery head	up to 150m	up to 15m
Efficiency	50-90%	20-60%
Expected life	10 years	3 years

This paper is concerned solely with the comparison of the 2" steel pump with its commercially available rivals. Such pumps have found the widest application to date in supplying water for domestic use.

During the research many designs of ram pump have been produced and tested. In 1990 a design was chosen as having proven itself sufficiently in terms of performance and durability to set a 'benchmark' against which furthest developments could be assessed. It is this model, Mark 6.4, that is used in the following comparison against commercial designs.

2. SUMMARY OF WORK CARRIED OUT AT DELFT

2.1 Selection of Pumps

Delft decided to select 12 rams from 6 manufacturers that were applicable in typical village or domestic water supply schemes. In all, details of pumps from 10 manufacturers were obtained and selection made based on the following criteria:

a) as many types of ram design as possible should be included.

b) tests should include both traditional and modern designs.

c) rams should show a reasonable price to performance ratio.

To enable the latter of the criteria, manufacturers were sent a set of conditions and asked to provide details of the pump they would recommend and its expected output and efficiency.

Table 1 shows the results of this comparison.

TABLE 1 - COMPARISON OF HYDRAULIC RAMS

Arrangement: Source Supply = 90 l/min

Supply Head Hs = 7.50 m

Delivery Head hd = 75 m

Type of Hydraulic Ram	Drive [inch]	Pipe [mm]	Volume of Driving Water Required [l/min]	Pumping Rate q [l/min]	Efficiency trd [%]	Approx Price for Ram Alone [US$-1982]
Vulcan 21/2	2	65	36-114	6.10	68	1200
Blake Hydram 31/2	2	65	45- 96	6.00	67	1000
Sano No. 5/65 mm	2	65	50-110	6.95	77	1000
Rife 20 HDU	2	50	38- 95	5.40	60	1100
Schlumpf 5A23	2	50	50-100	5.50	61	2700
Alto CH 66-110-18	2	65	50- 90	5.40	60	2100
Briau D4	2	50	45- 90	5.40	60	3200
CeCoCo - H50	2	50	25-115	6.90	77	3500
WAMA No. 6	2	65	60-100	4.50	50	1500
BZH-Ram W6	2	65	45- 90	2.70	30	1200

Delft concluded that in terms of performance, the choice should favour the first eight pumps and of these the first six provide the best performance to price ratio. From the information given the choice seems to be a reasonable one.

An alternative comparison to evaluate the performance to price ratio would have been to include a cost per litre delivered under these conditions. This significantly alters the ranking of pumps as is shown in Table 2.

TABLE 2

Type of Hydraulic Ram	Pumping Rate q [ℓ/min]	Efficiency (Trade) (%)	Approx Price for Ram Alone [US$-1982]	Cost per litre delivered	Rank
Vulcan 2½	6.10	68	1200	197	3
Blake Hydram 3½	6.00	67	1000	167	2
Sano No. 5/65 mm	6.95	77	1000	144	1
Rife 20 HDU	5.40	60	1100	204	4
Schlumpf 5A23	5.50	61	2700	491	8
Alto CH 66-110-18	5.40	60	2100	389	6
Briau D4	5.40	60	3200	593	10
CeCoCo - H50	6.90	77	3500	507	9
WAMA No. 6	4.50	50	1500	333	5
BZH-Ram W6	2.70	30	1200	444	7

It would also have been interesting to include details from rams currently manufactured in developing countries. Details of the rams selected are given in Table 3.

2.2 Assessment of Experimental Procedure

The tests conducted were fairly comprehensive with each ram being observed for approx. 1 month. The test rig employed allowed a supply head of between 0.5 and 3.0 m with a drive pipe length of 12m. Such a low drive head range is clearly the product of laboratory limitations and does not reflect typically observed ranges in the field of 2 to 20m.

Flows were measured by collecting water for a timed period and weighing it. For each setting this was repeated a number of times to give a more accurate average flow. This is potentially a very accurate method of flow measurement but is open to numerous experimental errors. However it does avoid the need to use flow meters that have their own inaccuracies despite careful calibration.

The designs of ram pump tested exhibit a number of different types of impulse valve. Four of the six have traditional valves above the axis of the pump body but the Schlumpf has its valve below the axis. No mention is made in the text of the Delft work as to where the supply head was measured from. To allow accurate comparison the head should be taken from the orifice of the impulse valve, not the axis of the pump body. In reality both the SANO and Schlumpf pumps may in some situations be able to utilise a given supply head more effectively by their impulse valve design.

TABLE 3 - HYDRAULIC RAMS SELECTED

Type of Hydraulic Ram	Manufacturer	Drive Pipe Diameter [ins]	[mm]	Intake capacity [l/min]	Description
Blake Hydram No. 2 Blake Hydram No. 3.5	John Blake Ltd England	1.5 2.5	40 65	12-25 45-96	A well-established standard design made of cast-iron. Both waste valve and delivery valve consist of a rubber disc covering a perforated gunmetal seat.
Alto J 26-80-8 Alto CH 50-110-18	J.M. Desclaud France	1 2	25 50	8-15 30-60	A recently renewed pump design made of steel pipe components, but using conventional valve designs. Weight-loaded gunmetal waste valve; spring-loaded rubber clack as delivery valve.
Vulcan 1" Vulcan 2"	Green & Carter England	1 2	25 50	4-18 23-46	A standard design made of cast-iron; like the Blake Hydram available for a long time. Both waste valve and delivery valve consist of a rubber disc covering a grid shaped, gunmetal seat.
SANO No. 1-25 mm SANO No. 4-50 mm	Pfister + Langhanss Germany	1 2	25 50	6-16 30-65	A rather unconventional' design, nowadays made of fire zinc-coated steel. Both waste valve and delivery valve are spring-actted and substantially made of gunmetal.
Davey No. 3 Rife 20 HDU	Rife Hydr. Eng Mfg. Co.	1 2	25 50	5-15 38-95	Rife: a fairly standard design made of cast-iron. Weight-loaded rubber waste valve, mounted on a rocker-arm; delivery valve is a rubber disc covering a grid iron seat. Davey: less efficient, less expensive low base configuration, using a weight-loaded gunmetal waste valve and a weight-loaded leather washer as delivery valve.
Schlumpf 4A5 Schlumpf 4A23	Schlumpf Ag Maschinenfabrik Switzerland	1.5 1.5	40 40	30-60 30-60	A design available in 2 models. Model A23 uses a spring-loaded rubber waste valve mounted on a rocker and a weight-loaded rubber washer as delivery valve. The less efficient model A5 uses a weight-loaded rubber waste valve.

The laboratory experiments also included the use of piezo-electric pressure transducers, displacement transducers and strain guages to observe in detail the changes occuring. Although the resolution of these observations is low they are well presented and provide useful insights into pump operation.

The major criticism of the information presented by Delft is that they supply no indication of how each pump was setup when the results were taken. They simply state that 'waste valve adjustment' was 'kept constant' over the whole range of tests. To ensure a fair comparison the waste valves were presumably initially adjusted to the manufacturers recommendation that would give the best overall performance (efficiency and power output) under typical operating conditions. If this was not the case then the results are practically worthless as some of the pumps may have been badly tuned whilst others were well tuned for the given operating conditions.

2.3 Summary of results

The results presented by Delft are comprehensive within the limitations of their test rig. Delft provide data for 3 supply heads for each pump over a range of delivery heads. Of these the highest (3m) has been taken as being the most representative and all results presented below are for this fixed supply head. Table 4 shows some results for efficiency and power at typical supply to delivery head ratios.

TABLE 4 SUMMARY OF TEST RESULTS

Pump	Efficiency (%)			Power (Watts)		
	at 30m	at 60m	max	at 30m	at 60m	max
Blake No 2 (1½")	70.5	67	70.5	15.2	12.8	15.1
Blake No 3½ (2½")	72.5	68	73	38.2	12.8	15.1

Davey No 3 (1")	54	-	60	3.4	-	4.7
Rife 20HDU (2")	43	48	48	19.1	19.6	12.7
Schlumpf 4A5 (1½")	-	-	62	-	-	15.2
Schlumpf 4A23 (1½")	43	15	62	8.8	2.0	17.2

Five of the pumps tested are of similar specification to the DTU models and were therefore selected for analysis and comparison. Graphs 1 and 2 show power and efficency curves for these five pumps. The large variations between pumps can be seen quite clearly and comparison is complicated by the marked differences in the power and efficiency curves. At low heads for instance the Vulcan 2" ram is the most efficient but has the lowest output power and will only run up to a delivery head of 85 m.

2.4 Conclusions about commercial pumps

Delft offer no conclusions or direct comparisons between the various pumps tested. The results are complex and comparison has to be based on many factors in order to produce sensible recommendations. In any given situation the exact requirements will vary. The points given below are an attempt to pick out the main items in order to draw some conclusions.

1) The Vulcan 2" has the highest efficiency recorded at 76.9% and at low heads (up to 36 m) has the best effiency of all the pumps.

2) The Rife 2" has the lowest efficiency up to 70 m and never increases over 50%. However it has the widest range of delivery heads over which it will operate. Overall it would be fair to say that the Rife pump has the poorest efficiency.

3) Overall the Blake 2½" is the most efficient closely followed by the smaller Blake 1½". They show good efficiencies over the normal operating range and will pump over a wide range of delivery heads.

4) Similarly the SANO 2" shows good efficiencies over a wide range of delivery heads and is more efficient than the Blake pump over about 75 m.

5) The Vulcan 2" has the lowest power output over its small range of delivery heads.

6) Blake 2½" is clearly the most powerful pump over its entire range.

7) At low delivery heads (up to 75 m) the SANO 2" has a slightly higher output than the Rife 2" which above 75 m is better. However there is little to choose between them over the complete range of operation.

8) Attempting to combine both power and efficiency it would seem reasonable to conclude that the Blake 2½" offers the best overall performance. Of the remainder the SANO 2" would seem to be the best compromise.

2.5 Non-Dimensional Comparison

Delft use a further means of pump comparison by graphically presenting the ratio of delivery to supply flow (q/Q) over a range of delivery to supply head (h/H) ratios. Thus a non dimensional comparison between pumps is possible. For any given head ratio the greater the ratio of flows the better the performace of the pump. Graph 3 shows these ratio curves for the five pumps chosen. Only two conclusions can sensibly be drawn from this comparison:

1) The Rife 2" is notably worse than all its rivals.

2) There is little to choose between all of the other makes of pump.

Despite this lack of obvious conclusions the ability to compare pumps using non dimensional parameters may prove valuable.

3. SUMMARY OF DTU TESTS

3.1 Experimental rig and procedure

The DTU has established performance testing rigs at the University to allow comprehensive analysis of prototype pumps. The major restrictions imposed by the rigs location are:

i) drive pipe length - limited to 10.5 m and horizontal
ii) drive head - restricted to 2, 3, 4 or 5 m

The delivery head is controlled using a needle valve providing an accurately variable orifice over which the desired head can be dropped (measured by a pressure guage). Both drive and delivery flows are measured by float type flow meters for fast and accurate readings.

For their tests Delft used three drive head setting, 1, 2 and 3 m. However for comparison between DTU and commercial pumps only one drive head was chosen (3.0 m).

3.2 Pump Tuning

The DTU pump design selected for testing was the Mark 6.4 which typically uses a 2" BSP drive pipe but also runs using 1½" pipe (see Figure 1). As the Delft work gives no clear indication of how pumps were tuned a series of results were recorded using different settings of the impulse valve. Low stroke, low weight settings generally give high efficiency and low power output Up to a point it is also true to say that high stroke,

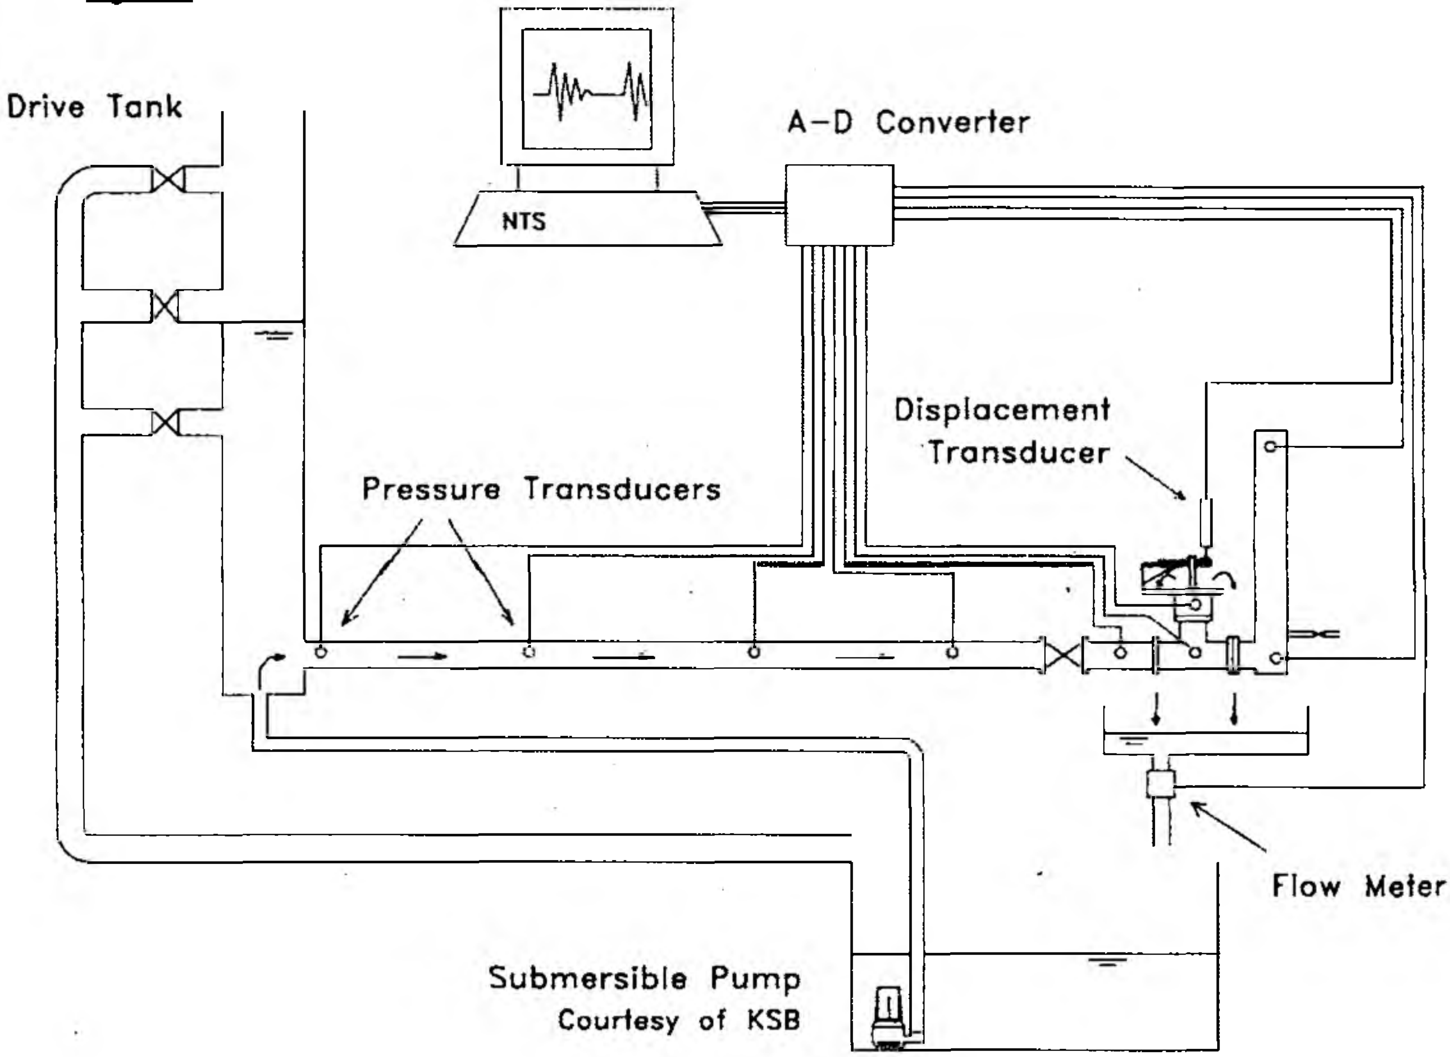
high weight settings give low efficiency and high output power.

Choosing which of these results are used to compare against the Delft ones is dealt with in Section 4.1.

Figure 1



3.3 Summary of test results

Table 5 gives a selection of results for identical conditions as those in Table 4 for the commercial pumps.

Graphs 4 and 5 show the variation in efficiency and power over the full range of potential delivery heads.

Graph 6 presents the non dimensional flow ratio to head ratio curves for these results.

The design of the M6.4 pump allows it to be tuned to suit a wide range of flow and head conditions, making one model applicable to many sites. The results show the wide range of efficiency and power obtainable under these given conditions and emphasize how important tuning can be. If drive water is limited then peak efficiency will be required to make best use of that available. If there is plenty of drive water pumps should be tuned to give maximum power output despite the lower efficiency of such a setting.

It is clear that both good efficiency and power are obtainable over a broad range of delivery heads and that the pump is capable of operating at very high head ratios.
The stroke of teh M6.4 design can range between 5 mm 40 mm with infinite adustment between these limits. The minimum weight of the valve assembly is 507g comprising the plug, stem, nuts etc. although recent modification to the pump enables further reduction. Maximum weight is limited by the physical dimensions but 1000g should be considered as the upper limit.

The results show for just a few combinations of stroke and weight how the efficiency and power output characteristics of the pump can be dramatically altered. Low stroke and weight give high efficiency but low power over a limited range of delivery heads whereas high stroke and weight give lower efficiency but high power output over a wider possible range of heads. Tuning of the pump to best suit any particular set of conditions is a complicated process to explain and is dealt with in other DTU literature.

4. COMPARISON OF DTU AND COMMERCIAL PUMPS

4.1 Problems in comparison

There are inevitably problems and potential inaccuracies in taking data from two separate sets of tests carried out on two different test rigs. The main areas of difficulty are outlined below along with some explanation of their significance and potential methods for overcoming them.

a) The drive pipe lengths of the two test rigs differ by 1.5 m with the Delft rig using an inclined pipe whereas the Warwick tests use a horizontal one. The length of the drive pipe of a hydraulic ram pump system affects (among other things) the time taken for pressure waves to traverse the length of the pipe, total friction in the system and the energy available for pumping. The exact effects of these parameters on pump performance are complicated to evaluate and given the relatively small difference can be assumed to have no major effect for the purposes of this comparison.

b) As has already been mentioned, the Delft work is unclear about the tuning of each of the pumps tested, other than the fact that they were left constant throughout testing once installed. To allow a sensible comparison it has been assumed that the commercial pumps tested by Delft were each set to some recommended point that gave a reasonable efficiency and power output across a broad range of conditions. In order to compare the DTU pump a best average setting from those taken has been chosen and also comparisons of the optimum settings for efficiency and power. The setting chosen for the general comparison is labelled as No. 5 in Table 5 using a standard 2" drive pipe, a valve stroke of 15 mm and weight of 507 g.

4.2 Efficiency comparisons

The efficiency of the DTU pump is of the same order as the better of the commercial models. Graph 7 shows the chosen average and peak efficiency settings of M6.4 against the 5 commercial pumps.

In a typical operating range say 20-80 m the DTU average setting gives efficiencies ranging between approx 63% and 74%. The DTU peak setting of those chosen returns results for the same range between 64% and 83%. Detailing the comparison between these settings and those for the commercial models is best don visually. The main points that can be drawn are:

GRAPH 7

a) The Blakes machines have the best efficiency over the widest range of delivery heads with between 62% and 75% in the 20-80 m operating band. This is very similar the DTU average setting although the shape of the curves is somewhat different giving maximum and minimum efficiencies at different heads.

b) The DTU M6.4 pump has a markedly different efficiency profile from all the commercial models with peak efficiency occurring at much higher heads.

c) The DTU M6.4 is capable of operating over a range of delivery heads as great as any of the commercial models.

Separate tests to determine the peak efficiency of the M6.4 have shown that it is capable of running at efficiencies of over 90%.

4.3 <u>Power Comparison</u>

Graph 8 shows the chosen average and peak power settings for the M6.4 against the 5 commercial pumps.

a) The average setting of the DTU M6.4 is clearly more powerful over a very wide range of delivery heads than all of the commercial models of the same size. The Blake 2½" model is clearly more powerful as should be expected from this considerably larger capacity pump.

b) The peak setting of the M6.4 used gives power output similar to and, at higher heads, better than even the Blake 2½" model. Increased weight on the M6.4 would further increase the power output although the limitation of the pipe size and drive head would probably limit peak power to around 40 watts.

5. COST COMPARISON

Table 2 in section 2.1 shows the costs of 10 rams in US$ in 1982 as given by Delft. These costs are for the pumps alone with no drive pipe, delivery pipe, shipping etc. included, and range from US$ 1000 to 3500. No updated prices are available for comparison with the DTU pump so an annual inflation rate of 5% has been assumed. A comparative cost for the DTU pumps is hard to ascertain as they have only been manufactured as one-off prototypes to date in the UK. The design of all the DTU pumps is intended to allow manufacture in the country of use, avoiding any shipping and importation problems but working to the constraints imposed in non-industrialised areas.

The Baptist Community of Western Zaire (CBZO) have a village water supply programme installing the DTU M6.4 in its rural areas. Currently the manufacture of these pumps is being contracted to a workshop in Kinshasa who are producing them in small batches as requested. The total cost of these units in Zaire is approx. US$450 but once proper manufacture has started it is estimated that this will reduce to $250-$300.

The actual cost to an end user in a developing country of a ram pump will include any shipping and importation costs if it is made eslewhere. To accurately compare the DTU pumps made in country with imported commercial models the costs associated with transportation should be included. However such costs are so dependant upon the shipping distance, customs duties etc. that they would be impossible to estimate with any accuracy.

Table 6 takes the information from Table 2 and adds to the costs an allowance for inflation. It also includes information about the DTU Mark 6.4 pump for the conditions specified by Delft. The information concerning expected delivery flow was arrived at by projecting measured performance figures for different conditions. The DTU is in the process of developing a sophisticated computer simulation and model which are being used in pump analysis and will form the basis of comprehensive design charts. Ultimately this will be able to predict the performance of any pump that has been suitably calibrated under any set of conditions with a good degree of accuracy.

The predicted performance of the DTU pump ranks it 5th in terms of delivery flow and efficiency. The comparison of costs shows the vast difference in the price of the pumping unit and the cost per litre delivered. This illustrates the legitimacy of the approach of producing high performance pumps at low cost in the country of use. If a true comparison to include transportation costs were made the results would clearly be more conclusive still.

TABLE 6 - COST COMPARISON

6. SUMMARY OF CONCLUSION

The following points summarise the conclusions that can be drawn from these tests.

a) The DTU Mark 6.4 pump gives efficiencies comparable with the more efficient commercial pumps over a wide range of condition.

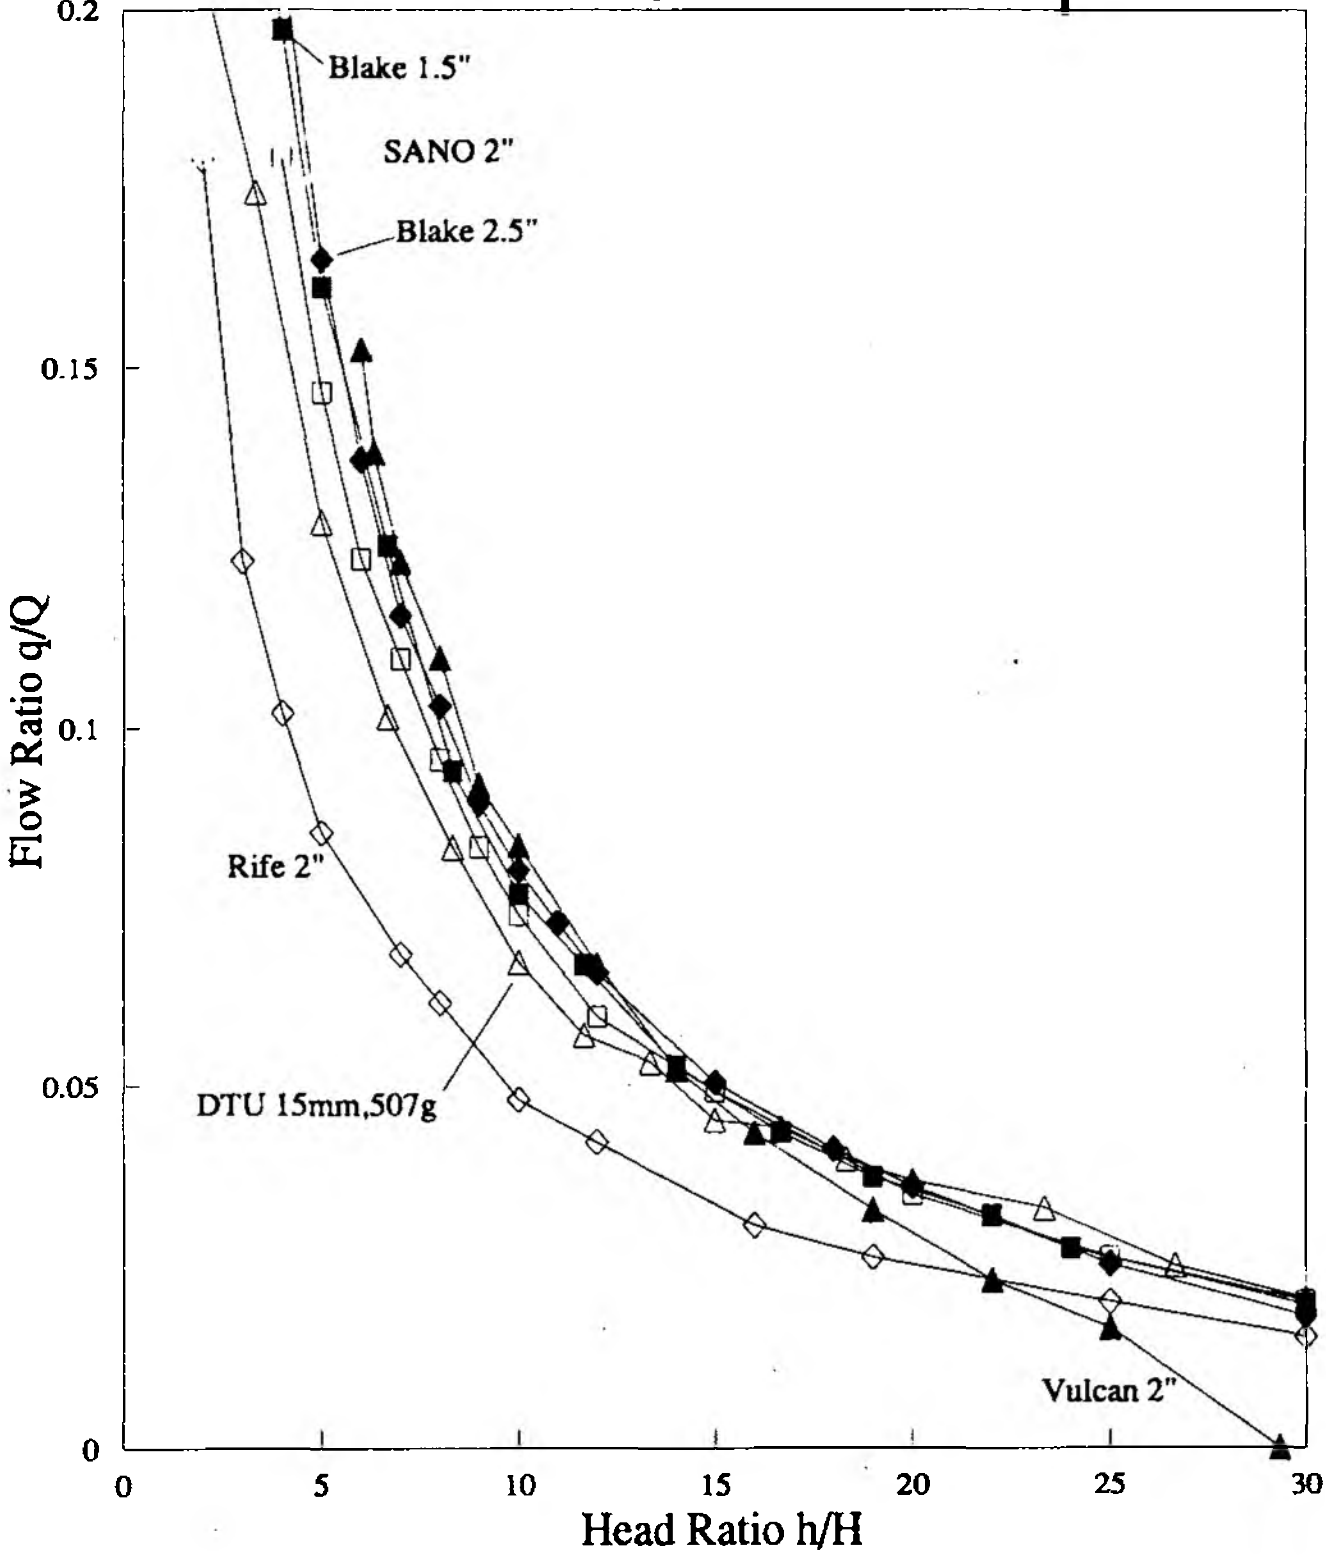
b) The M.6.4 produces a higher output power than all commercial models of the same size over a wide range of conditions.

c) The M6.4 has a cost to output ratio considerably lower than all of its commercial rivals.

The tests show that it is possible to produce simple and comparatively cheap hydraulic ram pumps that can match and exceed the performance of commericial models. Whilst endurance tests to date indicate that the DTU pumps are likely to exhibit adequate durability no data is yet available for a long term comparison with commercial rivals. The current design specification is to produce low maintenance pumps whose steel components have a 10 year life and rubber components last approximately 6 months.

More detailed information concerning the design, manufacture, installation and performace of DTU pumps is available on request.

Ratio Comparison of Commercial & DTU Pumps



Appendix A **CONTINUING DTU PUMP DEVELOPMENT**

The Mark 6.4 pump was set as a DTU standard in 1990 to allow organisations interested in using the pummp to have a standard model to work with. Since that time a number of developments have occurred in the on-going research programme and new design initiatives produced. One such is the development of the Mark 8.4 that uses the same valves as the M6.4 but replaces the 2" fittings used in the pump body witha body of 4" velded construction. This alteration dramatically reduces the peak overpressure experienced the system, damps out the high frequency oscillations experienced during the cycle and increases both the efficiency and power output for any given set of conditions.

Graphs 10 and 11 allow comparison of the M8.4 with the M6.4 under identical conditions.

Appendix C FURTHER NOTES AND COMMENTS ON THE WORK AT DELFT

The following are a series of points arising from the work at Delft that have not been mentioned in the main text of this paper.

1) Delft managed to record delivery valve movement of rubber type valves by bonding strain guages to the rubber. This technique overcomes the difficulty of recording and analysing delivery valve movement experienced by the DTU.

2) An electronic beat frequency counter was used at Delft to record the operating frequency and period of pumps under test. This is another technique worth pursuing for ongoing tests at Warwick.

3) There is some confusion and lack of consistancy between ram pump manufacturers and users as to how efficiency is measured. Delft produce the following summary

<u>Rankine</u> Drive tank water level is taken as the datum point and supply and delivery heads measured from that point. Therefore the net amount of potential energy in the water delivered $= pgq(h-H)$
the net amount of energy input $= pgQH$

Hence Rankine efficiency $\eta_R = \dfrac{q \times (h-H)}{Q \times H}$

<u>D'Aubuisson</u> The impulse valve orifice is taken as the datum point and therefore

work done $= pgqh$
energy supply $= pg\ (Q + q)H$

D'Aubuisson Efficiency $\eta_D = \dfrac{q \times h}{(Q + q) \times H}$

<u>Manufacturers</u>

Most manufacturers take a simplified efficiency that actually produces a higher value of efficiency under any given set of conditions

$$\eta_m = \frac{q \times h}{Q \times H}$$

Delft prefer the Rankine expression which yields the lowest results particularly at low delivery heads.

The DTU currently uses the D'Aubuisson formula as the test rig measures the total flow into the pump (Q + q) rather than just the waste flow. This has been used throughout this report.

There seems little to choose between these two which produce similar results under normal operating conditions. The simplified efficiency used by many manufacturers is more inaccurate but produces more flattering figures!

4) Observation on relative position of delivery and impulse valves concerning air intake during recoil.

During recoil, large quantities of air can be drawn in through the open impulse valve as water flows back up the drive pipe. Only a small quantity of air can be drawn through the snifter valve so section A remains relatively full of water. As acceleration of water towards the pump re-occurs the majority of the air is expelled through the impulse valve and only the small volume entering from the snifter enters the air vessel.

If the recoil is large in this configuration and a significant quantity of air drawn in through the impulse valve, the column may receed past the vertical pipe section leading to the delivery valve. When acceleration occurs a significant pocket of air may be trapped under the delivery valve. This would tend to dampen out the next pressure pulse and reduce delivery flow.

5) The Alto ram from France has an inflatable rubber air compartment in the air vessel to ensure a permanent separation of air and water. This is an attractive option as it reduces the need for a reliable snifter to replenish air lost from the air vessel.

6) The SANO rams are fitted with a 'drip valve' in the air vessel that appears to be located at a point where the air/water interface should be. It presumably operates by passing water if the level in the air vessel rises above it. What is its operating mechanism?

8) Delft draw the following conclusions about pump performance and operation from results produced by their mathematical model.

- given an available source supply the pumping rate (q) is primarily determined by the supply head (H_s)and the delivery head (h_d).
- an increase of the delivery head (h_d) decreases the quantity pumped per cycle (V_d) and by that the pumping rate (q) decreases.
- an increase of the supply head (H_s) increases the pumping frequency and by that the pumping rate (q) increases.
- an increase of u_c (ie. the velocity of the water in the drive pipe at waste valve closure) normally increases the pumping rate (q) while the pumping frequency decreases, but more water (Q) is needed to operate the ram. However, there is a limiation as to this point: an increase in u_c such that the value of the ratio u_c/u_o approaches unity (where u_o is the maximum attainable velocity of the water in the drive pipe) implies a decrease in pumping rate (q) while, as before, the waste flow (Q) increases, a condition to be avoided.
- the larger the size (ie. drive pipe bore) of the ram, the more water (Q) is required to operate the ram and the more water (q) can be delivered to a higher level (h_d).

9) Delft recommend that if the delivery flow from one ramains insufficient a second ram should be placed below the first and utilise its drive water. However if there is sufficient drive head available to be able to do this would a better performance be gained by having two rams each working from a portion of the drive head or one ram working with the total head available?

10) Delft state that the drive pipe length should be approximately 4 to 7 times the supply head. They make no justification for this statement.

11) Delft state that the best pumping results are usually obtained when the cut off velocity is between 60% and 80% of the terminal velocity of the system.

12) Delft produce equations for predicting pump performance, which require certain information about the system to tbe known.

A loss coefficient for the whole system is required which covers all the losses in the drive pipe, pump and delivery pipe. Delft state that this can be found by holding open the impulse valve, measuring the flow rate at terminal velocity and inserting this into the equation

$$\text{max velocity} \quad V = \sqrt{\frac{2gH}{\text{loss coef}}}$$

This does not take into account the delivery system losses and can only be measured once the system is installed, preventing prediction of performance prior to installation. It would be more useful to have a loss coefficient measured for each pump and also to have a simple method of calculating pipe loss coefficient based on diameter and length.

The other requirement for use of Delft's model is to find the cut off velocity for the particular impulse valve setting. They state that this can be found when the maximum delivery head obtainable is known using

$$\text{Cutoff} = (g/c) \times h_{max}$$

They recommend that h_{max} is found by closing the delivery side of the pump and letting the pump run up to its maximum head. This would provide a rather crude approximation producing a low result and could prove to be very dangerous.

Comparison between DTU and Commercial Ram Hydraulic Ram Pump Performances

UPDATE AND COMMENTS, APRIL 1996

Since this paper was written, the DTU Mark 6.4 pump has been phased out, to be replaced by first the M8.4 and more recently the S2. All these are pumps normally run with a 2" G.I. drivepipe and delivering to up to 100m using a drive flow of 40 to 120 litres/min. Preliminary results for the M8/S2 on a single setting are given at the end of this paper, indicating that, setting for setting, the M8 is superior to its predecessors. Generally the DTU later models are more efficient than the M6. Of course performance as measured in this paper is only part of the story. The DTU pumps are made largely of mild steel and are therefore more subject to corrosion than most 'commercial' machines. In recent years there has been a trend towards use of plastics in ram pumps as pvc or ABS piping replaces galvanised iron. However plastic pumps can rarely operate reliably at delivery heads exceeding 40 meters. There is also a growing interest in providing the air-cushioning of the output via an enclosed air packet (for example closed cell foam) instead of an air vessel with a free air-water surface. This arrangement can effectively increase the usable drive head by allowing the impulse valve exhaust to emerge under water.

In the paper, the early comparisons with commercial pumps use data from a study by T H Delft which were obtained from slightly larger models (from the respective manufacturers' ranges), and with a much higher drivehead, than the comparisons in the rest of the paper.

Details of the current (1996) DTU designs, namely S1 (for use with a 1" steel drivepipe), S2 (2" steel) and P90 (90 mm. pvc) are given in DTU Technical Releases TR11, TR14 and TR12 respectively.

1. INTRODUCTION

This paper details the performance of the DTU Mark 6.4 hydraulic ram pump in comparison to commercial models run under similar conditions. Details of the performance of a number of commercial pumps tested at Delft University, Netherlands are used for comparison.

1.1 Delft University

Between 1982 and 1984 J. Tacke of Delft University of Technology carried out tests on a number of commercially available hydraulic ram pumps. These were published in 1988 with comprehensive details of all results obtained and the development of a mathematical model for prediction of ram performance. As part of this programme field tests were conducted by the Foundation of Dutch Volunteers in Rwanda. These aimed to investigate the technical performance and durability under operating conditions in a community setting, social acceptance and community participation in installing, operating and maintaining a hydraulic ram system.

The presentation by Delft of all laboratory test results is excellent and allows a good level of comparison for tests on subsequent designs. Unfortunately no details of the findings or conclusions resulting from the field trials in Rwanda are made available. However the DTU are greatly indebted to Delft for their provision of such a useful resouce.

1.2 DTU, University of Warwick

The Development Technology Unit has been investigating hydraulic ram pump design, performance and manufacture since 1985. This began with student projects and has grown into a full-time research programme largely funded by the Overseas Development Administration. The aims of the programme are:

a) to analyse in detail the operation of the ram pump gaining a comprehensive understanding of the operating principles and complex hydraulic interactions occuring within the pump.

b) to produce pump designs suitable for manufacture in developing countries using available materials and production processes.

c) to thoroughly test such designs for their performance and endurance (including extensive field trials) and offer findings for widespread dissemination.

d) to develop and prove methods for surveying and design of complete water supply installations.

e) to produce design charts and computer based tools to enable design and field engineers to confidently include hydraulic ram pumps as an option in their water supply schemes.

f) to provide technical expertise and training for two African based programmes installing ram pumps for village water supply and irrigation.

In terms of hardware development the DTU has two distinct working areas. The first is the development of designs of steel hydraulic ram pumps based on the 2" diameter BSP pipe that has been found to be widely available in developing countries and is of an appropriate capacity for small village water supply schemes. The second area of hardware development is the production of plastic hydraulic ram pumps based on widely available 110mm plastic pipe and especially suitable for irrigation close to water courses. Rough specifications and performance indications are given below.

	Steel	Plastic
Materials required		
	2" Galvanised pipe	110mm PVC pipe
	2" Fittings	Small amount of
	Mild steel bar	mild steel parts
Manufacturing process		
	Welding	Hand tools
	Drilling	
	Turning	
Typical performance ranges		
	40-140	
Drive flow	40/140 l/min	200-350 l/min
Drive head	2-25m	0.5-2.5m
Delivery flow	2-12 l/min	2-25 l/min
Delivery head	up to 150m	up to 15m
Efficiency	50-90%	20-60%
Expected life	10 years	3 years

This paper is concerned solely with the comparison of the 2" steel pump with its commercially available rivals. Such pumps have found the widest application to date in supplying water for domestic use.

During the research many designs of ram pump have been produced and tested. In 1990 a design was chosen as having proven itself sufficiently in terms of performance and durability to set a 'benchmark' against which furthest developments could be assessed. It is this model, Mark 6.4, that is used in the following comparison against commercial designs.

2. SUMMARY OF WORK CARRIED OUT AT DELFT

2.1 Selection of Pumps

Delft decided to select 12 rams from 6 manufacturers that were applicable in typical village or domestic water supply schemes. In all, details of pumps from 10 manufacturers were obtained and selection made based on the following criteria:

a) as many types of ram design as possible should be included.

b) tests should include both traditional and modern designs.

c) rams should show a reasonable price to performance ratio.

To enable the latter of the criteria, manufacturers were sent a set of conditions and asked to provide details of the pump they would recommend and its expected output and efficiency.

Table 1 shows the results of this comparison.

TABLE 1 - COMPARISON OF HYDRAULIC RAMS

Arrangement: Source Supply = 90 l/min

Supply Head Hs = 7.50 m

Delivery Head hd = 75 m

Type of Hydraulic Ram	Drive Pipe [inch]	[mm]	Volume of Driving Water Required [l/min]	Pumping Rate q [l/min]	Efficiency trd [%]	Approx Price for Ram Alone [US$-1982]
Vulcan 21/2	2	65	36-114	6.10	68	1200
Blake Hydram 31/2	2	65	45- 96	6.00	67	1000
Sano No. 5/65 mm	2	65	50-110	6.95	77	1000
Rife 20 HDU	2	50	38- 95	5.40	60	1100

Alto CH 66-110-18	2	65	50- 90	5.40	60	2100
Briau D4	2	50	45- 90	5.40	60	3200
CeCoCo - H50	2	50	25-115	6.90	77	3500
WAMA No. 6	2	65	60-100	4.50	50	1500
BZH-Ram W6	2	65	45- 90	2.70	30	1200

Delft concluded that in terms of performance, the choice should favour the first eight pumps and of these the first six provide the best performance to price ratio. From the information given the choice seems to be a reasonable one.

An alternative comparison to evaluate the performance to price ratio would have been to include a cost per litre delivered under these conditions. This significantly alters the ranking of pumps as is shown in Table 2.

TABLE 2

Type of Hydraulic Ram	Pumping Rate q [C/min]	Efficiency (Trade) (%)	Approx Price for Ram Alone [US$-1982]	Cost per litre delivered	Rank
Vulcan 2½	6.10	68	1200	197	3
Blake Hydram 3½	6.00	67	1000	167	2
Sano No. 5/65 mm	6.95	77	1000	144	1
Rife 20 HDU	5.40	60	1100	204	4
Schlumpf 5A23	5.50	61	2700	491	8
Alto CH 66-110-18	5.40	60	2100	389	6
Briau D4	5.40	60	3200	593	10

WAMA No. 6	4.50	50	1500	333	5
BZH-Ram W6	2.70	30	1200	444	7

It would also have been interesting to include details from rams currently manufactured in developing countries. Details of the rams selected are given in Table 3.

2.2 <u>Assessment of Experimental Procedure</u>

The tests conducted were fairly comprehensive with each ram being observed for approx. 1 month. The test rig employed allowed a supply head of between 0.5 and 3.0 m with a drive pipe length of 12m. Such a low drive head range is clearly the product of laboratory limitations and does not reflect typically observed ranges in the field of 2 to 20m.

Flows were measured by collecting water for a timed period and weighing it. For each setting this was repeated a number of times to give a more accurate average flow. This is potentially a very accurate method of flow measurement but is open to numerous experimental errors. However it does avoid the need to use flow meters that have their own inaccuracies despite careful calibration.

The designs of ram pump tested exhibit a number of different types of impulse valve. Four of the six have traditional valves above the axis of the pump body but the Schlumpf has its valve below the axis. No mention is made in the text of the Delft work as to where the supply head was measured from. To allow accurate comparison the head should be taken from the orifice of the impulse valve, not the axis of the pump body. In reality both the SANO and Schlumpf pumps may in some situations be able to utilise a given supply head more effectively by their impulse valve design.

TABLE 3 - HYDRAULIC RAMS SELECTED

Type of Hydraulic Ram	Manufacturer	Drive Pipe Diameter [ins]	[mm]	Intake capacity [l/min]	Description
Blake Hydram No. 2 Blake Hydram No. 3.5	John Blake Ltd England	1.5 2.5	40 65	12-25 45-96	A well-established standard design made of cast-iron. Both waste valve and delivery valve consist of a rubber disc covering a perforated gunmetal seat.
Alto J 26-80-8 Alto CH 50-110-18	J.M. Desclaud France	1 2	25 50	8-15 30-60	A recently renewed pump design made of steel pipe components, but using conventional valve designs. Weight-loaded gunmetal waste valve; spring-loaded rubber clack as delivery valve.
Vulcan 1" Vulcan 2"	Green & Carter England	1 2	25 50	4-18 23-46	A standard design made of cast-iron; like the Blake Hydram available for a long time. Both waste valve and delivery valve consist of a rubber disc covering a grid shaped, gunmetal seat.
SANO No. 1-25 mm SANO No. 4-50 mm	Pfister + Langhanss Germany	1 2	25 50	6-16 30-65	A rather unconventional' design, nowadays made of fire zinc-coated steel. Both waste valve and delivery valve are spring-actted and substantially made of gunmetal.
Davey No. 3 Rife 20 HDU	Rife Hydr. Eng Mfg. Co.	1 2	25 50	5-15 38-95	Rife: a fairly standard design made of cast-iron. Weight-loaded rubber waste valve, mounted on a rocker-arm; delivery valve is a rubber disc covering a grid iron seat. Davey: less efficient, less expensive low base configuration, using a weight-loaded gunmetal waste valve and a weight-loaded leather washer as delivery valve.
Schlumpf 4A5 Schlumpf 4A23	Schlumpf Ag Maschinenfabrik Switzerland	1.5 1.5	40 40	30-60 30-60	A design available in 2 models. Model A23 uses a spring-loaded rubber waste valve mounted on a rocker and a weight-loaded rubber washer as delivery valve. The less efficient model A5 uses a weight-loaded rubber waste valve.

The laboratory experiments also included the use of piezo-electric pressure transducers, displacement transducers and strain guages to observe in detail the changes occuring. Although the resolution of these observations is low they are well presented and provide useful insights into pump operation.

The major criticism of the information presented by Delft is that they supply no indication of how each pump was setup when the results were taken. They simply state that 'waste valve adjustment' was 'kept constant' over the whole range of tests. To ensure a fair comparison the waste valves were presumably initially adjusted to the manufacturers recommendation that would give the best overall performance (efficiency and power output) under typical operating conditions. If this was not the case then the results are practically worthless as some of the pumps may have been badly tuned whilst others were well tuned for the given operating conditions.

2.3 Summary of results

The results presented by Delft are comprehensive within the limitations of their test rig. Delft provide data for 3 supply heads for each pump over a range of delivery heads. Of these the highest (3m) has been taken as being the most representative and all results presented below are for this fixed supply head. Table 4 shows some results for efficiency and power at typical supply to delivery head ratios.

TABLE 4 SUMMARY OF TEST RESULTS

Pump	Efficiency (%)			Power (Watts)		
	at 30m	at 60m	max	at 30m	at 60m	max
Blake No 2 (1¼")	70.5	67	70.5	15.2	12.8	15.1
Blake No 3½ (2½")	72.5	68	73	38.2	12.8	15.1
Alto (1")	29	-	47	2.2	-	4.3

SANO No 4 (2")	67	66	69	20.6	19.6	20.2
Davey No 3 (1")	54	-	60	3.4	-	4.7
Rife 20HDU (2")	43	48	48	19.1	19.6	12.7
Schlumpf 4A5 (1¼")	-	-	62	-	-	15.2
Schlumpf 4A23 (1¼")	43	15	62	8.8	2.0	17.2

Five of the pumps tested are of similar specification to the DTU models and were therefore selected for analysis and comparison. Graphs 1 and 2 show power and efficency curves for these five pumps. The large variations between pumps can be seen quite clearly and comparison is complicated by the marked differences in the power and efficiency curves. At low heads for instance the Vulcan 2" ram is the most efficient but has the lowest output power and will only run up to a delivery head of 85 m.

2.4 <u>Conclusions about commercial pumps</u>

Delft offer no conclusions or direct comparisons between the various pumps tested. The results are complex and comparison has to be based on many factors in order to produce sensible recommendations. In any given situation the exact requirements will vary. The points given below are an attempt to pick out the main items in order to draw some conclusions.

1) The Vulcan 2" has the highest efficiency recorded at 76.9% and at low heads (up to 36 m) has the best effiency of all the pumps.

2) The Rife 2" has the lowest efficiency up to 70 m and never increases over 50%. However it has the widest range of delivery heads over which it will operate. Overall it would be fair to say that the Rife pump has the poorest efficiency.

3) Overall the Blake 2½" is the most efficient closely followed by the smaller Blake 1½". They show good efficiencies over the normal operating range and will pump over a wide range of delivery heads.

4) Similarly the SANO 2" shows good efficiencies over a wide range of delivery heads and is more efficient than the Blake pump over about 75 m.

5) The Vulcan 2" has the lowest power output over its small range of delivery heads.

6) Blake 2½" is clearly the most powerful pump over its entire range.

7) At low delivery heads (up to 75 m) the SANO 2" has a slightly higher output than the Rife 2" which above 75 m is better. However there is little to choose between them over the complete range of operation.

8) Attempting to combine both power and efficiency it would seem reasonable to conclude that the Blake 2½" offers the best overall performance. Of the remainder the SANO 2" would seem to be the best compromise.

2.5 Non-Dimensional Comparison

Delft use a further means of pump comparison by graphically presenting the ratio of delivery to supply flow (q/Q) over a range of delivery to supply head (h/H) ratios. Thus a non dimensional comparison between pumps is possible. For any given head ratio the greater the ratio of flows the better the perfomace of the pump. Graph 3 shows these ratio curves for the five pumps chosen. Only two conclusions can sensibly be drawn from this comparison:

1) The Rife 2" is notably worse than all its rivals.

2) There is little to choose between all of the other makes of pump.

Despite this lack of obvious conclusions the ability to compare pumps using non dimensional parameters may prove valuable.

3. SUMMARY OF DTU TESTS

3.1 Experimental rig and procedure

The DTU has established performance testing rigs at the University to allow comprehensive analysis of prototype pumps. The major restrictions imposed by the rigs location are:

i) drive pipe length - limited to 10.5 m and horizontal

ii) drive head - restricted to 2, 3, 4 or 5 m

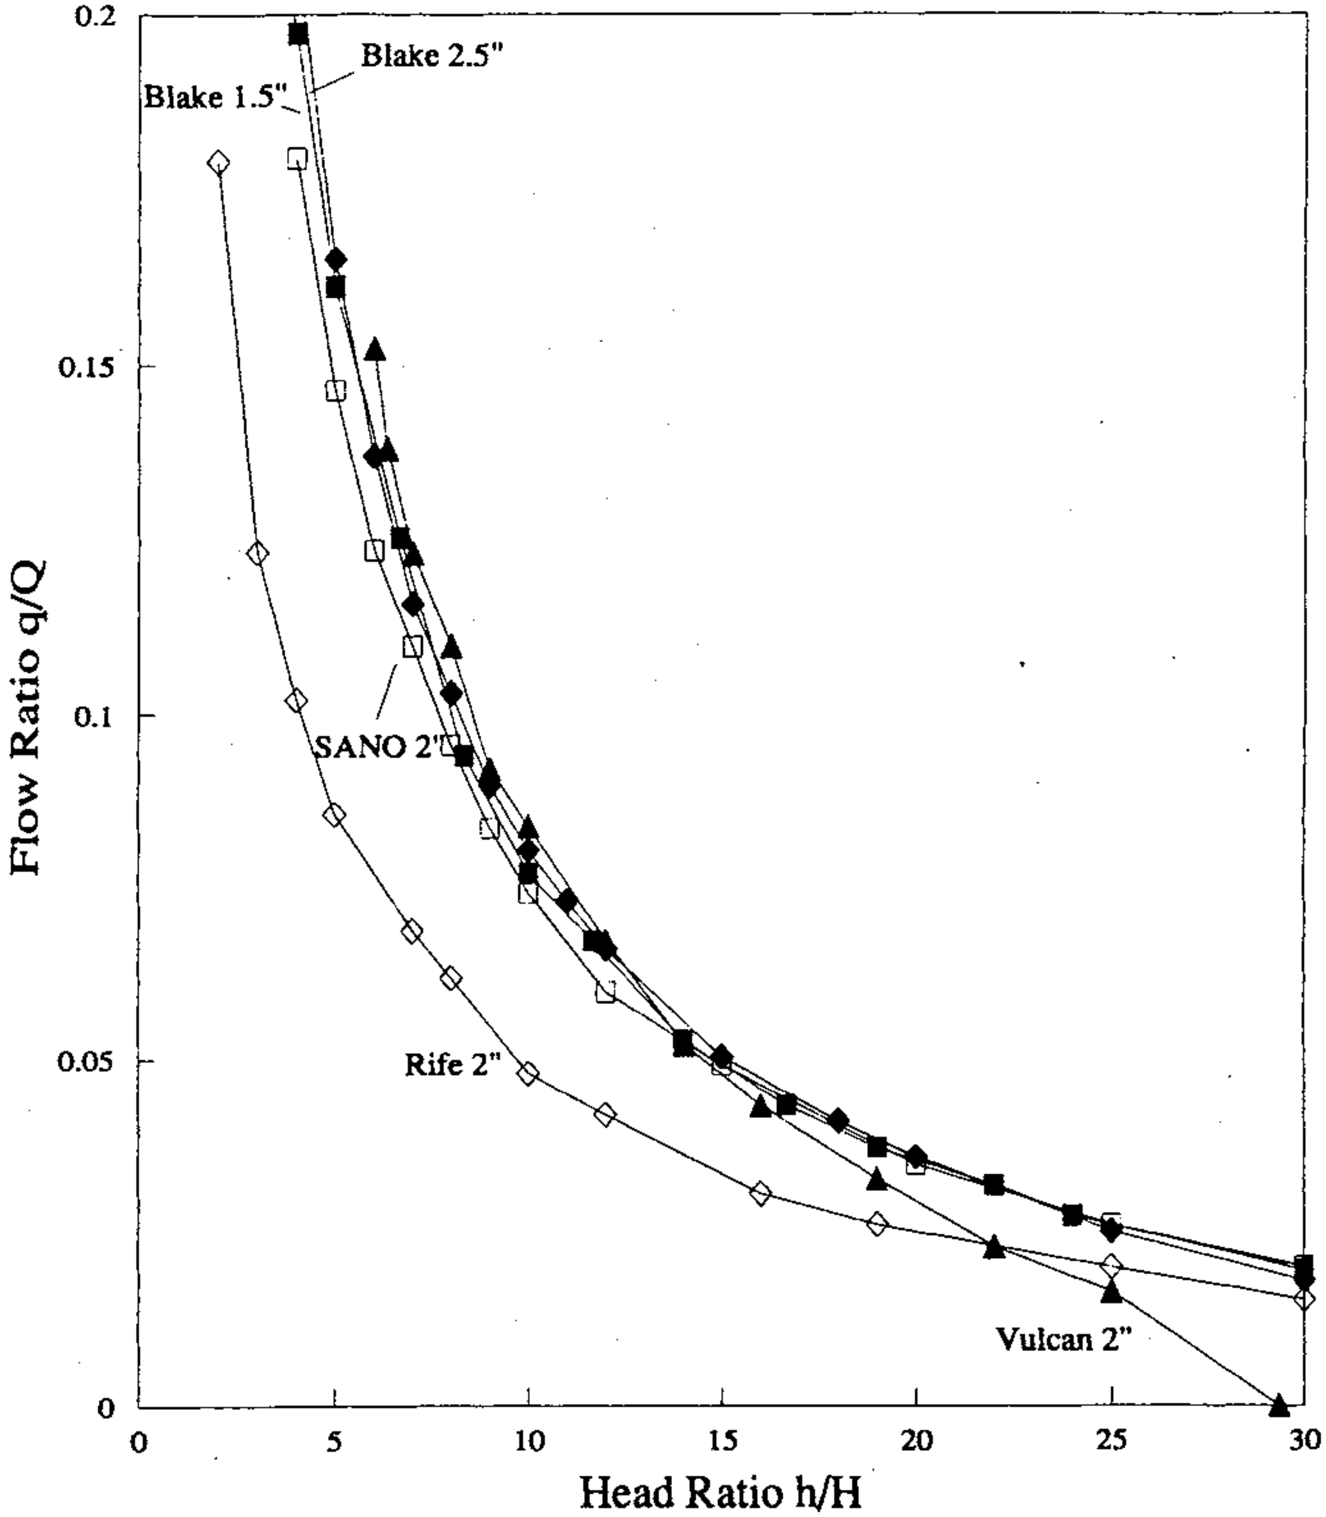
The delivery head is controlled using a needle valve providing an accurately variable orifice over which the desired head can be dropped (measured by a pressure guage). Both drive and delivery flows are measured by float type flow meters for fast and accurate readings.

For their tests Delft used three drive head setting, 1, 2 and 3 m. However for comparison between DTU and commercial pumps only one drive head was chosen (3.0 m).

3.2 Pump Tuning

The DTU pump design selected for testing was the Mark 6.4 which typically uses a 2" BSP drive pipe but also runs using 1½" pipe (see Figure 1). As the Delft work gives no clear indication of how pumps were tuned a series of results were recorded using different settings of the impulse valve. Low stroke, low weight settings generally give high efficiency and low power output. Up to a point it is also true to say that high stroke,

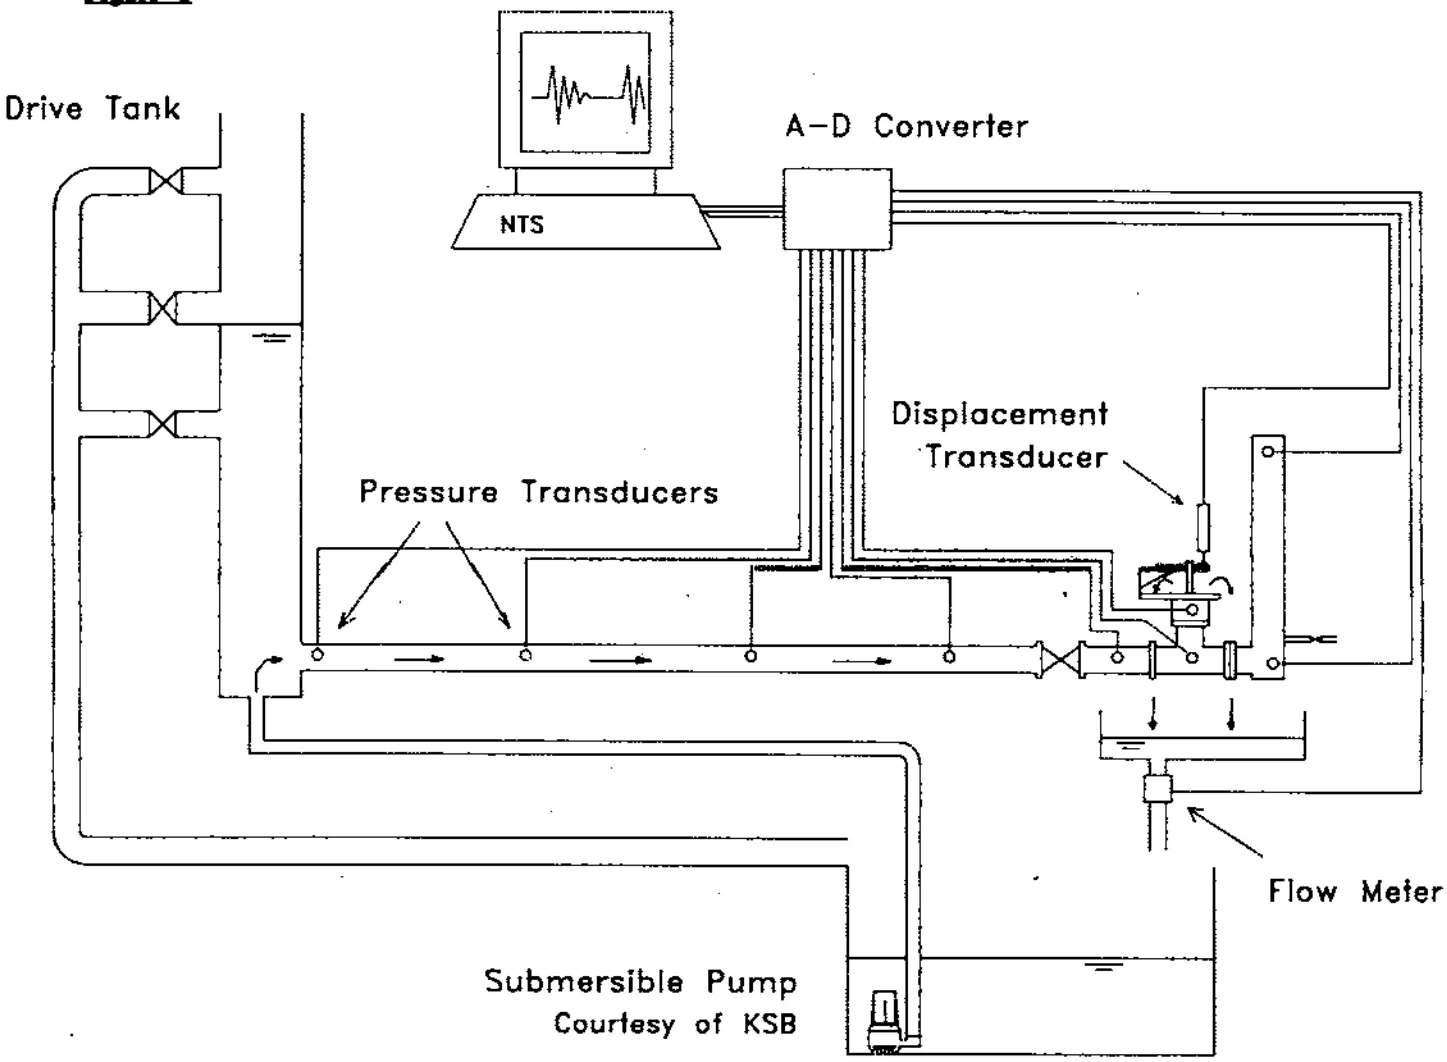
Ratio Graph of Commercial Pumps



high weight settings give low efficiency and high output power.

Choosing which of these results are used to compare against the Delft ones is dealt with in Section 4.1.

Figure 1



3.3 Summary of test results

Table 5 gives a selection of results for identical conditions as those in Table 4 for the commercial pumps.

Graphs 4 and 5 show the variation in efficiency and power over the full range of potential delivery heads.

Graph 6 presents the non dimensional flow ratio to head ratio curves for these results.

The design of the M6.4 pump allows it to be tuned to suit a wide range of flow and head conditions, making one model applicable to many sites. The results show the wide range of efficiency and power obtainable under these given conditions and emphasize how important tuning can be. If drive water is limited then peak efficiency will be required to make best use of that available. If there is plenty of drive water pumps should be tuned to give maximum power output despite the lower efficiency of such a setting.

It is clear that both good efficiency and power are obtainable over a broad range of delivery heads and that the pump is capable of operating at very high head ratios.
The stroke of teh M6.4 design can range between 5 mm 40 mm with infinite adustment between these limits. The minimum weight of the valve assembly is 507g comprising the plug, stem, nuts etc. although recent modification to the pump enables further reduction. Maximum weight is limited by the physical dimensions but 1000g should be considered as the upper limit.

The results show for just a few combinations of stroke and weight how the efficiency and power output characteristics of the pump can be dramatically altered. Low stroke and weight give high efficiency but low power over a limited range of delivery heads whereas high stroke and weight give lower efficiency but high power output over a wider possible range of heads. Tuning of the pump to best suit any particular set of conditions is a complicated process to explain and is dealt with in other DTU literature.

TABLE 5 SUMMARY OF DTU M6.4 TEST RESULTS

4. COMPARISON OF DTU AND COMMERCIAL PUMPS

4.1 Problems in comparison

There are inevitably problems and potential inaccuracies in taking data from two separate sets of tests carried out on two different test rigs. The main areas of difficulty are outlined below along with some explanation of their significance and potential methods for overcoming them.

a) The drive pipe lengths of the two test rigs differ by 1.5 m with the Delft rig using an inclined pipe whereas the Warwick tests use a horizontal one. The length of the drive pipe of a hydraulic ram pump system affects (among other things) the time taken for pressure waves to traverse the length of the pipe, total friction in the system and the energy available for pumping. The exact effects of these parameters on pump performance are complicated to evaluate and given the relatively small difference can be assumed to have no major effect for the purposes of this comparison.

b) As has already been mentioned, the Delft work is unclear about the tuning of each of the pumps tested, other than the fact that they were left constant throughout testing once installed. To allow a sensible comparison it has been assumed that the commercial pumps tested by Delft were each set to some recommended point that gave a reasonable efficiency and power output across a broad range of conditions. In order to compare the DTU pump a best average setting from those taken has been chosen and also comparisons of the optimum settings for efficiency and power. The setting chosen for the general comparison is labelled as No. 5 in Table 5 using a standard 2" drive pipe, a valve stroke of 15 mm and weight of 507 g.

4.2 Efficiency comparisons

The efficiency of the DTU pump is of the same order as the better of the commercial models. Graph 7 shows the chosen average and peak efficiency settings of M6.4 against the 5 commercial pumps.

In a typical operating range say 20-80 m the DTU average setting gives efficiencies ranging between approx 63% and 74%. The DTU peak setting of those chosen returns results for the same range between 64% and 83%. Detailing the comparison between these settings and those for the commercial models is best don visually. The main points that can be drawn are:

GRAPH 7

100
150

a) The Blakes machines have the best efficiency over the widest range of delivery heads with between 62% and 75% in the 20-80 m operating band. This is very similar the DTU average setting although the shape of the curves is somewhat different giving maximum and minimum efficiencies at different heads.

b) The DTU M6.4 pump has a markedly different efficiency profile from all the commercial models with peak efficiency occurring at much higher heads.

c) The DTU M6.4 is capable of operating over a range of delivery heads as great as any of the commercial models.

Separate tests to determine the peak efficiency of the M6.4 have shown that it is capable of running at efficiencies of over 90%.

4.3 Power Comparison

Graph 8 shows the chosen average and peak power settings for the M6.4 against the 5 commercial pumps.

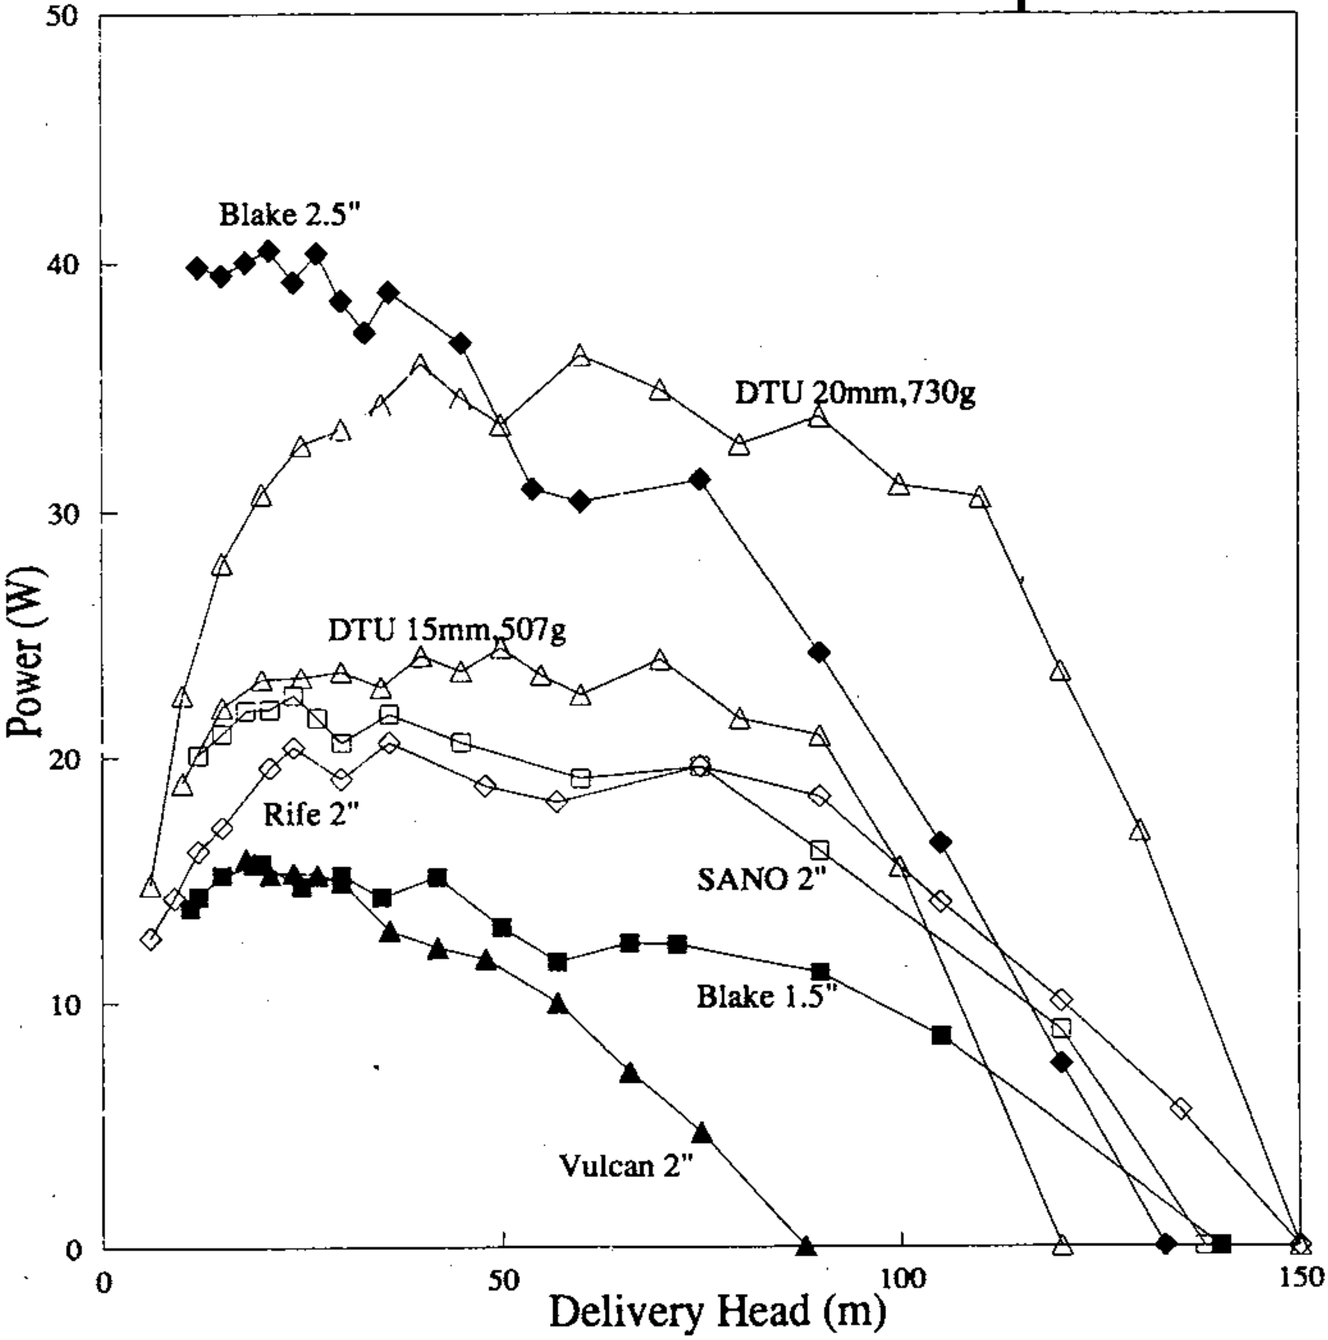
a) The average setting of the DTU M6.4 is clearly more powerful over a very wide range of delivery heads than all of the commercial models of the same size. The Blake 2½" model is clearly more powerful as should be expected from this considerably larger capacity pump.

b) The peak setting of the M6.4 used gives power output similar to and, at higher heads, better than even the Blake 2½" model. Increased weight on the M6.4 would further increase the power output although the limitation of the pipe size and drive head would probably limit peak power to around 40 watts.

5. COST COMPARISON

Table 2 in section 2.1 shows the costs of 10 rams in US$ in 1982 as given by Delft. These costs are for the pumps alone with no drive pipe, delivery pipe, shipping etc. included, and range from US$ 1000 to 3500. No updated prices are available for comparison with the DTU pump so an annual inflation rate of 5% has been assumed. A comparative cost for the DTU pumps is hard to ascertain as they have only been manufactured as one-off prototypes to date in the UK. The design of all the DTU pumps is intended to allow manufacture in the country of use, avoiding any shipping and importation problems but working to the constraints imposed in non-industrialised areas.

Power Comparison of Commercial & DTU Pumps



The Baptist Community of Western Zaire (CBZO) have a village water supply programme installing the DTU M6.4 in its rural areas. Currently the manufacture of these pumps is being contracted to a workshop in Kinshasa who are producing them in small batches as requested. The total cost of these units in Zaire is approx. US$450 but once proper manufacture has started it is estimated that this will reduce to $250-$300.

The actual cost to an end user in a developing country of a ram pump will include any shipping and importation costs if it is made eslewhere. To accurately compare the DTU pumps made in country with imported commercial models the costs associated with transportation should be included. However such costs are so dependant upon the shipping distance, customs duties etc. that they would be impossible to estimate with any accuracy.

Table 6 takes the information from Table 2 and adds to the costs an allowance for inflation. It also includes information about the DTU Mark 6.4 pump for the conditions specified by Delft. The information concerning expected delivery flow was arrived at by projecting measured performance figures for different conditions. The DTU is in the process of developing a sophisticated computer simulation and model which are being used in pump analysis and will form the basis of comprehensive design charts. Ultimately this will be able to predict the performance of any pump that has been suitably calibrated under any set of conditions with a good degree of accuracy.

The predicted performance of the DTU pump ranks it 5th in terms of delivery flow and efficiency. The comparison of costs shows the vast difference in the price of the pumping unit and the cost per litre delivered. This illustrates the legitimacy of the approach of producing high performance pumps at low cost in the country of use. If a true comparison to include transportation costs were made the results would clearly be more conclusive still.

6. SUMMARY OF CONCLUSION

The following points summarise the conclusions that can be drawn from these tests.

a) The DTU Mark 6.4 pump gives efficiencies comparable with the more efficient commercial pumps over a wide range of condition.

b) The M.6.4 produces a higher output power than all commercial models of the same size over a wide range of conditions.

c) The M6.4 has a cost to output ratio considerably lower than all of its commercial rivals.

The tests show that it is possible to produce simple and comparatively cheap hydraulic ram pumps that can match and exceed the performance of commericial models. Whilst endurance tests to date indicate that the DTU pumps are likely to exhibit adequate durability no data is yet available for a long term comparison with commercial rivals. The current design specification is to produce low maintenance pumps whose steel components have a 10 year life and rubber components last approximately 6 months.

More detailed information concerning the design, manufacture, installation and performace of DTU pumps is available on request.

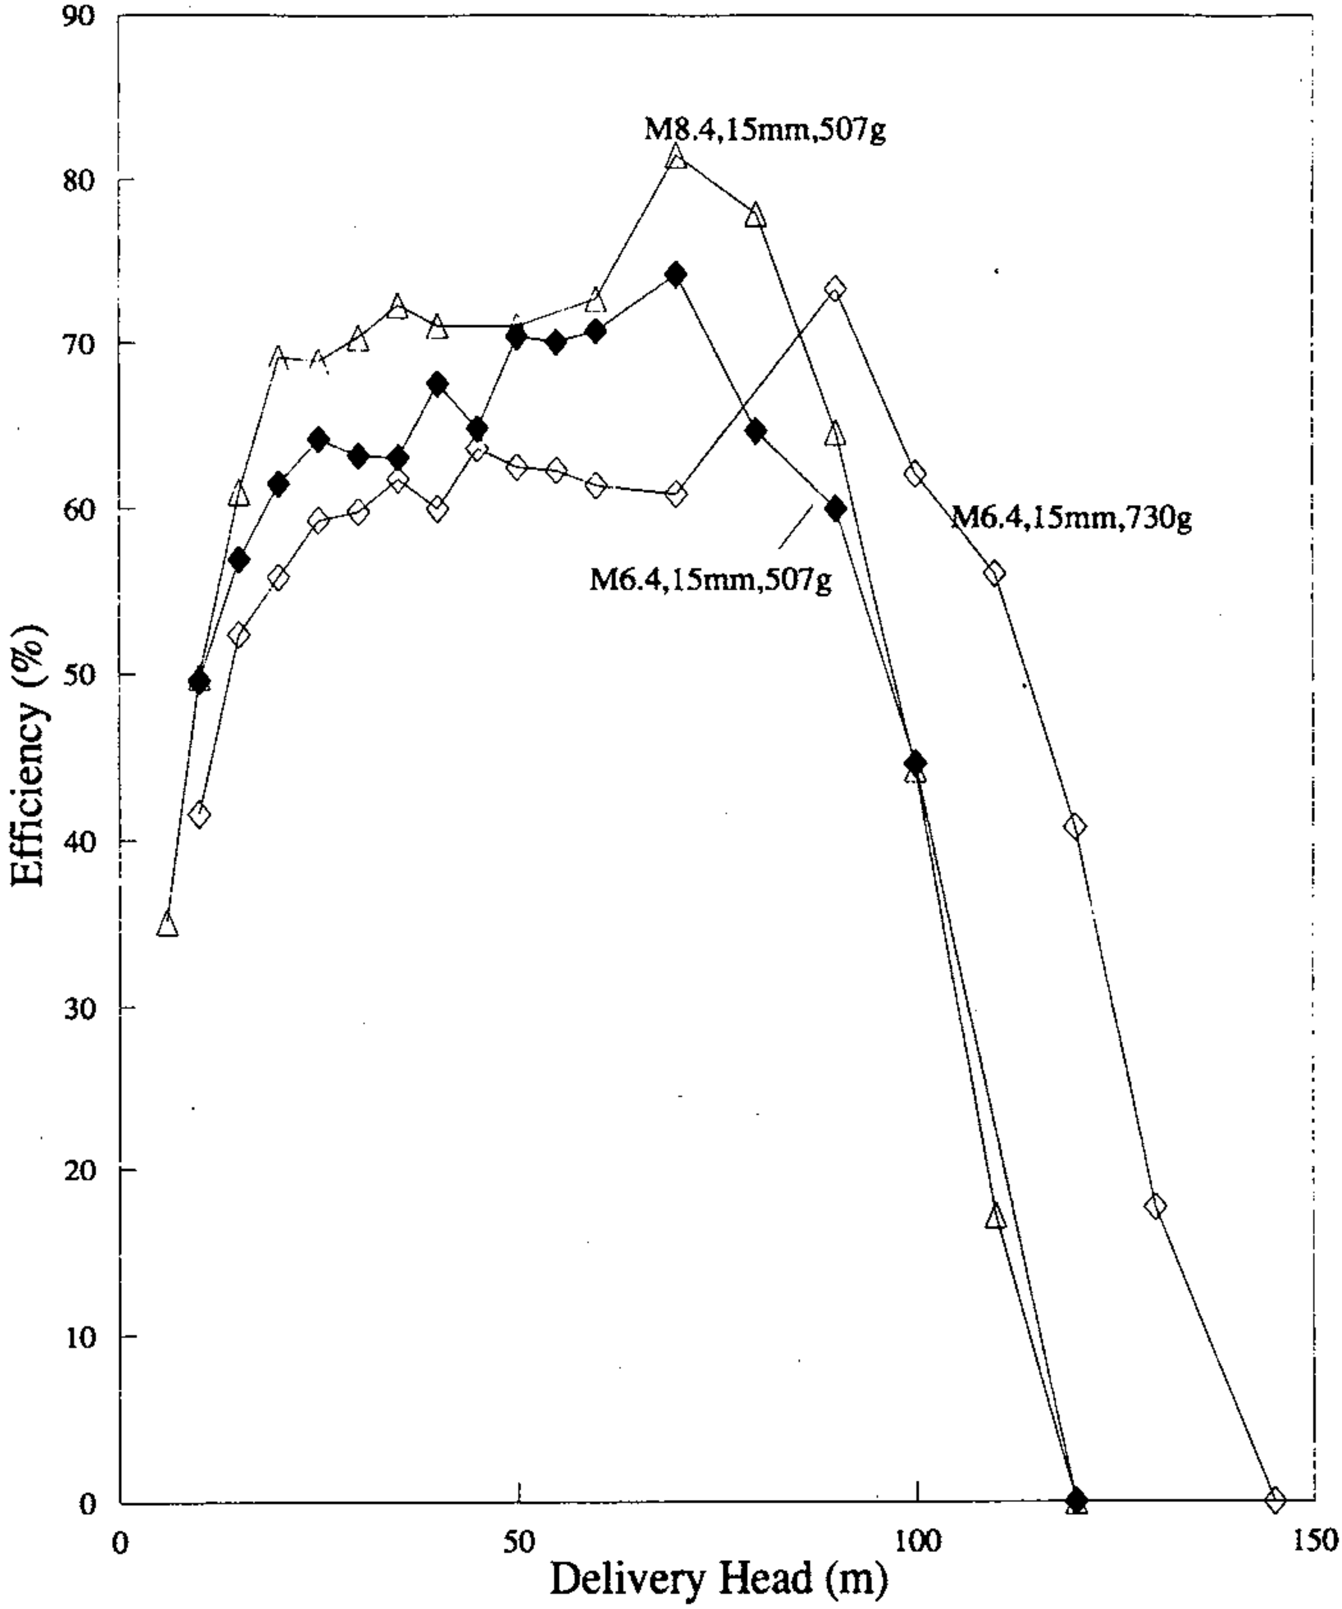
Appendix A **CONTINUING DTU PUMP DEVELOPMENT**

The Mark 6.4 pump was set as a DTU standard in 1990 to allow organisations interested in using the pummp to have a standard model to work with. Since that time a number of developments have occurred in the on-going research programme and new design initiatives produced. One such is the development of the Mark 8.4 that uses the same valves as the M6.4 but replaces the 2" fittings used in the pump body witha body of 4" velded construction. This alteration dramatically reduces the peak overpressure experienced the system, damps out the high frequency oscillations experienced during the cycle and increases both the efficiency and power output for any given set of conditions.

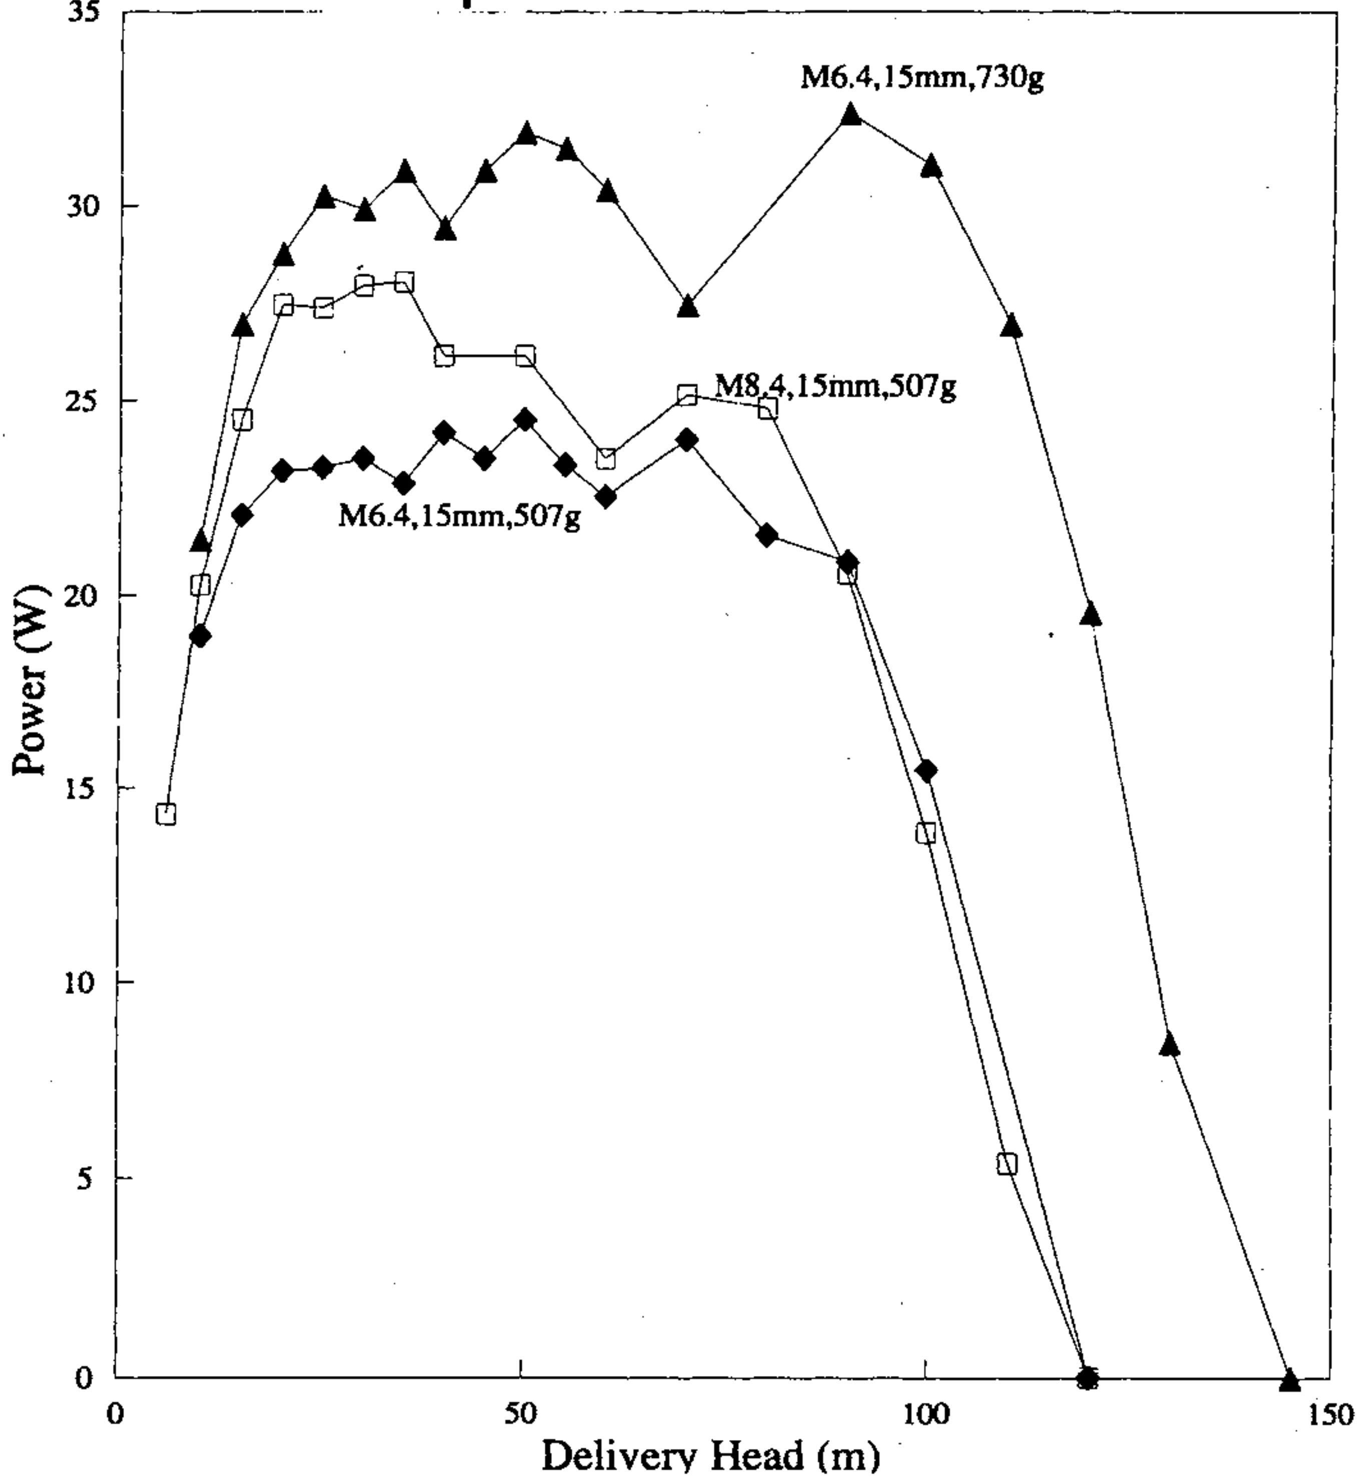
Graphs 10 and 11 allow comparison of the M8.4 with the M6.4 under identical conditions.

Efficiency Comparison of M6.4 & M8.4



GRAPH 11

Power Comparison of M6.4 & M8.4



Appendix B **TABLES OF PERFORMANCE RESULTS**

Tablulated results used in production of Graphs.

The following pages list the information supplied by Delft and that gained under similar conditions on the DTU pump. In all cases the **Supply Head = 3m.**

Appendix C **FURTHER NOTES AND COMMENTS ON THE WORK AT DELFT**

The following are a series of points arising from the work at Delft that have not been mentioned in the main text of this paper.

1) Delft managed to record delivery valve movement of rubber type valves by bonding strain guages to the rubber. This technique overcomes the difficulty of recording and analysing delivery valve movement experienced by the DTU.

2) An electronic beat frequency counter was used at Delft to record the operating frequency and period of pumps under test. This is another technique worth pursuing for ongoing tests at Warwick.

3) There is some confusion and lack of consistancy between ram pump manufacturers and users as to how efficiency is measured. Delft produce the following summary

<u>Rankine</u> Drive tank water level is taken as the datum point and supply and delivery heads measured from that point. Therefore the net amount of potential energy in the water delivered $= \rho g q(h-H)$
the net amount of energy input $= \rho g Q H$

$$\text{Hence Rankine efficiency} \quad \eta_R = \frac{q \times (h-H)}{Q \times H}$$

<u>D'Aubuisson</u> The impulse valve orifice is taken as the datum point and therefore

$$\text{work done} = \rho g q h$$

$$\text{energy supply} = \rho g\ (Q + q)H$$

$$\text{D'Aubuisson Efficiency } \eta_D = \frac{q \times h}{(Q + q) \times H}$$

<u>Manufacturers</u>

Most manufacturers take a simplified efficiency that actually produces a higher value of efficiency under any given set of conditions

$$\eta_m = \frac{q \times h}{Q \times H}$$

Delft prefer the Rankine expression which yields the lowest results particularly at low delivery heads.

The DTU currently uses the D'Aubuisson formula as the test rig measures the total flow into the pump (Q + q) rather than just the waste flow. This has been used throughout this report.

There seems little to choose between these two which produce similar results under normal operating conditions. The simplified efficiency used by many manufacturers is more inaccurate but produces more flattering figures!

4) Observation on relative position of delivery and impulse valves concerning air intake during recoil.

During recoil, large quantities of air can be drawn in through the open impulse valve as water flows back up the drive pipe. Only a small quantity of air can be drawn through the snifter valve so section A remains relatively full of water. As acceleration of water towards the pump re-occurs the majority of the air is expelled through the impulse valve and only the small volume entering from the snifter enters the air vessel.

If the recoil is large in this configuration and a significant quantity of air drawn in through the impulse valve, the column may receed past the vertical pipe section leading to the delivery valve. When acceleration occurs a significant pocket of air may be trapped under the delivery valve. This would tend to dampen out the next pressure pulse and reduce delivery flow.

5) The Alto ram from France has an inflatable rubber air compartment in the air vessel to ensure a permanent separation of air and water. This is an attractive option as it reduces the need for a reliable snifter to replenish air lost from the air vessel.

6) The SANO rams are fitted with a 'drip valve' in the air vessel that appears to be located at a point where the air/water interface should be. It presumably operates by passing water if the level in the air vessel rises above it. What is its operating mechanism?

8) Delft draw the following conclusions about pump performance and operation from results produced by their mathematical model.

- given an available source supply the pumping rate (q) is primarily determined by the supply head (H_s)and the delivery head (h_d).
- an increase of the delivery head (h_d) decreases the quantity pumped per cycle (V_d) and by that the pumping rate (q) decreases.
- an increase of the supply head (H_s) increases the pumping frequency and by that the pumping rate (q) increases.
- an increase of u_c (ie. the velocity of the water in the drive pipe at waste valve closure) normally increases the pumping rate (q) while the pumping frequency decreases, but more water (Q) is needed to operate the ram. However, there is a limiation as to this point: an increase in u_c such that the value of the ratio u_c/u_o approaches unity (where u_o is the maximum attainable velocity of the water in the drive pipe) implies a decrease in pumping rate (q) while, as before, the waste flow (Q) increases, a condition to be avoided.
- the larger the size (ie. drive pipe bore) of the ram, the more water (Q) is required to operate the ram and the more water (q) can be delivered to a higher level (h_d).

9) Delft recommend that if the delivery flow from one ramains insufficient a second ram should be placed below the first and utilise its drive water. However if there is sufficient drive head available to be able to do this would a better performance be gained by having two rams each working from a portion of the drive head or one ram working with the total head available?

10) Delft state that the drive pipe length should be approximately 4 to 7 times the supply head. They make no justification for this statement.

11) Delft state that the best pumping results are usually obtained when the cut off velocity is between 60% and 80% of the terminal velocity of the system.

12) Delft produce equations for predicting pump performance, which require certain information about the system to tbe known.

A loss coefficient for the whole system is required which covers all the losses in the drive pipe, pump and delivery pipe. Delft state that this can be found by holding open the impulse valve, measuring the flow rate at terminal velocity and inserting this into the equation

$$\text{max velocity} \quad V = \sqrt{\frac{2gH}{\text{loss coef}}}$$

This does not take into account the delivery system losses and can only be measured once the system is installed, preventing prediction of performance prior to installation. It would be more useful to have a loss coefficient measured for each pump and also to have a simple method of calculating pipe loss coefficient based on diameter and length.

The other requirement for use of Delft's model is to find the cut off velocity for the particular impulse valve setting. They state that this can be found when the maximum delivery head obtainable is known using

$$\text{Cutoff} = (g/c) \times h_{max}$$

They recommend that h_{max} is found by closing the delivery side of the pump and letting the pump run up to its maximum head. This would provide a rather crude approximation producing a low result and could prove to be very dangerous.

THE TREADLEPUMP

A human-powered pump for small-scale irrigation in Developing Countries

DTU Working Paper 34

prepared for The Ramat-Warwick Linkage Programme, Sub-Programme 4
under the North East Arid Zone Development Programme
Borno State, Nigeria

The Development Technology Unit, Department of Engineering
University of Warwick, Coventry, CV4 7AL, U.K.

SUMMARY

Using a treadlepump to lift water to a height of 5 metres it is possible for a farmer to irrigate approximately 0.25 hectares of land. The pump can be used for long periods of time because of good ergonomic design. The cost of construction is low and the pump can provide an appropriate technology for smallholders with little capital to spend on irrigation.

THE TREADLEPUMP

A human-powered pump for small-scale irrigation in Developing Countries

1.0 INTRODUCTION

This report has been prepared by the Development Technology Unit of the University of Warwick, Coventry, U.K. It is part of the studies carried out under an EEC funded linkage programme between the University of Warwick and Ramat Polytechnic, Borno State, Nigeria. The linkage is a sub-programme of the North East Arid Zone Development Programme (NEAZDP) which itself seeks to promote the development of rural people in the region and promote long-term sustainability.

The subject of this report is treadlepumps and their use for small-scale irrigation in Developing Countries. The treadlepump is a human-powered water pump that can lift irrigation water from ground or surface sources. The pump consists of two pumping cylinders that are worked reciprocally by the action of the operator standing on two treadle bars. This system gives a near constant flow of water and a comfortable pumping action for the user. The design of the pump allows operators to shift their position along the treadles and so vary the force on the cylinders; in this way a range of pumping heads can be achieved.

The principle advantage of the treadlepump over other forms of human-powered water pump is that it makes best use of the muscles of the body: The treadle action uses the large muscles of the legs, buttocks, and back. This allows sustained use of the pump and the pumping of large volumes of water that are needed for irrigation.

There are currently several designs of treadlepump produced, and a section of the report details their principal features, strengths, and weaknesses. For interested parties there are contact addresses for all the pumps described.

The report goes on to describe why it was thought valuable to develop a new design to cater to the special needs of African countries. The result was the Warwick treadlepump and the original design specification is included with a discussion of the pump's construction and performance. Complete construction details of the Warwick treadlepump, engineering drawings and notes, are given in an appendix. A second appendix discusses the use of the treadlepump in the context of Borno State, Nigeria.

2.0 THE NEED FOR TREADLEPUMPS
A Comparison of Pumping Technologies for Developing Countries

As the human population increases at an ever faster rate the need for increased food production is pressing. The greatest need is in Developing Countries where populations are growing fastest and the land available for the growth of staple crops is shrinking. One of the best ways this can be achieved is by making appropriate irrigation technology available to the small farmer.

In Developing Countries much of the land is family-owned in small plots. It is not uncommon for the majority of farming land to be owned in units of less than 2 hectares. These small lots are often worked solely by the owners and their families, and external inputs, in the form of mechanisation and fertiliser, are low.

The way to increased production has often been seen through incorporating small holdings into larger units and introducing mechanisation and large-scale irrigation. This approach, while successful if carefully thought out, often produces many problems that did not occur with indigenous farming methods; salination, hard-panning, and loss of fertility. Often this type of farming proves to be less efficient than traditional methods.

Modern thinking for the development of agricultural production in Developing Countries looks to retain the traditional ownership of the land and support the indigenous farmer by providing educational and appropriate technical support.

Irrigation is one of the principle ways to increase production in agriculture either by extending the growing season on existing land or by bringing further land into production. Providing small farmers with irrigation water from large schemes can be very expensive: The cost of civil engineering works must be subsidised by the government, or another agency, as the cost is beyond the reach of the rural poor. The collection of water fees from a large number of users is also difficult. Such schemes often achieve only low efficiencies (high water wastage).

The alternative is small scale irrigation using appropriate, locally maintainable technology that is directly controlled by the farmer. As a smallholder can only afford a small capital sum and low running costs the options for technological inputs are limited. A low initial cost eliminates the use of a renewable energy such as solar or wind even though these technologies offer very low costs in the long term. The cost of petrol or diesel engines is also high and although fuel is cheap in some countries, such as Nigeria, its supply can be uncertain and spare motor parts are, at best, expensive, at worst, unobtainable. This leaves the use of animal or human labour for water pumping activities. In areas where draft animals are already used animal power is a good option. However if the animal is used solely for irrigation activities it is unlikely that the extra return gained is sufficient to justify the expense of keeping the animal. In this case joint ownership would seem to be the answer but this brings with it a further set of problems regarding the upkeep of the animal.

Human labour on the other hand can be used for irrigation when not occupied with other tasks, and although the power output of a human is low, when compared to other energy sources, the farmer can decide exactly when and how much to irrigate the fields. This level of control given to the farmer can significantly increase yields.

For these reasons small, human-powered water pumps for irrigation are very useful to the smallholder with few resources. Pumps that can be operated and maintained at a village level also have the advantage reducing the dependence of farmers on outside support services and increasing their self reliance. The treadlepump is designed with these criteria in mind and as will be shown in Section 4.0 makes best use of the capabilities of the human body in providing power for water pumping.

3.0 TREADLEPUMPS- A Description

The treadlepump is a human-powered water pump that is used principally for irrigating smallholdings of land. In all its forms water is pumped by two direct-displacement pistons which are operated reciprocally by the walking/stepping motion of the user.

A general layout of the treadlepump is shown in Fig 3.1. The range of treadlepump designs can be split into two groups: Those that will lift water from a lower level to the height of the pump; and those that will both lift water from a lower level and lift it further to a greater height than the pump. These two types can be described as a suction pump, and a suction and pressure pump, respectively.

The basic components of any treadlepump are described below:

3.1 Pump Cylinders

The two pumping cylinders are operated reciprocally and give a near continuous flow of water. Depending on the operating head, the diameter of the pump cylinders is normally between 75mm (for high heads) and 150mm (for low heads), most often 100mm diameter is chosen. A cylinder diameter of 100mm is suitable for pumping water to heads of between 3 and 8m.

Cylinder materials vary from curved steel sheet to bamboo to pvc pipe. Choice of material is strongly influenced by local availability and cost. Steel is a good choice if there are sufficient skills and machinery to work it; pvc pipe is often more readily available and easier to work. Bamboo is cheap and plentiful in some locations and has the advantage of maintainability at the farm level but suffers from having a short working life: It is not suitable for pressure pumps. The choice of material will also be influenced by the type of pump manifold and how it connects to the cylinders.

3.2 Pump Manifold

The manifold connects the inlet and outlet pipes to the cylinders (in a suction pump it is not necessary). It is separated into two; water enters the pump at the entry side of the manifold, and after passing through the cylinders, leaves on the discharge side. The manifold normally houses the non-return valves which prevent backflow in the pump.

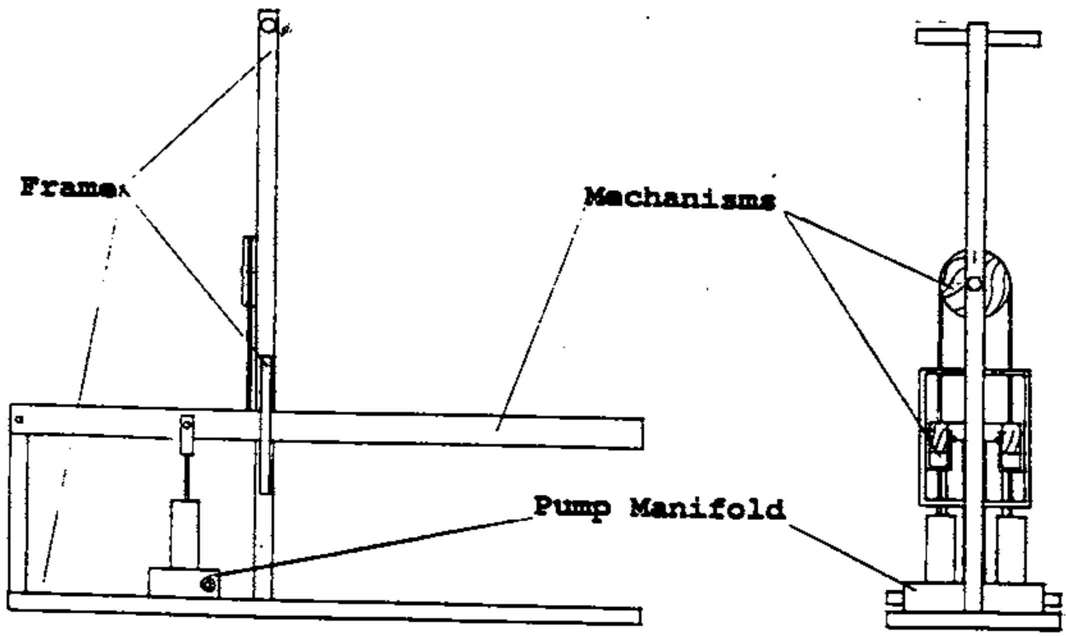
The manifold can be constructed from steel sheet welded into the form of a box, or more easily, in a pump with pvc cylinders, from pipe fittings or straight pipe. The design of the manifold must allow for the removal of the non-return valves for maintenance.

3.3 Non-Return Valves

In a suction only pump the non-return valves are situated in the piston heads and in the inlet pipe. In a suction and pressure pump there are two pairs, one on the inlet side of the pump and one on the outlet. The valves allow water to travel through the pump but prevent its backflow to the source. The valves open and close due to the positive and negative pressures developed during pumping.

Various types of non-return valve are used in treadlepump designs, these include rubber flaps, swinging gates, and poppet valves. The Warwick design uses a new type of valve that relies on the stretching of a rubber flap over a pattern of holes and is unique in that it involves no moving parts.

FIGURE 3.1 Main Components of the Treadlepump



3.4 Piston Assembly

The pistons are driven up and down within the cylinders by the weight of the operator on the treadles. The piston rod is connected to the treadles by a hinge that allows the piston to stay vertical in the cylinder as the treadles are moved up and down. This is important to maintain a good seal between the piston cups and the cylinder.

The piston rods are normally of round steel bar and are threaded at one end to attach the piston cups or rings. The piston cups can be made of rubber or leather but must provide a good water seal and sustain the rigours of continual friction against the cylinder wall.

3.5 Treadles

The pump operator stands on the treadles and pushes them up and down to work the pump. They are normally hinged at one end but in one bamboo version the hinge is between the cylinders and the operator. At the opposite end, the treadles are supported by a pulley wheel and rope or a rocking bar. The range of movement is dictated by the stroke length of the pistons and most importantly by the comfortable operating step of the operator.

The treadles can be made from wood, bamboo, or steel. Steel is only normally used when the treadles are to be cranked to bring the operator closer to the ground.

3.6 Pulley Wheel

The pulley wheel allows the cylinders to move reciprocally and so provides a natural operating style for the user. The wheel has a central axle mounted to a frame; a simple axle, such as a 16mm diameter bolt, is normally used. The wheel can be made from hard wood and boiling the wheel in oil treates the wood and lubricates the bearing for a substantial time.

An alternative to the wheel is a rocking bar which is pivoted in the middle. This arrangement is harder to balance but may be easier to construct in some instances.

3.7 Frame

The component parts of the treadlepump are mounted on a frame or in some designs buried in the ground: A frame allows the pump to be carried to where it is most needed. Although an expensive part of the pump, portability adds significantly to its value in irrigation.

Angle iron or box section are most often used to make a frame that will stand the weight of the user and the rigours of transportation.

If the pump does not need to moved regularly it may be acceptable to dispense with the frame and support the treadle hinges and the pulley wheel on stakes knocked into the ground. This will reduce the cost of the pump. In Bangladesh the Tapak-Tapak pump uses this set-up but it is reported that the pump is carried back to the house each night for security; obviously here the lack of a frame has not stopped the pump being portable!

3.8 Summary of Treadlepump Components

If the parts just described are well designed and matched, the pump will operate smoothly and efficiently. To end this section here is an attempt to describe the action of powering the treadlepump.

The motion of the operator's legs on the treadles is similar to a combination of walking on the spot and of climbing a ladder. Operators can become accustomed to this movement very quickly and in a well designed pump will find that it can be sustained for several hours a day with appropriate rests. A full description of the ergonomic design of the pump is given in Section 4.0.

4.0 THE ERGONOMICS OF TREADLEPUMPS

Using human labour to power a water pump has several advantages: Given a constant water source the farmer can choose exactly when to irrigate. If irrigation is not required the farmer can usefully work at other tasks without having expensive animals or machinery standing idle. However the human body is not very efficient at converting food stuffs into work energy and requires what is, in effect, very high-grade fuel. Also the total amount of power available from one person for manual work is not high- it is in the range 200-300 watts per day. So any machine that uses human power should be efficient to make best use of the scant power available. Another important point is the ergonomic design of the machine that enables it to be used comfortably and for sustained periods of time.

The human body will quickly tire if isolated groups of muscles are used exclusively or if the body is forced to work in an awkward position. Where only a small power input, in human terms, is required, for short periods of time, these points do not need to be considered so carefully. A good example of this is the community handpump where the work done by each individual user is small: The arms are required to do almost all the work, and often the body is bent over, but the water is soon lifted and the activity ceases.

But for irrigation the volumes of water that are necessary to irrigate even small areas of land (0.25 hectare) are very large- several thousand litres when compares to 50-100 litres for household use- and consequently the pump design is paramount. Therefore the human-powered, small-scale irrigation pump must be able to pump large quantities of water and be comfortable to use for several hours a day.

4.1 Utilising Human Power

Perhaps the best way for utilising human power is the bicycle: The pedalling motion of the legs uses the large muscles of the legs, buttocks, and back. A power output of approximately 75 Watts can be sustained for up to 4 hours a day. However the bicycle design requires the use of sprockets and chains which are costly to produce and cannot be easily repaired in rural areas of Developing Countries.

A much simpler arrangement that approximates to the action of pedalling is that used in the treadlepump. The operator stands with one foot on each treadle bar and operates the pump by moving the bars up and down in a reciprocating motion. This is a natural movement for the human body, somewhat akin to walking, and can be sustained for long periods if the parameters of stroke length, cadence, and foot force are matched to the operator.

4.2 Stroke Length

The stroke length is the vertical distance between the feet when one foot is at its uppermost position and the other at its lowest. Too short a stroke and the leg muscles will tire quickly, too high and the leg muscles are straining. On a bicycle a crank of approximately 170mm gives a comfortable and efficient action; this is equivalent to a stroke length of 340mm on a treadlepump. In the case of the stepping action of the treadlepump this is a long stroke and results in a low pumping cadence (the speed of pumping). The relationship between stroke and the cadence is inversely proportional: The stroke lengths is governed by what is a comfortable speed to operate the pump. Another point to consider is the difficulty of sustaining a high foot force when pumping to high heads if the stroke length is long.

Bearing in mind these factors a pump that offers stroke lengths in the range of 100-350mm will be comfortable to operate. The operator will normally choose a short stroke length at high heads and a longer stroke with decreasing head.

4.3 Cadence

The cadence is the frequency with which the treadles are moved up and down: One cycle is completed when a treadle bar is pushed down and rises once again to its starting position. A cadence of up to 60 cycles per a minute is comfortable.

With increasing foot force (at higher heads) the cadence will tend to drop and the stroke length increase. The opposite is true for low heads where the stroke can be very short and fast; this can be tiring. In this case moving along the treadles nearer to the hinge will reduce the mechanical advantage and so improve the pumping action of the operator.

4.4 Foot Force

The pumping head is overcome by the force on the piston acting against the water in the cylinders. The piston force must also overcome the friction losses is the pipes.

The force exerted on the pistons by the operator can be varied by the operator moving along the treadles: This varies the mechanical advantage between the operator and the cylinders. This is one of the most useful features of the treadlepump. Not only can the operator find a comfortable position for different pumping situations but also the pump is adaptable, without modification, to a wide range of people of different strengths and weights.

For extended periods of pumping the foot force should not exceed 50% of the operators body weight, the maximum for short periods of time is approximately 70%. Therefore to be suitable for men , women, and children a pump should be designed to give foot forces of 15-50kg across the range of pumping heads.

If a pump is to be used almost exclusively for a particular head application then the cylinder diameter can be chosen to obtain suitable foot forces. The most common cylinder diameter is 100mm and is suitable for heads of between 3-8 metres. Below 3m a 150mm cylinder is suitable and above 8m a 75mm can be used. However a 75mm cylinder reduces the quantities of water pumped significantly and therefore pumping irrigation water to heads of more than 8 metres using human power is not normally economic.

4.5 Mechanical Advantage

Moving up and down the treadles varies the mechanical advantage of the treadlepump. In this way the operator can vary the force exerted on the pistons while maintaining an approximately steady foot force. This is much less tiring than a pump where the force required is fixed according to the head of water.

To allow the pump to be used by the widest range of operators and across varying pumping heads it can be calculated that the mechanical advantage must vary between 0.5 to 1 and 3 to 1 for a 100mm cylinder. The low values of mechanical advantage, less than 1 to 1, can be easily obtained by the pump operator moving on top of the pistons and even past them, next to the hinges. For high mechanical advantage, of 3 to 1, the distance between the hinge and the end of the treadles must be three times the distance between the hinge and the piston. Care must be taken to ensure the pump does not overturn when the operator stands at the extreme end of the treadles.

4.6 Treadle Spacing

A comfortable spacing of the treadles is between 175-200mm. Slight variations can be achieved by the operator moving the feet to one side of the treadle bars. In practise the spacing of the cylinders will probably dictate that the treadle spacing is close to 200mm.

4.7 Summary of Ergonomic Features

A pump that provides the maximum range of adaptability while retaining a comfortable pumping action will have the following features:

Stroke Length	100-350mm
Cadence	as chosen by operator
Foot Force	15-50kg
Mechanical Advantage	from 0.5 to 1 upto 3 to 1
Treadle Spacing	175-200mm

5.0 CURRENT TREADLEPUMP DESIGNS

5.1 The Bellow Pump

The Bellow Pump design evolved at the International Rice Research Institute (IRRI) in the Philippines. However although having some characteristics in common it is not a true treadlepump and so only a brief description is given here. The pump has two sets of flap valves and is both a suction and pressure pump.

Construction

The pump utilises a pair of flexible bellows fitted together on a base plate; see Figure 5.1 for a general layout. The pumping action is a rocking one with the bellows being operated reciprocally. The material for the bellows is principally canvas which is reinforced with steel sheet with a rubber bladder inside. The bellows are stitched together to achieve the desired shape and considerable care is needed to ensure a water-tight seal. The discharge box, a kind of manifold, is made from steel sheet folded into shape. The non-return valves are a rubber flap with a hard rubber stiffener; the valve assembly bolts over a hole in the discharge box.

In general the construction requires accurate marking out of the component parts and skillful stitching to produce a durable pump. However few machine tools are needed; there is a small amount of welding. The materials used are many: steel, canvas, two types of rubber, bolts, rivets, steel and plastic pipe.

Performance

The output flow of the bellow pump is large by human-powered pumping standards- nearly 90 l/s at 1.5m head falling to 40 l/s at 3.5m head. The pump testing was carried out by pumping for 15 minute periods and so even the quoted maximum efficiency figure of 40% at 2.5m, calculated using a human power input of 75 Watts, could be over optimistic. Pumping to heads of greater than 3.5m is not suitable since the foot force the operator must apply is excessive; unlike a treadlepump there is no way to vary the mechanical advantage of the bellow pump.

Summary

The Bellow Pump requires considerable skill in its manufacture although few tools are required. It can pump large volumes of water to small heads but is, at best, only 40% efficient. Reports of field trials call into question the durability of the pump and it appears that, now, few are still used or manufactured.

5.2 The Tapak-Tapak, Bangladesh

The Tapak-Tapak Treadlepump, or TT Pump, is almost certainly the most widely used of treadlepump designs. The design originates from northern Bangladesh, where there are reported to be 50,000 pumps in use, and has also been adapted by IRRI for use in the Philippines.

The pump is for suction only and so is suitable only for pumping from shallow wells (upto a maximum 7m, but more normally 5m) or from surface water. In Bangladesh this is ideal since the water table is close to the surface even in the dry season.

Construction

The original version of the TT Pump was made predominantly of bamboo which kept its cost very low- US$8 in 1986. Modifications to the pump have used sheet steel and even cast iron cylinders. A layout of the TT pump as built in the Philippines is shown in Figure 5.2

Water is sucked up to the pump manifold and through non-return valves into the cylinders. The valves are simple flaps of car tyre. The cylinder material is bamboo or a more durable material in the improved pumps. The piston heads contain bucket valves that allow water to flow through the piston on the downstroke and drain into a channel that carries the water to the field. The bucket valves use prefabricated piston cups that are made for handpumps; these are commonly available in some countries but can be very expensive in Africa.

The layout of the pump is typical of treadlepumps in general: The treadles are supported at one end by a rotating hinge and the cylinders are placed approximately 1m from the hinge to avoid excessive twisting of the piston cups in the cylinder. The operator stands at the far end of the treadles next to the pulley wheel that supports the treadles. In the Bangladeshi "Dheki" design this has been modified to eliminate the pulley wheel and supporting rope: The hinge has been placed between the operator and the cylinders. This arrangement has several ergonomic disadvantages but the cost savings appear to override these as the design is now the best seller. The frame and the pipe work for the original TT pump are very cheap since they are all made from bamboo by the farmer.

In the improved version of the pump developed in the Philippines the construction is much more complicated: Part of the frame is welded steel and the cylinder unit is of intricately folded sheet steel; the piston bucket valves need some machining; steel pipe is used for the suction pipe. This increased the cost of the pump to US$25 in 1987 but the pump is a very good product. However the materials and skills used in the construction of this pump are prohibitively expensive in some countries, many parts of Africa especially.

Performance

The figures available for the TT pump suggest that efficiency is quite high. At low rates of exertion the water power delivered by the pump is in the range of 40-50 Watts for lifts of between 3.4-5.5m. From this an estimate of the pump efficiency is approximately 50% Surprisingly the results for the modified or "Dheki" design of pump show only a slight reduction in efficiency even though the pumping action and mechanical advantage are poor. This could possibility be due to the operators familiarity with the "Dheki" as the same mechanism is used in rice pounding devices.

As the pump is suction only it is unlikely that it is suitable for use where water is at a depth of more than 5m; below this the quantity of water required for irrigation is very hard to pump using human power.

NOTE: DETAILED PARTS IN THE FOLLOWING PAGES ARE SERIALIZED BY REFERENCE NUMBERS AND ARE ENCLOSED IN HEXAGONAL FIGURE ⬡ TO INDICATE FABRICATED PARTS. THOSE ENCIRCLED ○ DENOTES PURCHASED STANDARD PARTS.

PERSPECTIVE VIEW

Summary

The Tapak-Tapak Pump is the most widely used treadlepump and is suitable for pumping from wells and surface water where the lift is less than 5m. Construction can be very cheap if bamboo is used for the principal parts but the introduction of more durable materials and commercial piston rings increases the cost. Increased levels of skill are required to make the improved versions.

5.3 The USAID treadlepump, Ivory Coast

The USAID treadlepump is another design based on the Tapak-Tapak Pump (TT Pump) from Bangladesh. The design has been adapted to use commercially available pvc pipe and fittings. There are also two versions of the pump; suction only, and suction and pressure.

Construction

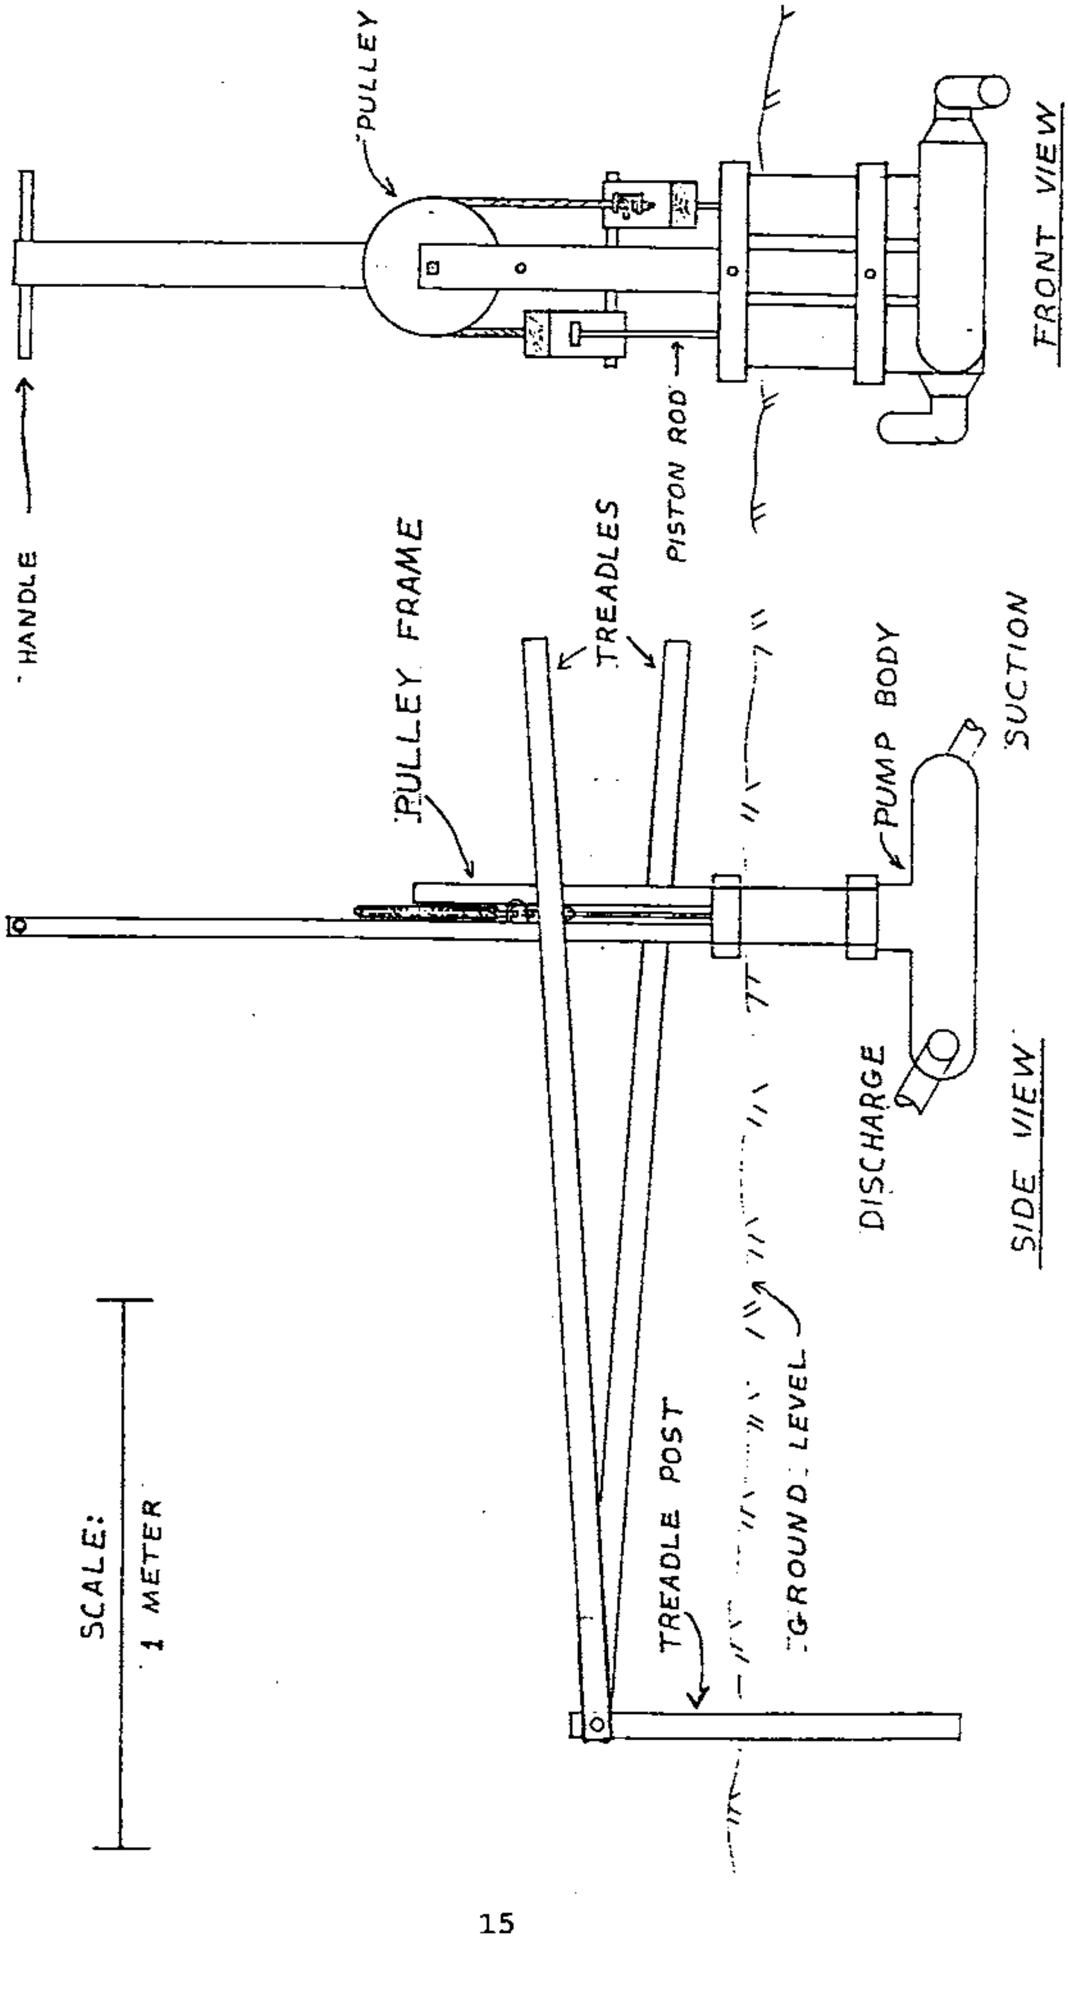
The design is shown in Figure 5.3. It has no frame and is buried in the ground on site. This is a disadvantage if the pump is to be moved frequently. The treadles and pulley wheel are similar to the TT Pump but the cylinders and the manifolds are made from pvc pipe and pipe fittings. The manifolds contain the non-return valves and so are fixed together using a non-hardening joint compound to allow for removal during maintenance. This compound might be difficult and expensive to obtain. There are two designs of non-return valve offered for the pump, a simple rubber swinging gate valve or a more complex flap valve that closes over a metal disk perforated with drill holes. Both systems require some machining to obtain a good fit with the inside of the pipe. A suction only version uses valves in the piston cup and it too requires machining.

The use of pvc fittings and pipe makes the manifold and cylinder assembly extremely easy to construct. However in many countries fittings such as the T-pieces and elbows required are both difficult and expensive to obtain. The piston cups are also commercial products although leather could be substituted.

Performance

The pumps were tested over 15-30 minute intervals and so using a human power output figure of 75 Watts maybe misleading: For short periods such as these a fit person can sustain a higher power rating. Even so the figures give by the designers of approximately 1.5 l/s at 6m head and 2 l/s at 4m head indicate that efficiency of the pump must be quite high- perhaps 75% This is not so surprising considering the quality of materials and construction in the pump.

FIGURE 5.3 The USAID Treadlepump



Summary

This is a good design of pump if pvc pipe and fittings are available and there are the necessary machines and skills to construct the non-return valves. Its lack of portability might also restrict its appropriateness. The use of many bought materials will make this an expensive pump in many parts of the world.

5.4 The Harare treadlepump, Zimbabwe

This pump has been designed with the aid of Loughborough University in the U.K. and has been called the Harare treadlepump for the purposes of this report because that is where it is manufactured (in the Loughborough University literature it is called the Pressurised Discharge Treadle Pump). It is a suction and pressure treadlepump which has a familiar layout.

Construction

Like the USAID pump pvc pipe is used for the cylinders but the manifold is made from welded sheet steel. Access to the manifold is via a cover plate that bolts to a flange plate in the manifold. Internally the manifold is divided in two to provide a separate valve chamber for each cylinder. The non-return valves are of a novel design that allows the whole valve assembly to be removed for maintenance: The valve is not attached to the manifold but is restrained from "popping out" by a stop of thick car tyre. Diagrams of the manifold and the valve design are given Figure 5.4.

The frame is of welded angle iron and allows the pump to be transported easily. The treadles are supported by a pulley wheel and rope and the frame includes an adjustable handle for the operator to hold.

Performance

Only very limited performance data is given for the Harare treadlepump; for test periods of 15 minutes the pump delivered 0.4 l/s to a head of 14m. This is a power output of 60 Watts and suggests that the operator must have been working hard. Efficiency is hard to estimate in this case.

Summary

The Harare treadlepump uses pvc cylinders and a steel manifold and as a suction and pressure pump can lift water to high heads. The construction requires a good deal of welding. The cost is high at US$275 in 1989 and this is due most probably to the amount of steel and the welding involved.

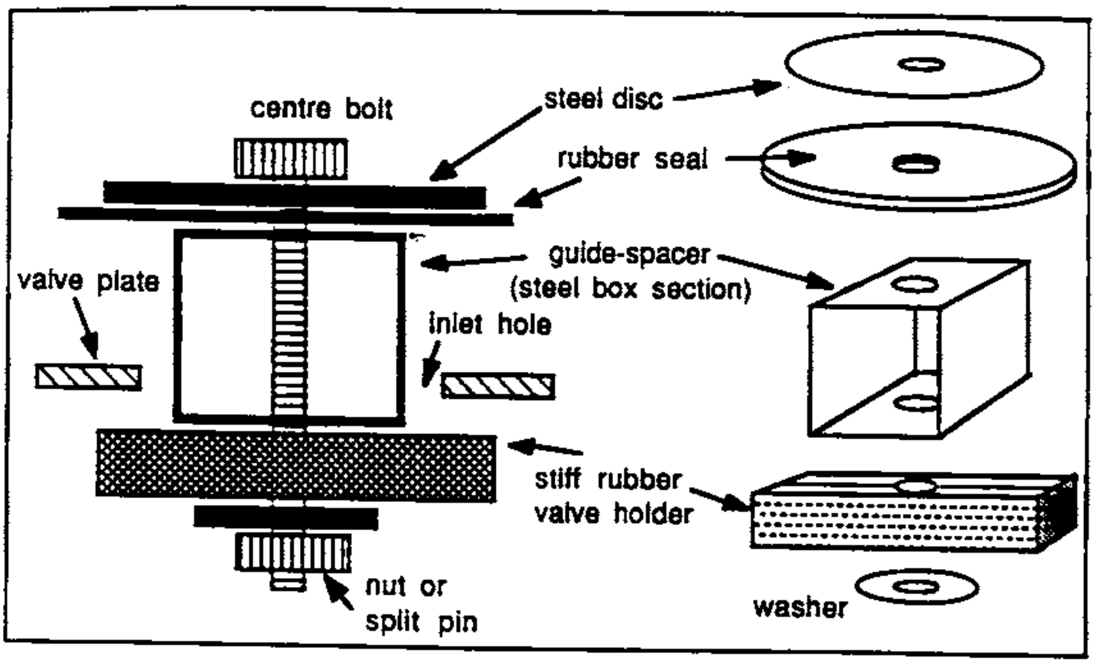

Figure 5: Valve details

5.5 The Warwick treadlepump, (Nigeria)

The Warwick Treadlepump is a suction and pressure treadlepump that has been designed to reduce the cost and complexity of other currently available designs particularly in African countries. At the time of writing, October 1991, it is about to undergo field trials in the North East Arid Zone of Borno State, Nigeria. A picture of the pump is shown in Figure 5.5.

Construction

The unique feature of the Warwick treadlepump is the use of pvc pipe to form both the cylinders and the manifold. The intersection of the cylinders to the manifold is made by cutting the pipe using a metal jig: No pipe fittings are needed in its construction. The intersection is sealed with a rubber gasket which also acts as a non-return valve by stretching away from the pipe wall during pumping. As the non-return valves have no moving parts, and are made completely from rubber, they are easy to make and cheap to replace.

The pump has a frame of angle iron and treadles of wood. The piston rods are made from round steel bar and the piston cups of leather. The parts of the pump can all be made using hand tools, although the frame needs some welding and the pipe intersections must be cut using a special jig.

During assembly much care must be taken to align the valves and intersections correctly otherwise the pump will not seal properly. Dismantling the pump for maintenance is very straightforward.

The engineering drawings and construction notes of the Warwick treadlepump are presented in Appendix A of this report.

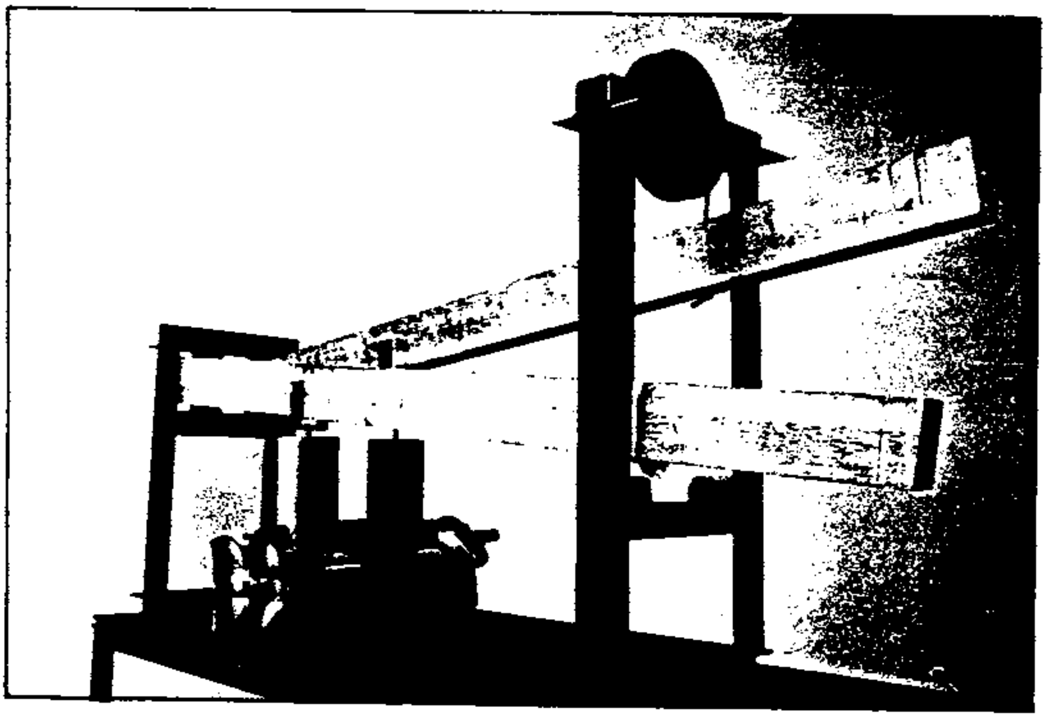
Performance

The performance of the Warwick treadlepump is given in detail in Section 6.0

Summary

The Warwick design of treadlepump uses straight pvc pipe and rubber flap valves to create a cylinder and manifold assembly that can be cheaply made. It is most suitable for lifts of between 3-8m. It is a design that is well suited to countries where steel prices are high and machine tools and metal working skills scarce.

FIGURE 5.5 The Warwick Treadlepump



6.0 THE WARWICK TREADLEPUMP

Although some of the pump designs discussed in Section 5.0 have good qualities, the Development Technology Unit (DTU) at the University of Warwick felt it was worthwhile to develop a further design that:

(a) was ergonomically effective as the best existing designs,
(b) was well suited to the needs of African smallholder irrigation in terms of flow rate, range of heads, portability, and ease of maintenance,
(c) was simpler to make than other designs and considerably cheaper,
(d) used materials fairly readily available in African countries and avoids components (such as pipe fittings) which are not.

With any technology for rural application the DTU tries to serve not just the user but the artisan interest group as well- it seeks to identify products and designs suitable for income generation via manufacture in villages and small towns. Sometimes user and manufacturer interests coincide, as they appear to in this case; sometimes the user (e.g. farmer) is best served by equipment made by large-scale urban industry. The Warwick treadlepump is intended for production in small workshops with little equipment: The materials specification was determined based on the availability of materials in Zimbabwe, Zambia, and Nigeria in 1990-91. The use of scarce pipe fittings was deliberately avoided.

For reasons of simplicity and standardisation only one size of pump has been developed using a nominal 100mm diameter piston. This size is well suited to heads of 4-10m at full "adult" power but has a poor efficiency at lower heads, and hence higher flows, for which a larger diameter pump would perform better. Since the "head" supplied by the pump has to overcome friction losses in the pipes as well as lift the water, the pump is suited for lifting water in excess of 3m. At "child" power levels the optimum range of lifts is lower and the efficiency at any given head higher. The table overleaf shows the specification to which the pump was finally designed.

Figures 6.1 to 6.4 shows performance test results. These tests were undertaken in August 1991 at relatively high powers, namely those which could be sustained by a fit and healthy young man of weight 80kg for periods of 15 minutes. From Figure 6.1 it can be seen that the input power exceeded 80 Watts, giving flows higher than the specification and, in consequence, lower efficiency than the specification (the main source of inefficiency is the friction in the valves which becomes substantial at flows greater than 1 l/s). Figure 6.2 shows the effect of increasing head: Namely a fall in flow rate and a strong rise in efficiency. The rise in efficiency, combined with a slightly better ergonomic match with the test operator, explains the increase in "water watts out" with the increase in head, shown in Figure 6.1. Water Watts is a measure of the pumping power achieved.

The penalty for operating the pump in suction is shown in Figure 6.3. For example, with a total head of 5m, having all that head in suction results in a flow, 0.73 l/s, which is only 70% of the flow, 1.06 l/s, obtained when all the pump is in pressure. Thus when lifting water from a 5m high river bank, a pump close to the water level will lift significantly more than a pump situated on the bank top. It is recommended that the pump is not normally used higher than 5m above the source of the water.

In tests the pump was found to be efficient and easy to use with a number of speeds, heads, and people: The performance specification was met. However the tests were performed on a new pump; long term testing may indicate changes in efficiency over time, especially if the piston or valve wear is severe.

The materials specification was met provided pvc components are painted or well shaded to protect them from degradation by prolonged exposure to sunlight.

The required case of manufacture was achieved in that only hand tools and downhand welding are required. However cutting of the manifold intersections needs to be quite accurate, within 1mm, and is best is achieved using a purpose-made jig. The production of the jig itself requires skills higher than for the manufacture of the pump.

6.1 Table of Specification: The Warwick Treadlepump

Performance Criteria

a) *Operating Efficiency*
i) Normal Range 3-7m, 75% efficient
ii) Extended Range 1-3m and 7-10m, 50% efficient

b) *Head Range*
i) Adult 1-10m
ii) Child 1-7m (up to 10m if two children)

c) *Treadle Height*
The height of the treadles to be as low as possible to avoid instability

d) *Pumping Force*
i) Adult 50kgf maximum
ii) Child 15kgf maximum

e) *Mechanical Advantage*
A variation of between 0.5:1 to 3:1

f) *Flow Rate*
For an adult operator producing 40W at 3m head: 1l/s

Materials used in Manufacture

a) Only materials fairly readily available from provincial merchants have been used.
i.e. 50x50x5mm angle iron, 110mm OD pvc pressure pipe

b) Resistant to degradation by moisture, weather, and ultra-violet radiation.

Manufacture, Maintenance, and Durability

a) The purchase cost of the pump should be less than one profits from one dry-season crop (DTU Working Paper 32)

b) No machining

c) Minimum fabrication

d) Low tolerances

e) No requirement for specialised tools

f) The pump should be maintainable with a few common tools. Wearing parts should be locally made and should have a working life of at least one crop season. Non-replaceable components should have a service life of over five years.

6.2 Status of the Warwick Treadlepump

The design of the Warwick treadlepump has evolved over the course of three years, 1989-1991. The primary feature that sets it apart from other treadlepump designs is the unique manifold and cylinder joint that does away with the need for pipe fittings, such as t-pieces and elbows. The intersection of the cylinders and the manifolds also houses a stretch rubber non-return valve that has the advantage of no moving parts and simple manufacture. The rubber valve also acts as the gasket for the pipe intersections.

This valve and manifold design was perfected in a BSc dissertation by Rebecca Scott in 1989-1990 and was incorporated into a treadlepump design by Simon Lucas during 1990-1991. Following testing of the pump at the University of Warwick in the summer of 1991 design changes were made to improve the clamping arrangement that holds the pipe intersections together. A jig was also constructed to aid the manufacture of accurate pipe intersections and so reduce the possibility of the rubber gasket failing at high pumping heads.

At time of writing, October 1991, the treadlepump design is about to be constructed at Ramat Polytechnic, Borno State, Nigeria as part of the Ramat-Warwick Linkage Programme supported by the EEC and part of a large development programme in the North East Arid Zone of Borno State aimed at the development of rural areas and the increased security of rural people.

After initial testing of the pump at Ramat Polytechnic and, possibly, design changes to suit locally available materials, the treadlepump will be introduced to selected villages in the North East Arid Zone for field testing. This testing will take place with the close cooperation of village development representatives and the field staff of the development programme.

If the field trials of the treadlepump are successful training courses will be offered to local artisans in the construction of the pump. The credit facilities of the development programme will be offered to artisans wishing to start production. It is hoped that the treadlepump will provide a valuable contribution to irrigation technologies in the region and a chance for smallholders, who cannot afford more expensive pumps, to grow a dry season crop and protect main crops from drought.

APPENDIX A

The Warwick Treadlepump
Engineering Drawings and Construction Notes

CONSTRUCTION NOTES

The Frame

The frame is constructed of 50x50x5mm Angle Iron and welded at joints. The choice of angle is an economic one being the cheapest section per kg and the most widely available. A lighter frame could be made from box section if the cost is permissible.

Care should be taken in the orientation of the angle as this is critical for the fixing of some components. Holes for bolts (for bolt axles and pulley wheel) should be drilled before welding. Good welds will add considerably to the robustness of the frame.

The Treadles

The treadles should be made from well-seasoned soft wood and be straight along their length. The holes drilled in the treadles for the hinge and the piston rod hangers should be as accurate to the dimensions given so as little wood is removed from the treadles as possible. If treated wood is not available then the durability of the treadles can be improved by, preferably, soaking the wood in old engine oil, or painting on the oil.

The Pulley Wheel

The pulley wheel is to be of hard wood as locally available. After the pulley is finished it is boiled in oil for a day; this not only treats the wood but provides lubricant for the bearing. Take great care when boiling oil as there is a danger of the oil catching fire. The centre hole is 16mm and to achieve a running fit the bolt axle will need to be sanded down. Washers are used on the axle in the gap between the pulley wheel and the frame. A 50mm diameter piece of tin sheet can be used as a bearing cover for the end of the bolt; it can be held in place by a rivet drilled into the frame. This cover will stop dust entering the bearing.

The Cylinders and Manifolds

Once the cylinders and manifolds are cut to length the first task is to fit the end caps. This will help the pipes retain their shape during the cutting of the intersections.

The end caps are made from flattened pieces of plastic pipe. To flatten a piece of pipe cut it along its length and place it in a oven at 120°C for a few minutes. The time necessary will depend on the type of plastic pipe, so experiment. (if there is no oven the pipe can be softened in boiling oil but take care). Once the pipe is soft it can be clamped between two flat sheets and allowed to cool.

The other part of the end cap is a ring of plastic, again cut from a piece of pipe. Cut a ring of plastic 15mm long and remove a small piece from it so that it can fit just inside the cylinder pipe. This can now be glued in place in the position shown. A circular piece of plastic with a diameter equal to the internal diameter of the pipe is cut from the flat sheet and glued into place on top of the plastic ring inserted before. The end cap is then finished off by gluing another ring of plastic on top of the flat plate. Apply plenty of glue to ensure a complete seal.

On one of the end caps of each manifold pipe there is a smaller diameter pipe to allow the attachment of the inlet and outlet hoses. These fittings are made from 37.5mm diameter pipe that is belled out at one end. The belled end is fitted inside the end cap and prevents the fitting pulling out. The bell is formed by heating the small diameter pipe in the oven, and when soft, pushing the pipe over a wooden former or other suitable forming tool. The smaller diameter pipe must be glued into place in the end cap <u>before</u> the cap is fitted in the manifold.

The end caps are now fitted and the pipe intersections in the cylinders and the manifold must be cut. They are cut using a metal template and, to achieve an accurate finish, a metal jig. First place the pipe to be cut in the jig and mark a line along its length that will pass through the centre of the two intersections. Now place the template on the pipe and mark round where the two intersections will be cut (the template is 5mm undersize to allow for errors in cutting). Cut out the two intersections with a jig-saw or similar and place the pipe back in the jig. The intersections can be accurately finished using the pipe-shaped sanding tool.

Once all the intersections are cut the valves can be made. The valves are made from car innertube and marked using the valve template. It is important that the valves are cut so that the rubber that is used curves in the same direction when fitted in the pump as it did in the innertube. This is achieved by lining up the valves so that their short axis is along the length of the innertube.

Piston Cups

The cups are made from leather that is approximately 5-10mm thick. It is necessary to form the cups into shape using a steel mould. The leather is soaked for a day and an oversize piece put in the base of the mould. A fly press or similar is used to force to top of the mould down into the base. Leave the mould overnight and then cut off the excess leather before removing it from the mould. The mould can then be separated and the cup removed.

The cups are fitted to the piston rod by a nut and washer each side. The washers can be made from flat plastic sheet, as the end caps, to save materials.

Assembling the Pump

The first job when assembling the pump is to put together the cylinders and the manifolds. A lot of care is needed at this stage to line up the valves very accurately with the intersection holes. If the valves are not put in straight then the pump will blow a seal very quickly and must be dismantled once more.

Lay the manifold pipe that has two holes on a desk and place two valves in the holes. Align the valves very carefully in both directions (this is made much easier if the centre lines of the intersection holes are marked on the pipe) and then press the two cylinder pipes into place. Again align very carefully the drilled holes in the cylinder pipes with the intersection holes. You can check if the alignment is approximately right by looking into the cylinders and seeing if all the drilled holes are covered by the rubber valve. Also check that the rubber valve sticks out a little way from the intersection all the way round. If anything is looks wrong take it apart and try again- it is easier to put it right at this stage!

The next stage is to lay the other two valves in the intersection holes of the two cylinders, again taking a lot of care, and push the other manifold pipe into place. Once again the drilled holes must be perfectly central to the holes in the manifold. Now the cylinders and manifolds are together it is a good idea to hold them in place with a thick rubber band at each end.

The cylinders and manifold can now be placed in the frame and the clamping pieces fitted. Tighten the bolts evenly and be careful not to crush the pipe. Fit the pistons in the cylinders and the treadles and then attach the treadles to the frame at the hinge. Put the pulley rope over the pulley wheel to support the treadles at the other end. Connect the inlet and outlet hoses with jubilee clips- don't get them the wrong way round! The pump is now ready for use.

At certain heads it may be necessary to prime the pump by pouring water into the top of the cylinders. Also the pistons will not seal properly until the cups are thoroughly soaked. After a few strokes the pump should fill with water and the operator can find a comfortable position on the treadles.

APPENDIX B

Treadlepumps for North Borno State, Nigeria

The North East Arid Zone Development Programme (NEAZDP) concerns the northern part of Borno State in Nigeria. The area straddles the Sudan Savannah and Sahel climatic zones having both open savannah and stabilised sand dunes. It is crossed by rivers whose winter flow is slight but whose flow during the summer rains creates extensive swamp lands and permits basin (fadama) irrigation. The basic crops away from "fadama" lands are sorghum, millet, and dates. The nomadic Fulani fraction of the population move large herds of oxen, goats, and camels through the area. The population of the region is in excess of one million.

Water lifting in the Zone can be divided into: (a) The raising of water from village wells for domestic needs and livestock; (b) Lifting irrigation water from streams, swamps and (in the oases) shallow wells; (c) Pumping into urban water supply systems.

Treadlepumps are non-motorised and therefore unsuitable for pumping tasks requiring powers above 250 Watt-hours per day or 100 Watts over short periods. Moreover petrol and diesel fuels are extremely cheap in Nigeria and although engine-driven pumps are not cheap, they are readily available. For these two reasons treadlepumps are unsuitable for the last application listed above or for any large scale irrigation.

For normal village wells, treadlepumps have three disadvantages over handpumps or rope-and-bucket. Firstly the wells are normally deeper than the 6 metres any surface-mounted pump can efficiently draw up from: treadlepumps are only able to operate at ground level. Secondly treadlepumps do not have the proven robustness that one would look for in selecting any pump that is to be used by many different people. Thirdly the physical method of working a treadlepump- somewhat akin to cycling- may be culturally unacceptable for women in North Borno in places as public as a village well. Of these three disadvantages, the second and third may be perhaps overcome or accepted, given the much greater efficiency of treadle pumping over arm-powered pumping. The first disadvantage is more fundamental and rules out use of treadles at most village wells in the Arid Zone since they are over 6 metres deep.

It is primarily for low-lift irrigation of small plots that treadlepumps may find application in the Zone. For this activity both adequate output and low capital cost are required.

Treadlepumps can deliver (for a given human effort) nearly twice as much water as handpumps and three times as much as rope-and-bucket methods; except at lifts of less than 2 metres. Treadlepumps are likely to be more efficient than all other human-powered water-lifting devices. Even the smallest engine-driven pumpset has an output greater than 10 treadlepumps; however for small scale irrigation this high capacity of motorised pumps cannot be made use of. Worked for 4 hours a day and lifting water 3 metres, for example, a treadlepump will irrigate about 0.4 hectares and a motorised pump at least 5 hectares. The latter figure is much larger than one family could intensively cultivate using manual methods, so motorised irrigation implies either mechanical agriculture or multi-family cooperation.

Treadlepumps have a <u>running</u> cost that is lower than that of handpumps or buckets but higher (in Nigeria, because of low fuel costs) than that of motorised pumps. In <u>capital</u> cost, the treadlepump is dearer than the handpump and (for small scale irrigation) much cheaper than the motorised pump. For peasant scale irrigation, the form as well as the size of the costs is often important: Family labour costs may be more easily borne than external money costs. There are other important considerations in pump selection besides running and capital costs- availability in the market, maintainability and portability are examples.

Treadlepumps have two potential niches in irrigated agriculture in the Arid Zone. They might replace existing, less efficient, manual devices. They might open to irrigation new lands for which the capital costs and complexity of motorised irrigation are unacceptably high. As no treadlepumps are at present in use in North Borno or apparently on sale in Nigeria, it is timely to access which, if any, of the designs available world-wide it might be worth introducing. Introduction is taken to mean selection, demonstration, acceptance by users, and establishment of local manufacture.

Building Materials Survey

W. Lawson, BSc, PhD

Introduction:

The survey was undertaken in two parts. In the first, visits were made to a variety of educational and government institutions and building material manufacturers in Northern Nigeria in order to assess present practices, availability and cost of materials, and their advantages and disadvantages. In the second, a visit was made to the North East Arid Zone and several villages and other sites were visited to assess present building practices.

Samples of some typical masonry building materials were taken and their compressive strengths evaluated at the Department of Building and Civil Engineering at RAMAT. The results are contained in Table 1, and show that there is considerable variation in quality and that some, concrete blocks and the stabilised soil cement blocks used by the Borno State Housing Corporation, are of a consistently low quality.

Suggestions for improvements in building and building materials were made particularly with respect to RAMAT and RAMCAT involvement with NEAZDP.

Prompt action on there recommendations would ensure that they could be incorporated in planning for 1992.

Relevant references for additional information have been included where appropriate.

Table 1 Compressive strength of some Northern Nigerian masonry building materials

	Clamp fired bricks [MPa]	Kiln fired bricks [MPa]	Concrete blocks [MPa]	Stabilised earth blocks [MPa]
	2.42	3.70	2.62	0.62
	3.11	5.46	2.86	0.99
	4.18	6.04	3.10	1.23
	4.69	6.24	3.34	2.09
	4.79	6.63	3.58	2.46
mean	3.84	5.61	3.10	1.48
standard deviation	1.04	1.15	0.38	0.77

NB. No aspect ratio correction has been made.

Earth Blocks

Outside the largest cities earth blocks are the traditional and most common building material.

The earth blocks are made from a blending of the soil profile (relying on feel and experience to assess its suitability), mixing it with sufficient water to make a soft mix, and forming the blocks in simple wooden moulds.

The blocks are sun dried and turned regularly to minimise cracking or warping through uneven drying.

At Kaska and Yin in the North East Arid Zone a considerable quantity of fine dry grass is also added to the mix.

The mortar and render which are more durable than the blocks, are made from the same soil with cow dung added. Split Azara palm was used for reinforcing. Roofing, either flat or domed was formed by short lengths approximately 1m long, of split Azara palm, covered with Azara palm woven mat and further covered with a layer of earth of the same composition as the walls. Internal walls were protected with a white clay whitewash with no additives. Durability of the earth walls and roofs was the major problem identified. Some roofs had collapsed.

Sadly, the Emir's palace at Yorgoram which was in excellent restored condition just six months ago was now in a serious state of disrepair, with walls and roofs collapsed, including a portion of the entrance gate. A significant factor in this deterioration apart from the poor durability of the soil, would appear to be termite attack of lintels, arch supports, reinforcing and other timber parts of the structure.

On some sections of the Emir's palace coatings of bitumen (roof of toilet) had been used to significantly improve durability. Another technique was to take the shell of the fruit (Kuba) of the Dorawa tree, soak it in water and use this water mixed with earth to make a hard, black protective coating.

At Yin, termites also appeared to be a significant factor in the deterioration of earth buildings. Bitumen disolved in kerosene and added to the earth render was reported to greatly improve its durability. The bitumen costs about N45 per 50kg bag and with the kerosene would be comparable in cost to cement stabilised render. Bitumen was reported to not always be easy to obtain in the market.

Used unstabilised and unprotected from rain earth blocks need regular attention to maintain their structural integrity. Renders are often employed to protect the earth blocks. These may be of a similar composition to the block itself, a gypsum(?) plaster or a sand/cement render. Studies conducted at ABU by Solanke (1984) have shown that the sand/cement render is the most durable but has poor adhesion to the earth blocks. Mud and gypsum plaster/renders adhere better but are less durable. It would appear that few attempts have been made to make stabilised blocks thus largely negating the need for a render. Similarly, no studies have been done to assess the cost difference between cement stabilised blocks and un-stabilised blocks with a cement render.

Earth blocks may be improved by attention to the mix composition and the mixing process, compression, stabilisation and curing, by rendering, and by attention to the design and construction of the building in which they are used (eg. overhanging eaves or verandah, damp course, positioning of windows and doors to minimise structural stresses). Siting of the building and choice of roofing materials may also imporve its comfort and usefulness. Secure attachment of roofing to earth buildings seems to be poorly understood. A brief description of various suitable techniques is given by Middleton (1987;3).

Palm Building Materials

Some buildings utilised Goruba palm in Y shaped post and beam construction with Azara palm woven panels for walls and roofs. Sometimes a thinner bent frame was used. The woven Azara palm lasts 2-3 years before it has to be replaced. The Goruba palm is very durable and is termite resistant. It is recycled from old buildings when they fall into disuse. Small quantities of galvanised iron were used, usually for doors and for open spouts to conduct water from earth roofs.

Recommendations

Essentially there are two main problems to address: the poor durability of the earth material and the termite attack of timber in the buildings.

1. Earth Durability

The durability of the earth material itself can be improved in various ways; by attention to the making of the blocks, by the development of effective protective coverings, by design changes to the buildings or by a combination of these.

Making blocks.

Some improvement in the durability of the earth blocks is likely with more thorough dry mixing of the materials, i.e the earth should be dried and crushed to a powder, mixed, then water added slowly as it is returned to a mouldable condition. Whether the extra work involved is justified by the improvement in durability achieved should be determined by some simple tests conducted in the villages and under RAMCAT/NEAZDP supervision.

The binding quality of the clay may also be improved by ensuring the water used is acidic. This can be simply achieved by testing with pH indicator strips and adding citric fruit juice. RAMCAT/NEAZDP should again supervise.

Further and much more significant improvements in the durability of the blocks may be achieved by stabilisation of the mix with small quantities (approximately 5% - 10%) of cement or bitumen and by forming the blocks in a simple hand operated compression machine. Research has shown that compression is most important in improving water resistance of earth blocks (Ola, S.A. and Mbata, A; 1990).

However, an initial inspection of the earth block making machine (made by RAMAT and based on an existing design) which was used by the Borno State Housing Corporation in their recent Maiduguri hosuing project, indicates some serious deficiencies. It appears that the machine applies very little compression to the blocks, particularly as it becomes clogged in use.

This was supported by the general "loose", uncompacted appearance of the blocks and also by their very poor compressive strength (mean 1.48 MPa), despite containing 10% by volume of cement. They are not likely to be very durable although fortunately most of the buildings are rendered. It is of great concern that in the first really significant application of compressed, stabilised, earth block building that such poor results have been obtained. There is an urgent need for RAMCAT to be further involved in this project in order to monitor the performance of the buildings, to review the block making and construction process (very quick but poor quality) and to evaluate other block making machines, of which various types are available. It is likely that the most appropriate block making machine will be of a simple and uncomplicated design, robust construction and able to be used effectively by unskilled labour.

Some other points to examine include:

. the adequacy of the mixing procedure
. the use of the coarse laterite material which was transported a considerable distance
. variations in cement content
. Cost comparisons of stabilised blocks with unstabilised, rendered blocks and other building materials/construction methods
. the residents' response to the houses and housing development in general. (RAMCAT and RAMAT Dept of Architecture and Town Planing) This is known as post occupancy evaluation and provides useful feed-back for future improvements.
. pressed blocks made with a cinva ram type device could be tried with interested block makers to assess the response to this technology. (RAMCAT/NEAZDP)
. a joint project with ABU could examine the problems associated with render durability and adherence.

The durability of blocks can be assessed using a water erosion test rig for which Warwick University has a design. Durability of blocks should also be assessed but the project should not be delayed while the water erosion test rig is built. The previously mentioned evaluation of block making machines and construction processes is more urgent at this stage.

Protective Coverings.

Earth walls can also be made durable with a protective render or other protective covering. Various possibilities exist which should be evaluated by RAMCAT in association with NEAZDP and preferably with builders rather than in the laboratory.

i) cement stabilised render
ii) bitumen stabilised render (also more likely to deter termites)

iii) render made from termite mound soil

iv) protective coating of vegetable oil or vegetable oil/clay mix. Palm oil and ground nut oil should be evaluated. Linseed oil has been found excellent in Australian conditions but does not appear to be available. Other possibilities for earth wall protective finishes have been tried in Ghana (Schreckenbach, H, 1991;21).

Design Changes.

Protection of earth walls can also be achieved by simple design changes in buildings;

i) use arches for doorways and windows as this reduces the tendency for cracking and hence water ingress. It also conserves the wood that would have been used in lintels and reduces the possibility of termite damage. Arches require wooden form-work for their construction but this can be reused. A technique using car tyres as arch form work has been used elsewhere (Stulz, R and Mukargi, K. 1988) and should be tried with Nigerian earth builders.

ii) Fix panels made from Azara palm woven mat to the walls to keep them dry.

iii) Extend the roof to have approximately 1m eaves or surround the building with roofed verandahs.

iv) Make the roof structure independent of the earth walls using termite resistant Goruba palm posts and long Azara palm roof timbers and woven mats. An earth coating could be optional. (see Figure 1)

v) Give roof structures sufficient slope (pitch - greater than 10°) to ensure water run off. (see Figure 2)

vi) Site buildings on raised ground and place drainage channels to keep surface water away from the walls. (see Figure 3)

vii) A radical suggestion is to build underground but thorough assessment of the suitability and stability of the soil, particularly in the wet season, is essential before this is done.

RAMCAT/RAMAT/NEAZDP should initiate and conduct courses on site in villages building model buildings to illustrate some of the above points. In particular basic design and construction techniques appear to be the least costly for builders to implement yet should result in significant improvements.

2. Termite Resistance

Termites are attracted to wood or biomass materials which contain cellulose which is their food. Some woods contain oils and other chemicals which repel termites making them termite resistant. Termites live underground, from where they gain entry to wood in contact with the ground. They perfer dark moist conditions. It follows that if timber parts of buildings are not in contact with the ground, and the amount of timber or other biomass they contain is small, then the chance of termite damage is greatly reduced. Use of termite resistant timbers also reduces the possibility of termite damage. Periodic inspection of exposed timber sections of buildings is also a good preventative measure as any termite conduits found can be destroyed before damage becomes serious. Reducing the amount of non-termite resistant timber in buildings and grass (biomass) in earth blocks will reduce the attractiveness of the building to termites. The use of termite resistant timber where ever possible, and particularly in hidden applications, is highly desirable.

The use of chemical barriers (soil impregration with chlordane or similar chemicals) must not be used because the water supply will become contaminated. Chemical impregration of timber or coating with waste oil, creosote or similar materials is likely to be costly and not necessarily very effective.

The introduction of some of the other recommendations, such as stabilisation and design changes, should enable durable buildings much less susceptible to termite damage to be built. RAMCAT and the Department of Agriculture at RAMAT will soon be commencing a project to improve grain storage structures. This would provide an ideal opportunity to trail the above recommendations in a practical and small scale manner.

The association with NEAZDP should provide access to well organised field offices and villages, for constructing the trial structures.

Fired Clay Bricks

Fired clay building products are made by techniques ranging from extremely simple, through intermediate to highly sophisticated. At the extremely simple end of the continuum clay and sand which occur naturally together in river banks are mixed with water and kneaded by foot to a soft plastic state. The bricks are formed in simple wooden moulds, sun dried and fired in a wood fired clamp kiln. The clamp kiln is very inefficient and costly to operate and the bricks produced are of a very variable and low quality. In particular, they appear to be neither very strong nor durable. They sell for N0.30 per brick. These brickmakers are disheartened by the lack of follow-up from earlier studies of brickmaking and lack capital to improve their production facilities.

The British built Government brickworks at Maiduguri is over 50-years old and represents an intermediate level of brickmaking technology. Similar materials and preparation as described above are used by these brickmakers. The bricks are made on a moulding table in simple wooden moulds and dried slowly under cover before firing in a downdraught wood fuelled kiln. This kiln is well maintained (internal walls are replastered with clay/sand mix after every 3 firings) and relatively efficient. Each firing contains 25,000 bricks of which 3,000 are rejects (ie 12%). Some of these are salvageable as half bricks.

The bricks sell for N0.20 per brick and are of a fairly consistent quality. About 30 people are employed and live on site with their families. Brickmaking appears to have become a family tradition and they are proud of their work and achievements.

During the early 1980s a continuous clay product extrusion plant was built in Maiduguri by a German Company. This plant only operated for about five years. The major reasons for the failure would appear to be inadequate assessment of the raw materials, poor quality control of the materials in the factory and lack of adequate technical training of personnel to operate the plant, including the gas/oil fired tunnel kiln, when the German management left.

About the same time a similar plant costing N5m was set up nearby by the Federal government. The plant utilised two large oil fired Hoffman kilns. This operation also failed reportedly due to a lack of marketing management expertise; the company being unable to adjust successfully to fluctuations and competition in the market.

The critical need for precise technical control in continuous production operations makes such systems inappropriate where the requisite skills are lacking or not developed. They are also inflexible manufacturing systems.

Other large scale brickmakers were observed; some closed and others operating. The viability of such operations depends on many factors which can vary, sometimes quite quickly (eg. markets) and so require skilled and flexible management as well as technology. Capable, well trained management able to plan and adapt to changing conditions is an important aspect of the success of such plants.

Recommendations

Further improvements to intermediate technology brickmaking plants may include:

* improved mixing and moulding with a drier mix and simple hand press.
* Use of simple kiln monitoring techniques such as pyrometric cones to identify cool/hot spots in kiln and to reduce these to give a more consistent product.
* Sorting and pricing of bricks according to quality and intended use (likely to be difficult while bricks are in short supply).
* Setting up of similar intermediate technology brickmaking in other areas.

* Reduction of fuelwood use by incorporation of waste oil burners of the flat plate drip feed type.

RAMCAT should make contact with the Maiduguri brickmakers to discuss the above points and plan action where necessary. Specific technical backing may be provided by Warwick University and other useful information is provided by Beamish, A and Donovan, W (1989).

RAMCAT could also conduct basic bricklaying courses and investigate the need for multi-skilled builders courses.

Concrete Blocks

Small and medium scale concrete block makers are common throughout Northern Nigeria.

A typical small scale concrete block maker employs three people and produces about 320 blocks per day from seven bags of cement and 35 barrows of sand. Cement costs 65-75 Naira per 50kg bag, sand about N200 for $10m^3$. The price of cement is rapidly escalating at present, from N65 to N90 in less than a month.

The mix used is usually quite lean, 1:10 by volume, and the blocks are often dried in the sun and sold after 3 or 4 days. The concrete is mixed by hand but a mechanical press is used to form the blocks. Waste oil or similar material is used as a release agent. Water may often be contaminated with organic matter. The blocks sell for around N4.30 each.

A larger plant with a multiple mould machine was seen at Maiduguri. This plant was designed to produce three times the present production but as machinery became in-operable it was scavenged for spare parts. Minor maintenance and repair did not apppear to be of concern. (A simple repair to a mould, which would have been easily within local capacity, was not attended to even though it produced a defective block). It appeared that because defective blocks could still be sold at the full price there was no perceived need to repair the production equipment. At this larger plant mixing was mechanical and the mix was transported to the block making machine by a mobile skip. Blocks were also wet down each day. A sample of blocks from where the blocks were wet down four times a day for three days were tested. Their compressive strength was poor, averaging 3.10MPa. (See Spence, R.J.S. and Cook, DJ 1983;89). It should also be noted that there blocks had undergone the best curing regime seen; others would be much worse.

The effects of cultural differences in perceiving and understanding production problems with concrete blocks has been discussed by Harder (1991) who suggests that special training is probably necessary.

Recommendations

Improvement to the quality of concrete blocks made could be achieved through:

* proper mix ratios/water content
* proper moist curing
* maintenance of machinery and equipment.

RAMAT could organise short courses held in afternoons, on simple concrete block making technology, including maintenance of equipment. RAMAT could sponsor a block making industry group to discuss common problems in the industry with the aim of improving standards of production.

Roofing Materials

Traditional thatch materials are used in some areas but have largely been replaced by galvanised iron. Light gauge galvanised iron costs approximately N520 for 20 standard 8ft x 4ft sheets. Corrugated fibre cement sheeting is slightly more expensive, costing almost N27 per m^2, for the cheapest sheet.

Galvanised iron is easy to transport and fix, but has a limited life. Fibre cement sheet requires some special skills to fix, but is more durable than galvanised iron. Fibre cement sheet also keeps the building cooler than galvanised iron.

The sole Nigerian owned fibre cement sheet manufacturer, Turners Building Products Limited at Kaduna, is currently trying to eliminate the use of asbestos in its products.

Wooden roofs with earth cover are also used occasionally but require significant maintenance.

Recommendations

* RAMCAT to conduct short practical courses in rural area, on fixing fibre cement sheets.
* RAMCAT to develop and run courses in rural areas on the fixing of roofs to earth building.
* RAMCAT to explore the possibility of a joint research project with Turners on the elimination of asbestos from fibre cement sheet. Apart from the obvious health benefits such a project also means import replacement as asbestos is currently imported from Canada.
* RAMCAT/NEAZDP to investigate the potential for intermediate technology fibre cement roofing tile manufacture in rural areas.

Miscellaneous

Some general points of interest;

* products developed by students and staff at the Institute of Agriculture Research at ABU are advertised in the local press to find manufacturers. The manufacturers have the right to the design in return for a donation of money or equipment to the Institute. Manufacturers may also sponsor further product design and development.
* Some University staff and students see development oriented projects, particularly those of a practical nature, as being of low prestige. Reward systems to alter this perception should be instituted in tertiary educational organisations.
* During travels in Nigeria it has become apparent that there are many geographic similarities with parts of Australia. Problems of development and the role of appropriate technologies in remote communities lacking in resources are also common to Australia. Study tours or other means of Nigerians living and working in selected parts of Australia may be very useful training and educational experiences. The Centre for Appropriate Technology in Central Australia may be a useful model on which RAMCAT and NEAZDP can improve their mode of operation.

Acknowledgements

The author would like to thank Ibrahim Mshelia, Head, Department of Civil Engineering and Building at RAMAT, Habu Yalwa of RAMAT, John Higham and Alistair Dunn of Warwick University for their assistance in the collection of the data on which this report is based.

Thanks are also due to the Rector of RAMAT Alhaji Baba Gara Tijani, Bellar Mamza, Head of RAMCAT and Gaban Tembo of NEAZDP for their support and the Warwick/RAMAT linkage for making this study possible.

The author is also very grateful to those individuals and organisations which gave freely of their time. Without their contribution the study would have been superficial and of little real value.

DTU Working Paper No.38 January 1993

Soil Testing For Soil-Cement Block Production

by Dr D.E.Gooding

ABSTRACT:

This working paper describes how to test soils to determine their suitability for use in soil-cement building blocks. Several reports covering this topic have been published over the last twenty years by a variety of organisations. This paper provides a brief description of the effects of soil properties on the handlability of blocks during moulding and the performance of the blocks after curing. It then undertakes a practical critique of the published tests for selecting soil, and for determining how much cement should be added to them, identifying a number of ambiguities, difficulties of performance and actual error in them. It concludes with recommended testing plans and three appendices. Appendix A describes selected procedures for field-testing soils to be used for block making, Appendix B describes laboratory test procedures: in both appendices the shortcomings identified earlier have been corrected. Appendix C is a bibliography.

CONTENTS:

INTRODUCTION

The purpose of this review is :

- to accurately describe the main soil selection tests and assess their usefulness
- to recommend test procedures for block makers under different circumstances.

The following report examines the process of soil selection for the purpose of soil-cement block production. Initially a brief explanation is given concerning the susceptibility of unstabilised earth constructions to water damage. This is followed by an introduction to soil-cement as a building material giving reasons for its use. Soil suitable for soil-cement construction is then considered from a particle grading and plasticity viewpoint, with due consideration to the underlying mechanisms responsible for strength and durability. Factors characteristic of a generally suitable soil are then put forward followed by a review of more specific criteria, previously published by other authors. The testing of soils for use in soil-cement is discussed with sections highlighting some misleading and inaccurate statements present in some of the soil testing literature. A coherent plan is then given to show the order in which the tests should be used. The main soil selection tests are fully described in Appendix A as field tests and Appendix B (simple) laboratory tests.

1. SOIL BUILDING

Some form of soil covers virtually the whole land surface of the Earth. This soil is usually readily processed with simple hand tools into an easily mouldable material which possesses good compressive strength when dry. Given soil's widespread availability, it is not surprising that it was traditionally widely used as a building material.

The major drawback to building with soil is its susceptibility to water. A soil wall may be considered as a load bearing skeleton of silt and sand glued together by clay. This glue-like behaviour when dry is caused by micro-droplets of water which exist at clay particle interfaces. Clay particles are usually electrostatically charged as a result of surface ion substitution. The charge tightly bonds a thin adsorbed layer of water to the particle's surface. The bonding is sufficiently strong for some adsorbed water to remain even at oven drying temperatures (105 -110°C). At the point of contact between two adjacent particles, a micro-droplet of water can exist where the two adsorbed water layers come into contact. These micro-droplets generate both surface and capillary tension forces which hold the clay particles together. However when any significant quantity of water is absorbed into empty soil pores, the droplets increase in size and the capillary and surface tension forces reduce, causing the soil to quickly soften and subsequently swell. On repeated wetting and drying the outer surfaces of a soil wall expand and contract more quickly than the main body. In a comparatively short time this leads to cracking and spalling of the outer surfaces and low durability for the wall. Moreover if the wall becomes saturated with water the compressive strength may fall sufficiently to allow complete collapse.

There are many methods to reduce a soil's susceptibility to weakening by water. These fall into the following broad categories: protecting the wall from exposure to water, reducing the permeability of the wall by increasing the soil density, making the soil water-repellant by the addition of a water-proofing agent and providing a secondary cementitious-type strength mechanism which is largely unaffected by water. I propose to centre the following report on the final category namely cementitious additives and concentrate on soil-cement.

2. WHAT IS SOIL-CEMENT AND WHY USE IT ?

Soil on its own can be used for construction, but unless it is protected from water the resulting building will not be very durable in any but the driest climates, as has been described above. Cementitious stabilisation in combination with densification gives soil both wet strength and erosion resistance. Densification or compaction reduces the soil's permeability and enhances the secondary cementitious bonding mechanism. Ordinary portland cement is the most commonly used stabiliser and at present usually the cheapest. Lime and lime-pozzolan stabilisation are growing in popularity because, unlike cement, lime may be produced economically by small-scale batching kilns. However, at present the quality of lime produced by such small-scale kilns is highly variable and liable to change from one batch to another. Moreover, a system of price subsidy exists in many countries so that despite cement relying on lime as a raw material and being more expensive to manufacture, it still remains cheaper than lime in the market place. The higher cost and variability of lime have led to the current dominance of cement.

Soil-cement is produced by dry-mixing a suitable soil[1] with a small quantity of cement and re-mixing the product with a specific quantity of water. The resulting damp soil is normally compressed in a mould, ejected and subsequently wet cured for 3-4 days then damp cured for at least two weeks before incorporation in a building. In many ways soil-cement may be seen as a simpler version of sand-cement, not requiring the sand to be first separated from other soil constituents. Sand-cement is widely used, though variable in quality as a result of poor curing.

---

[1]. The criteria for a suitable soil will be examined in detail later but it should be noted that two or more unsuitable soils may be combined by simple mixing to produce one more successful soil.

Soil-cement blocks produced with compression are in general more dense and hence less porous than sand-cement. The resultant reduction of moisture loss during curing leads to a greater consistency in quality for soil-cement.

The minimum amount of cement required to stabilise a block depends on the type of soil, the degree of compression and the final application for the blocks. Generally the interest is to minimise the cement content to below 10%. Given suitable conditions, contents as low as 3% are possible.

The exact mechanism by which a small content of cement may stabilise a large mass of soil is not fully understood. Ordinary Portland Cement is made up of 45% tricalcium silicate (C_3S)[2] and 27% dicalcium silicate (C_2S). In the presence of damp soil these components hydrate to form mono and di-calcium silicate hydrate gels (CSH and C_2SH, see equation below). These gels then slowly crystallise into an insoluble interlocking matrix throughout the soil voids binding the soil particles together. As the matrix is insoluble it gives a strength mechanism which works to restrain the softening and swelling of the unaffected soil, thereby dramatically reducing the weakening effect of water. The interlocking calcium silicate fibres may be seen when a cured soil cement sample is examined under an electron microscope. The hydration of the calcium silicate also results in the release of free lime (CH) according to the reaction:

$$C_3S + 2H = C_2SH + CH$$
$$C_2S + 2H = CSH + CH$$

The free lime then reacts further with the clay fraction (pozzolanic reaction) by the removal of silica from the clay minerals and subsequently forms more calcium silicate gel which also gradually crystallises.

In summary soil cement is a building material which has superior strength and erosion resistance compared to unstabilized soil, without incurring the cost of the large quantities of cement found in concrete.

---

[2]. C and S represent Calcium and Silicon respectively, not carbon and sulphur. This is in keeping with most of the published concrete literature and is acceptable, allowing these simple equations to be given as illustrations instead of the more complicated fully balanced chemical equations.

3. SOIL FOR SOIL-CEMENT

3.1 GENERAL PROPERTIES

Using a suitable soil for soil-cement block production will result in:

- strong blocks, namely those that after curing possess high wet strength and erosion resistance.
- handleable blocks, that immediately upon demoulding can be transferred to a curing area without a high breakage rate.
- blocks which will not seriously distort or crack during curing.
- blocks which will not expand and contract excessively in the building if subjected to wetting and drying cycles.

Specifically disqualified soils are:

- those containing organic matter.
- those which are highly expansive.
- those containing excessive soluble salts e.g gypsum and chalk.

For building purposes soil can be generally characterised in two ways, by a particle size distribution analysis and by a plasticity index. The particle size analysis will give information on the soils ability to pack into a dense structure and the quantity of fines present (combined silt and clay fraction), while the plasticity index gives an idea of the cohesion of the fines.

3.2 PARTICLE GRADING

The British Standard and MIT classification of soil particle sizes is given below:

coarse gravel.................. 60 to 20 mm.
medium gravel.................. 20 to 6 mm.
fine gravel................... 6 to 2 mm.

coarse sand................... 2 to 0.6 mm.
medium sand................... 0.6 to 0.2 mm.
fine sand..................... 0.2 to 0.06 mm.

coarse silt................... 0.06 to 0.02 mm.
medium silt................... 0.02 to 0.006 mm.
fine silt..................... 0.006 to 0.002 mm.

clay.......................... < 0.002 mm.

Gravel is not usually used in soil-cement production, as the large particle size may lead to a poor (rough) surface finish. A suitable soil will contain a mixture of sand, silt and clay-sized particles. The proportions of each of these three fractions influences the properties of the block and will be discussed below.

A particle size analysis will determine the fraction of a soil's particles that fall within each of the above size bands. If a dense block is to be produced, it is important that the soil used is "well graded". The theoretical distribution of particle sizes to provide a perfectly packed structure is called the Fuller curve. The Fuller curve is based upon the assumption that all of the particles are spherical and that the largest particles just touch each other, while there are enough intermediate particles to fill the voids between the largest, but without holding them apart. The intermediate sized particles are also similarly arranged with progressively finer particles filling the voids between larger ones. The Fuller distribution is an ideal model and never occurs naturally. However, a natural soil which has an even distribution of particle sizes, termed well-graded, is a good approximation.

The value of a well-graded soil for soil cement is that such a distribution of sizes gives a dense structure with a low specific surface area. A dense structure is important for several reasons. A densely packed arrangement will have a higher number of contacting particles, giving a better load bearing skeleton. The number and size of the inter-particle voids will be reduced, as will the number of linked voids. This will reduce the porosity of the soil and hence also its permeability, thereby reducing susceptibility to water penetration. As the interlocking calcium silicate matrix extends through the soil voids, a more compact void system requires less cement to provide a matrix of equal efficiency. Similarly if it is imagined that cement coats the soil particles' surface, a high specific surface area will lead to cement blinding, or a lower specific surface area soil will require less cement to provide the same particle surface coverage and consequently the same strength and durability.

The upper and lower limits to the soil's grading also need to be considered. A soil may be considered well-graded with a uniform distribution of particles from fine silt to coarse sand (coarse soil) or with a distribution from clay to fine sand (fine soil). The coarse soil will have a lower specific surface area than the fine soil as the same mass of soil will contain fewer and larger particles.

From the above consideration of specific surface area, it might be concluded that the more coarse soil would produce strong blocks with a lower cement content than that needed for the fine soil. This is however only the case when the blocks are kept within the mould to cure. A coarse soil containing no fines (silt and clay) is non-plastic and will not have sufficient cohesion to retain its shape on ejection from the mould or to allow easy transportation to the curing area. If the blocks are left to cure in their moulds (and the moulds are made strong enough to withstand a significant compaction pressure) then the machinery costs escalate unacceptably. The coarse soil could be considered to be a form of sand-cement containing large voids (a result of the lack of fines). Large voids would increase the porosity of the block and lead back to the common sand-cement problem of rapid drying before the cement has had time to adequately cure. Such a soil would be considered well-graded but still be unsuitable for soil-cement block production. Conversely a well-graded fine soil, containing little sand but a high clay content, would have a high specific surface area and expansivity (see below). The high clay content would give the soil cohesion and stability on ejection from the mould, but the high specific surface area would require a large amount of cement to provide a reasonable particle coverage.

A suitable soil will be well-graded but certain other limits should also be imposed: The largest particle size present should not be sufficiently large to cause a poor surface finish. Sufficient fines (silt and clay) should be present to allow handleability on demoulding but not enough to blind the small quantity of cement to be used.

3.3 PLASTICITY (FINES CONTENT)

The silt and clay content of a soil are responsible for soil cohesion and it is these fines which provide the fresh blocks with handleability until the initial set of the cement has occurred. The degree of cohesion provided to the block is dependant both on the fines present and the degree of compaction used to form the block. In general terms, a low-pressure moulding process will require a higher fines content than a high-pressure moulding process. This is because increased compaction will force the soil particles into more intimate contact, thus strengthening the fresh compact.

However, the fines and in particular the clay fraction can also lead to blinding of the cement as a result of their high surface area (see above). Head (Ref 2, Head 1980) reports that the approximate surface area of fine sand and medium silt are 0.023 and 0.23 square meters per gram, while for three major clay groups, kaolinite, illite and montmorillonite this increases to 10, 100 and 1000 square meters per gram respectively.

The fines also affect the final cured block's expansion on wetting. Clay usually exists in small agglomerations which expand in three dimensions on wetting as water penetrates some of the numerous individual particle boundary fissures. The expansion of the clay fraction must be largely restrained by the calcium silicate matrix in order to minimise expansion and contraction of the cured block, on repeated wetting and drying. Hence for durability the clay fraction should be as small as possible to allow the lowest cement content. It might be expected from the large difference between the specific surface areas of the three clay types mentioned above that different clays have significantly differing expansion characteristics on wetting. This is the case, in general as the surface area of the clay fraction rises, so does the amount it will expand on wetting. As a result the type of clay as well as the quantity present will affect the block.

The fine fraction can be seen to be helpful to the block production process but to adversely affect the wet strength and durability of the final cured block. The quantity and type of clay should therefore be considered important soil parameters. The quantity of fines may be measured by using one of the sedimentation tests described later, however the clay type present is very difficult to determine without highly complex tests. In fact it is not necessary to know the clay type present but it is important to know the properties exhibited by the clay. The Atterburg tests defining liquid limit, plastic limit and plasticity index are used to quantify the plasticity of the finer fraction of a soil (only particles less than 0.425 mm are tested). These tests measure the percentage water contents at which the soil passes from a liquid state to a plastic state (liquid limit) and from a plastic state to a solid state (plastic limit). The numerical difference between the liquid and plastic limit (the plasticity index) thus gives the range of water content over which the soil may be considered plastic. As plasticity is dependent on the soil cohesion, it has been found that this index reflects the cohesive characteristics of the soil. Furthermore as cohesion is largely dependent on the specific surface area of the fines, these plasticity limits also reflect the expansivity of the soil. A soil with a low plasticity index will display low cohesion and usually low expansion on wetting, while a high index soil will display the reverse.

3.4 SUITABLE SOILS

A suitable soil should not contain organic material or excessive soluble salts which would interfere with the setting of the cement. It's sand fraction should be well graded to provide a densely packed load-bearing skeleton for the block and it's largest size particle should be small enough to give a smooth surface finish. The fine fraction should be just sufficient to provide enough cohesion to the fresh block to prevent damage on ejection and transportation from the mould. Too large a fines content will either require a large cement content for adequate stabilisation or will reduce the durability and wet strength of the final cured block. The cohesion of the fresh block will depend on the compaction pressure used and the type as well as the quantity of clay present in the fines.

From the above it should now be possible to see the role that each of the soil's component fractions plays in a soil-cement block and the importance of selecting a suitable soil. If the soil available on site appears unsuitable, it should be remembered that natural soil exists in distinct strata with differing compositions. If the different strata are adequately tested then it is a comparatively simple operation to mix suitable masses of two or more strata to produce an acceptable soil. Given the need to select at least a broadly suitable soil then the case for adequate soil testing should be clear.

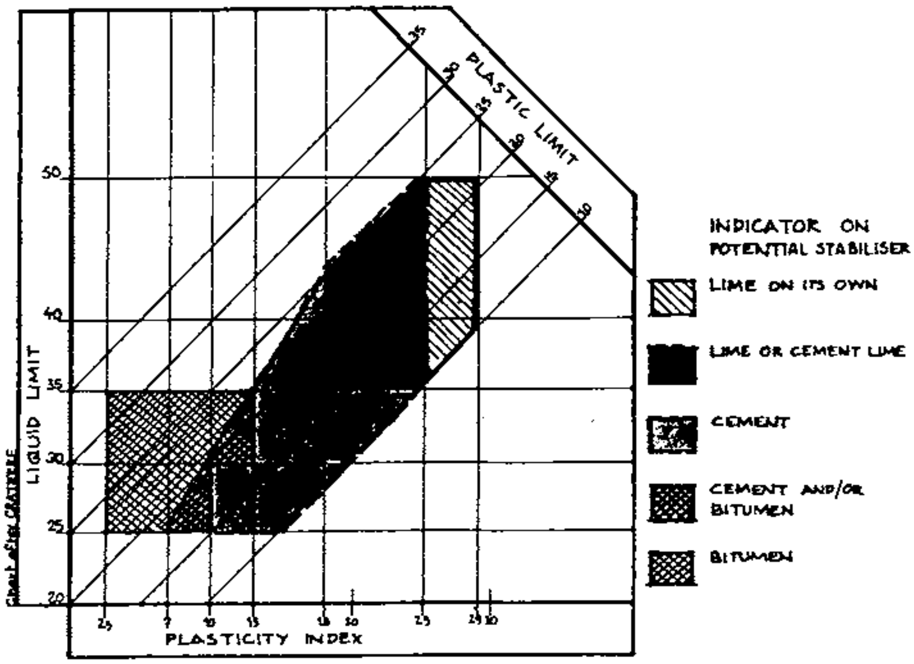
3.5 SURVEY OF CURRENTLY AVAILABLE CRITERIA FOR SOIL SUITABILITY.

The following is a brief review of published selection criteria from other authors. It is not an exhaustive review but rather included as an indication of the variation between authors and as a warning that such criteria should be used as a guide in initial soil selection rather than as a rigid set of rules. This variation is not surprising given the enormous variability of soil itself and the variation in production methods used by the different authors working in different climates. Some of the authors recommend criteria based only on particle size while others use criteria based solely on the Atterburg limits (Plasticity Index). In general it would be wise to consider both.

Ref No.3, Norton 1986. **Building With Earth, a Handbook**.

Atterburg limit criteria for stabilisation:

<u>Interpretation of Atterburg limits</u> (reproduced unmodified by Norton from a CRATerre original, Ref No. 7).



Particle size criteria for soil cement:

Optimum: no specific optimum, "should have a high sand content".

Limits :	sand/fine gravel (<5-6 mm)	45 - 75 %
	silt	15 - 30 %
	clay	10 - 25 %
cement :	variable	8 - 16 %

Not mentioned whether above is by weight or volume.

Ref No.6. United Nations 1964. **Soil-cement, its Use in Building**.

Particle size criteria for soil-cement:

Optimum: 75% sand. 25% silt and clay, of which more than 10% is clay.
Limits : minimum of 45% sand. 55% silt and clay.
maximum of 80% sand. 20% silt and clay.
cement : variable, between 4.75 % and 12.5 % by volume.

Ref No.4. International Labour Office 1987. **Small-scale Manufacture of Stabilised Soil Blocks**

No criteria is explicitly mentioned. Instead it is said that "Ideally, there should be an even distribution of each soil fraction in order to manufacture good-quality stabilised soil building blocks. If this were to be the case, about five per cent cement would be needed as a stabilising agent." The five fractions mentioned are: greater than 6 mm (coarse and medium gravel), greater than 2 mm (fine gravel), greater than 0.2 mm (coarse and medium sand), greater than 0.06 mm (fine sand) and less than 0.06 mm (combined silt and clay).

Ref No.11. Fitzmaurice, Robert 1958. Contained in Spence 1983. **Manual on Stabilised Soil Construction for Housing**

Atterburg criteria for soils most suitable for stabilisation:

liquid limit :	less than 40 percent
Plasticity index :	less than 22 percent and greater than 2.5 percent
Fitzmaurice's note :	primarily derived from temperate soils and only of limited application to tropical soils particularly laterites.

Ref No.2. Stulz, Roland 1983. **Appropriate Building Materials**.

Atterburg criteria for portland cement stabilisation.

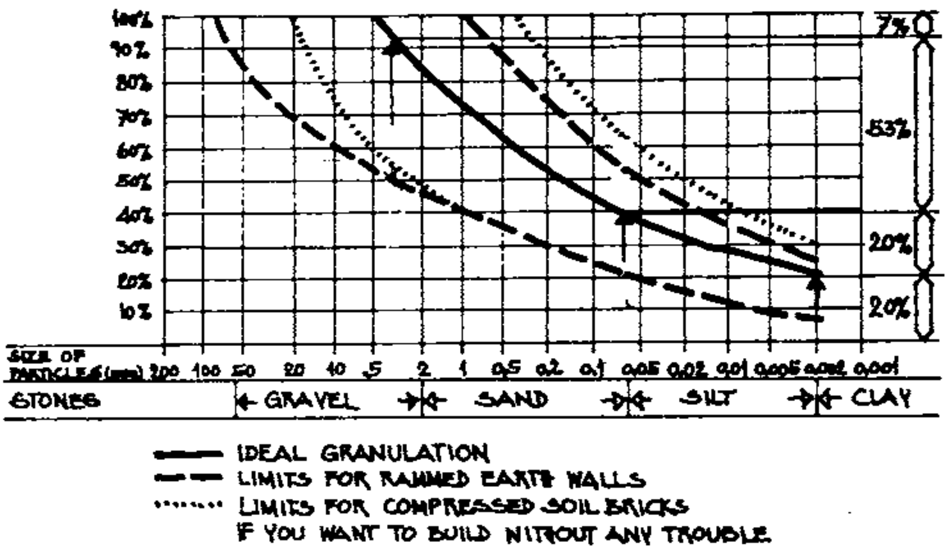
Plasticity index : 0 - 12
Cement content : 6 -10 % (down to 3 % for sandy soils).

Also "cement stabilisation of clayey soils (like red cotton soil) seems not to be useful."

Includes atterburg three-axis graph by CRATerre. Identical to that used by Norton (as shown above) but without a similar key.

Particle size criteria for compressed soil bricks:

<u>Particle size criteria granulation curve</u> included in Stulz after CRATerre (Ref No.7)

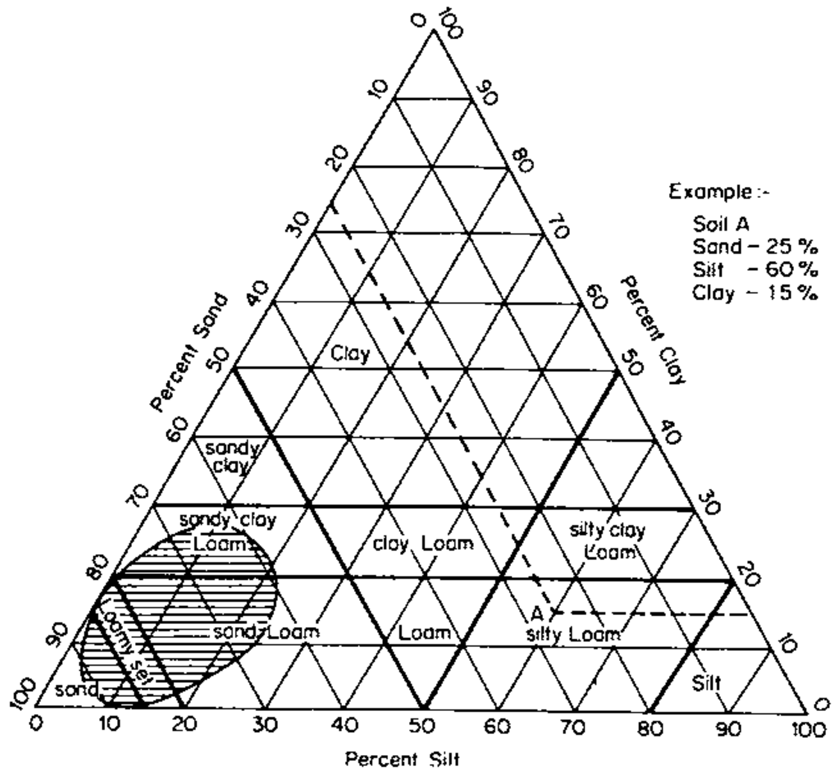


Ref No.11. Spence,R.J.S & Cook,D.J. 1983. **Building Materials in Developing Countries**.

Particle size criteria for soil-cement:

Spence and Cook include a graphical plot on a triangular U.S. Bureau of Public Roads particle-size graph roughly between the limits:
sand:90 - 60 % silt:25 - 0 % clay:25 - 0 %

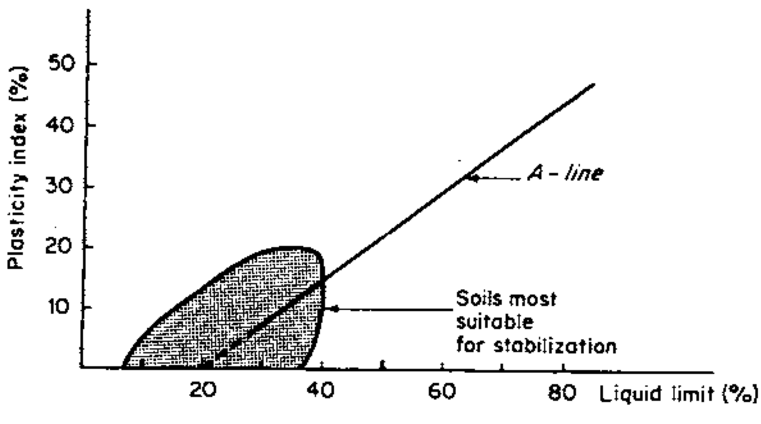
Triangular chart for particle size classification of soils:
(shaded area indicates soils most suitable for stabilisation)



Atterburg limit criteria for stabilisation:

Applicable only to the fraction of soil finer than 0.4 mm, roughly between the limits; plasticity index 0 - 22 %, liquid limit 7 - 40 %.

Plasticity chart showing soils most suitable for stabilisation



It can be seen from the above that there have been a number of criteria put forward for soil selection based on particle size or Atterburg limits or both. In broad terms these criteria are in agreement. A soil suitable for cement stabilisation should have a significant sand content (at least greater than 50%, preferably closer to 75%) and a low plasticity index & clay content (typically less than 25% clay). These criteria are however intended for use as a broad initial guide for soil selection. It must be emphasised that the testing procedure is not complete until the soil or soils selected have been used to produce, cure and test a trial set of blocks. Only after a trial set of blocks have been tested and proven to be acceptable should the main production run begin.

4. TESTS FOR SOILS.

4.1 TYPES OF TEST

Prior to soil-cement block production there are three main types of test which may be conducted:

First, field tests can divide the soils into broadly suitable and unsuitable categories and if suitable into potential high and low cement classes.

Second, laboratory tests can be used to characterise the soils by particle size distribution, plasticity or other numerical measures for relation to the selection criteria (see section 3.5) and enable simple soil modification by blending. Most small-scale manufacturers of blocks, especially those producing blocks at a rural building site, have little or no access to laboratory facilities and in particular accurate mass measurement to 0.01 g. For these block makers, judicious use of the field tests, the shrinkage test, production trials and past experience has to suffice. The laboratory tests are appropriate where medium or large-scale production is planned, where minimising cement content is especially important or when soil-cement block making is moving into a new area.

Third, trial production tests can be carried out on manufactured blocks to check that the final block properties required (dry strength, wet strength and durability) can be achieved. This paper is concerned with tests which are carried out on the unformed soil. It will therefore not cover the trial block testing procedures; for information on compression and durability testing of formed blocks, "Small-scale Manufacture of Stabilised Soil Blocks" should be consulted (Ref 4, ILO 1987).

The field and laboratory test procedures reported in the literature have been conducted by the author and evaluated using a carefully characterised soil (of a type suitable for soil-cement block making). For each published test he observed the accuracy of its description, its ease of performance and the accuracy of its results (in terms of internal consistency and agreement with British Standard Tests). A number of the tests examined were found to be misleading and incorrect in parts. The following sections are concerned with highlighting these problematic areas in an attempt to improve testing procedures as a whole.

4.2 FIELD TESTS

Field tests are for preliminary site surveying, to identify the soils most likely to be suitable and so restrict the number of soils to be more rigorously assessed by laboratory tests or trial production. The tests (described in appendix A) will provide a rough idea of a soil's grading and plasticity and also indicate whether a soil contains significant organic matter (reject outright), a predominance of gravel, a predominance of sand or a predominance of fines. They may also be able to distinguish whether silt or clay is the more significant fraction of the fines. They are generally fairly easy to perform and often require little or no experimental equipment, making them very cheap to implement.

However field tests are frequently reported without acknowledging the reliance they place on the operator's senses: although the methods employed are generally simple, the interpretation of the results is a skilled operation. Consider for example the dry strength test. The prepared soil sample is crushed between the fingers and the ease of crushing is taken as a measure of the soil's clay content. For a novice operator the ease of crushing is difficult to assess and as a result so too is the clay content. A skilled operator may compare the ease of crushing with that of soils he/she has previously tested and hence arrive at a more precise conclusion. Tests which rely on personal judgement are open to differing interpretation between operators and depend on the operator's skill for their accuracy. With training and experience these tests may provide a fast, quite accurate determination of the soil's characteristics, however for a novice they can only be expected to provide a more basic picture.

Table 4.2 (below) shows which tests are reported by which publication. The glass-jar sedimentation test will be discussed under laboratory tests (section 4.3) as it contains problems in common with the syphon sedimentation test. The remaining field test methods are generally in agreement and as such no further detailed comments will be made. The test descriptions and notes included in appendix A have been compiled by the author and are a combination of earlier reported methods and the author's own modifications. Each test begins with a brief resumé by the author giving comments on the use to which the test may be put, the accuracy which may be expected from the results, the time taken for completion and the limitations of the test.

All of the test results observed (both the good and the bad), plus the location and depth of the soil samples in question should be recorded in case it is later necessary to use a soil for blending which on preliminary examination had been rejected.

TEST NAME	REF.1	REF.2	REF.3	REF.4	REF.5	REF.6
SMELL	√	√	√	√	√	X
VISUAL-TOUCH	√	√	X	X	X	√
THREAD	√	√	X	√	ND	X
RIBBON	√	√	√	X	ND	√
SHINE	√	√	√	√	√	√
SEDIMENTATION GLASS-JAR *	X	√	√ a	√ b	√ c	√
DRY STRENGTH	√	√	√	X	X	√
SURFACE WATER	√	√	X	X	√	√

Table 4.2. Reported Field Tests

ND : Mentioned but not adequately described.
* : These tests are described in the laboratory test section covering sedimentation test.
a : Ill advised recommendation to add salt, ignores flocculation.
b : Over-concentrated solution causes inaccurate estimation of sand and fines content, salt added ignoring flocculation
c : Over-concentrated solution, test not intended to discriminate fines into silt and clay

4.3 LABORATORY TESTS

4.3.1 GENERAL CLASSIFICATION

The laboratory tests establish numerical values for certain soil parameters, primarily the percentage distribution of the different sizes of soil particle present and the plasticity limits. These values are subsequently used to determine the best available soil or combination of soils. All of these tests rely on accurate weighing and or some form of laboratory equipment. Scales with a resolution higher than one thousandth of the chosen sample weight are desirable.

There are four main types of test:

The sieving tests separate the different size fractions of the soil into discrete parts thereby indicating the soil's particle grading. The silt and clay fractions are too small to be easily separated by sieving and as such are normally reported as a combined fraction. The larger particles may be separated into a number of size fractions, depending on the number of sieve seizes available, according to the MIT and British Standard particle classification boundaries, given in section 3.2. A full laboratory analysis would give the percentage by weight of each of these size bands.

The sedimentation tests if correctly conducted have the ability to separate the larger sand and gravel size fractions from the combined fines fraction and under favourable circumstances to further distinguish the combined fraction into separate silt and clay fractions. However the simplest test, the glass-jar sedimentation test, is usually included under field tests because visual discrimination of the silt/clay boundary may not be possible. In this case the test can only be used to give an idea of the general relative proportions of sand and fines. In its coarsest form the glass-jar sedimentation test provides no more information than a sieving test and although less accurate, it does not require any mass measurement. Further, although the sedimentation time is long the operator time required to conduct the test is less than that for a sieving test.

The Atterburg or plasticity tests define the soil's liquid limit, plastic limit and plasticity. The test methods included are simplified versions of the more rigorous British Standard methods after Norton (Ref 2, Norton 1986). The Atterburg limits allow the soils plasticity characteristics to be related to the criteria given above in section 3.5.

The shrinkage test is a test of the soil's contraction on drying and gives a combined measure of the soil's particle grading, plasticity and clay type. It gives an overall idea of the soils behaviour and suitability for stabilisation. The degree of contraction may be thought of as a measure of the expansive force which the soil stabiliser will have to withstand when a manufactured block is exposed to water. The degree of contraction is then taken as a measure of the quantity of stabiliser required. The shrinkage test may be used as a straight-forward method of determining a soil's suitability for use where more complex testing is not possible or not justified for small-scale production. However it must be remembered that this test gives no direct information on the soil's constituent parts and as such will not allow easy soil modification. It was empirically designed for use with the Cinva Ram, a low-pressure (2MPa) manual-compaction moulding machine developed by VITA. It was intended to gauge the amount of stabiliser required for a given soil compacted with this machine[3]. It is very suitable

[3]. It should be remembered from the above discussion of soil suitability that the compaction pressure used to compact the block does affect the soil requirements. The shrinkage test was empirically calibrated for the Cinva Ram (2MPa) and is not directly applicable to a machine operating at a different compacting pressure. In general if the

for small-scale production if soil modification is not considered cost-effective but it must be used in conjunction with tests on trial blocks.

If the results from these tests are to be useful, a great deal of time and care must be taken. This point is seldom mentioned. These tests appear simple to carry out and they produce numerical values which are relatively easy to interpret, but they are not fool-proof and will produce misleading results if not carefully performed. The sedimentation tests in particular are very delicate, requiring time and practice to perfect. In general soil tests are subject to two accuracy limitations, experimental care and measurement resolution. The following four sections deal with each of the four main test types, giving a simple theoretical background and examining certain misleading and inaccurate aspects contained in earlier reported test methods.

4.3.2 SIEVING TESTS

The sieving tests may be conducted wet or dry, on a complete natural soil sample or on the residue from a syphon sedimentation test. In order to appreciate which of these is the more suitable for any given circumstance a brief consideration of the underlying theory should be given. A sieve test separates the soil fractions by allowing particles with a diameter slightly smaller than the diameter of the sieve holes to pass and retains those which are slightly larger. For an accurate determination of the size fractions present the soil particles must be separate i.e. the soil should be in distinct particles not agglomerations of particles. The ease with which any given soil may be broken up into separate particles determines which method of sieving is appropriate. It should be noted here that dry sieving is only recommended by the British Standards Institute (BS 1377) for clean sands and gravels (i.e. without any significant quantity of cohesive material).

A sieve test conducted on oven-dry soil particles (Dried to constant weight at 105-110°C) should be preceded by a breaking-down operation where the particle agglomerations are broken into separate particles. For low cohesion soils, those with only a small clay content, this is quite readily done with a pestle and mortar; however for soils with a high clay content this may be very difficult. If the soil is not adequately broken down then an overestimate of the larger sizes and an underestimate of the combined silt and clay fraction is likely. This is particularly so for lateritic soils which become very hard on drying. In this case a significant quantity of clay-sized particles may remain trapped with the larger sand sized particles. If on examination it appears that the soil has not been completely broken down then

---

machine compacts to a higher pressure then the cement content may be reduced for a given soil shrinkage, or alternatively the range of acceptable soil shrinkage values may be increased.

the soil is unsuitable for dry sieving and should be wet sieved or sedimented and subsequently dry sieved (see below).

For wet sieving a measured weight of oven dry soil is soaked in a large quantity of water or preferably water and a suitable dispersing agent. By soaking the soil any particle agglomerations soften and subsequently break up if the resulting suspension is adequately stirred. In order to successfully sieve this soil suspension a large quantity of excess water is required both to wash the particles through the sieves and to separate those particles which loosely adhere to each other as a result of the water's surface tension. Moreover a number of particles slightly smaller than a given sieve's diameter may be retained by water tension across the sieve holes. As a result an improvement in accuracy will be found if the retained samples are dried and resieved.

If the soil is first subject to a syphon sedimentation test, which removes the clay fraction, then a dry sieve test may be conducted on the settled soil residue. This soil residue will be cohesionless, if sedimentation separation has been successful, and therefore very easily broken down into separate particles.

ILO (Ref 4, ILO 1987) reports the dry sieve test as a "further soil testing procedure" without any mention of the necessity to break down the lumps of soil which are usually formed on drying and the consequent inaccuracy. The ILO also includes a section on laboratory testing methods which are "briefly discussed". A wet sieve test is mentioned[4] but without discussing when or why it should be used in preference to the dry sieve test, indeed the only sieving test method contained in the publication is the under-explained dry sieve method.

Norton (Ref 3, Norton 1986) does not report a dry sieve test on soil in a natural condition but rather only a dry sieve test on the residue from a syphon-sedimentation test. This is acceptable providing that the sedimentation test is correctly carried out. However the syphon-sedimentation test as reported by Norton may lead to flocculation (see Sedimentation Tests below) and consequently lead to subsequent further inaccuracy in the dry sieving.

A wet sieve test has also been reported by Norton. He states that "it should be used for analysing lateritic soils in order to ensure that clay particles trapped in fissures on larger particles are washed out." However he does not advocate soaking of the soil to facilitate this but rather to "mix the soil sample with water, and wash it through the sieves. " If the soil sample is not soaked before mixing then significant quantities of clay will remain adhered to the larger particles. The wet sieve test

---

[4]. A reference is given to a Road Research Laboratory paper, West,G & Dumbleton, M. J. "Wet sieving for the particle size distribution of soils" (Crowthorne, United Kingdom, Road Research Laboratory, 1972).

relies on water to disperse the soil grains, if sufficient soaking time is not allowed for this dispersion to take place then the test will be subject to the same inaccuracies mentioned above for the dry sieve test.

Norton does not mention that the initial soil sample to be tested should be carefully weighed out nor does he state whether the sample should be oven dried, air dried or damp. Rather he suggests that all of the material remaining on the sieves should be dried out and weighed and that the material carried by the wash water should be collected, dried out and separated with the syphon sedimentation test. In order to sieve such a wet sample a considerable quantity of water is required to wash the particles through, frequently tens of litres (several gallons). To collect and dry such a large quantity of water is both time consuming and impractical without very large collection vessels. If this method is employed for soils containing significant quantities of combined silt and clay then concentration problems will be encountered with the syphon sedimentation test. For example if 1kg of a fine soil containing 40% combined silt and clay fraction is wet sieved either 400g of material will have to be sedimented (four times the recommended concentration) or the dried material will have to be re-wetted, thoroughly mixed (to evenly re-distribute the silt and clay fractions) and subdivided before re-drying to ascertain the new dry weight of the smaller samples.

The wet sieving test, as reported by Norton, will not give reliable results unless the soil is left to soak adequately and will be very time consuming if the wash water is collected and dried. A more sensible method would be to accurately weigh an oven-dried soil sample, soak this in water or preferably water and a dispersing agent and allow the wash water to go uncollected. The weight of the separate dry retained materials may then be related to the original dry sample weight to give the percentage of each size fraction and the combined silt and clay fraction may be assumed to be the difference between the original total dry sample weight and the sum of the dry fraction weights. The clay content may be determined by a separate syphon sedimentation test and the silt fraction assumed to be the difference between the original sample weight and the combined sand, gravel and clay fractions.

4.3.3 SEDIMENTATION TESTS

The sedimentation tests are based upon Stoke's law of sedimentation which predicts the velocity in free fall of any diameter spherical particle of known specific gravity in a fluid of known viscosity at low concentration. For sedimentation testing it is assumed that the specific gravity is the same for each soil particle, each particle is approximately spherical and each soil grain exists as a separate particle. Hence the rate of fall is dependant only on the diameter of the particle. Larger diameter particles will fall more quickly than smaller diameter ones and hence the settled material will be graded with large particles at the bottom and fine particles at the top. One problem which may be thought of with this method of separation concerns the distances that particles have to fall. A small particle initially close to the bottom of the vessel falling slowly may settle in the same time as a large particle initially at the top of the vessel, leading to contamination. This does occur, but as the velocity of fall is proportional to the square of the particle diameter larger particles fall significantly faster than small ones and the contamination is only minor.

At high concentrations the particles interfere with each other, leading to "wipe-down" whereby small particles are carried down by larger ones. Similarly if the soil sample is not sufficiently dispersed agglomerations of particles will fall more quickly than would be the case for separate particles. Particle agglomeration may occur as a result of two separate factors; firstly, as the result of insufficient soaking whereby particles, primarily clay and silt, remain bound together or bound to larger sand particles and secondly when the silt and clay particles, initially dispersed, reassociate as a result of electrostatic interaction to form flocs (flocculation). In either case settlement will be affected and the measured fractions incorrect.

The glass-jar sedimentation test uses the differential settlement phenomena to give an idea of the relative proportions of different sized particles. A suspension of soil is allowed to settle undisturbed in a parallel sided vessel. As a result of the differential settling and a usually slightly discontinuous range of particle sizes, the material forms settled layers of gravel, sand, silt and clay. The height of each different soil layer formed is measured relative to the total settled height and taken to be the relative proportions of each discernable size fraction. The formation of layers is readily visible in light coloured soils which do not contain a perfectly continuous range of particle sizes but for other soils the layers may be less visible. For most soils it is possible to determine the boundary between the sand and silt layers as sand grains may be individually discriminated while silt grains appear as a homogenous mass. However it is frequently difficult to see the boundary between silt and clay as both material's grains are too small to be discerned. More complex timed methods have been put forward to attempt to overcome this discrimination problem but there are problems with these too (see below).

The syphon sedimentation test also uses the differential settlement phenomena. Rather than attempting to use the settled layers as indicators of the sample's different size fractions it attempts to separate the clay fraction by allowing heavier soil fractions to settle out of a suspension so that the remaining fluid, containing the clay particles, can be dried separately. If the initial dry soil mass is known then the percentage of clay may be found. This test depends on the clay remaining in suspension longer than any other heavier soil component and as such relies on the initial suspension being dilute and effectively dispersed. If "wipe-down" or agglomeration occur then the material syphoned off in suspension will be less than the true clay fraction. Moreover if flocculation occurs it is frequently not possible to discern the level of the settled material and hence the correct level for the separation disk. The flocs, containing both silt and clay particles, interfere with each other and slowly settle en masse in a loosely packed arrangement rather than as discrete particles. In this condition silt does not settle significantly faster than clay and hence cannot be distinguished. The formation of a flocculated suspension is usually readily apparent as a pronounced clear layer of water will form quite rapidly above the remaining suspended material during settlement. If the syphon sedimentation test is to be used the soil suspension must be both fully dispersed and deflocculated, a point frequently neglected by the literature.

The "sedimentation bottle test" (glass-jar sedimentation test) of ILO (Ref 4, ILO 1987), reports that "the bottle is first filled to one third with clean, uncontaminated water. Approximately the same volume of dry soil (which has passed through the 6 mm sieve) and a teaspoon full of common salt are added. Salt facilitates the dispersion of soil particles." Using equal volumes of dry soil and water will give a highly concentrated suspension of soil and lead to significant wipe-down of the fine fraction (see above). The diagram included with this description actually worsens this situation with mistaken captions. Diagram 1 shows "1. Bottle one third filled with water." diagram 2 then shows a full bottle with a one third volume of water resting on a two thirds volume of soil stating "2. Add one teaspoon full of salt and fill bottle with soil." Filling a bottle containing one third of water with dry soil will produce an intensely concentrated suspension.

Having shaken the soil bottle it is stated that "Two or three minutes later the water will start clearing....Two or three distinct layers will be observed, with the lowest layer containing fine gravel, the central layer containing the sand fraction and the top layer containing the combined silt and clay fraction....The individual percentages can be determined by direct measurement of the depth of each layer." This is most misleading. The above implies direct measurement of the layer height after only two to three minutes. Only the sand sized fraction would have settled in this short time, silt and clay particles fall much more slowly (clay falling at approximately twelve millimetres per hour) and would still be in suspension. Moreover unless the soil were to be predominantly clean gravel and sand, a high concentration of fines would be present which would not enable "distinct layers" to be seen rather the entire depth would appear muddy. This sedimentation bottle test has failed to produce any distinct layers when performed by the author on a known well-graded soil containing seventy six percent sand, fifteen percent clay and nine percent silt. The solution was too concentrated, the whole appearing as thick flocculated liquid. The relative volume of soil to water should be reduced to at least one quarter to three quarters.

Furthermore, Grimshaw (Ref 9, Grimshaw 1971) has reported that salt is a clay flocculant causing these particles to agglomerate into larger flocs, not to disperse as mentioned above. The addition of salt has been put forward, by Webb (Ref 5, Webb 1988) reporting that "salt will speed up the final settlement of particles". This is correct as the flocs formed are larger and heavier than individual clay particles and hence fall more quickly. However Webb puts forward this glass-jar type sedimentation test with salt to quickly and roughly determine the relative sand and fines content. It must be remembered that the fines are not separated into silt and clay fractions and may not be distinguished when flocculation occurs (see above). More suitable dispersants which do not cause flocculation are listed in appendix A page 39.

Norton (Ref 3, Norton 1986) suggests a "Simple particle separation by sedimentation" test which uses a timed observation system rather than visually discriminating settled layers. This test advises that a jar should be one third filled with slightly compacted dry soil and this height (h), measured from the base of the jar, be recorded. Water and a pinch of salt is then added to fill the jar to three quarters full. The jar is shaken, soaked for one hour and re-shaken. After the final shaking the jar is left to stand and a stopwatch is started. "When one minute is up, mark on the side of the jar....This amount (T1) is fine gravel and sand....After 30 minutes mark again....(T2) is fine gravel, sand and silt together. After 24 hours mark again....(T3) includes fine gravel, sand, silt and clay. The depth of clay = T3-T2. The depth of silt = T2-T1. Divide each depth by the total (h)...." and so gain the percentage proportion of each particle size. As has been mentioned earlier, a dry soil will expand on wetting. If the settled heights are related to the initial compacted height of the soil as described, then in general the sum of the soil fractions will exceed one hundred per cent. A more satisfactory solution is to relate the measured heights to the total settled soil height of the soil after twenty four hours. Again it is recommended that "a pinch of salt" should be added. This is not correct, in this test Norton is proposing to separate the silt and clay fraction and has apparently ignored the flocculating effect of salt. If flocculation occurs the level of the fully settled material will be obscured by the semi-settled flocculated layer. If the top of the flocculated layer is taken to be the settled height nonsensical results will follow as the settled height apparently reduces as the floc settles. Again flocculation will be apparent as a marked clear layer quickly appearing above the remaining suspended material. If flocculation occurs the suspension must be deflocculated.

Soil flocculation may occur without the addition of salt (chlorinated water among other things may have this effect), if it does then the suspension must be treated with one of the compounds listed in appendix A, page 39, to deflocculate and redisperse it.

4.3.4 ATTERBURG TESTS

The Atterburg or plasticity tests define the moisture content at which the soil passes from a liquid state to plastic state and from a plastic state to a solid state; these boundary points are the liquid and plastic limits respectively. The transition from liquid to plastic to solid is a gradual process, viscosity and shear resistance increase as the water content decreases. The precise boundaries between the states are defined by the tests themselves and not as a result of theoretical analysis or an intrinsic soil property, e.g. the plastic limit of a soil is the moisture content at which a thread of soil with particles greater than 0.425mm removed will break when rolled down to 3mm. Because of this reliance on the testing method different test procedures and even different test operators will give varying results. It is therefore most important that care is taken to follow the method given and to have the tests conducted by the same operator. The most important piece of equipment for the plasticity tests given in appendix B is the hand of the operator.

The plastic limit test described in appendix B is that used by the British Standards Institute (BS1377). The liquid limit test reported is a simplified version of the Casagrande liquid limit test. The full Casagrande test requires the use of a piece of specialised equipment which mechanically taps the curved dish by vertically dropping it a set distance at a set rate. In the simplified version of the test the curved dish is tapped horizontally by the operators hand. The simplified test given was first reported in "Handbook for Building Homes of Earth" (Ref No.1) and subsequently repeated unaltered by Norton (Ref 3,Norton 1986) and Stulz (Ref 2, Stulz 1983). It should be remembered when using this variant of the test that it is likely to give more variable results than the original. The force which is used to manually tap the curved dish depends on the operator, so it is desirable that the same operator conducts each test if comparisons are to be valid.

Other authors either describe very similar tests to those given in the appendix or refer the reader to the British Standard tests (BS1377). Concerning those tests which they describe two points need to be mentioned. Firstly sample preparation may be incompletely specified, it is not always clear that the soil sample to be tested must have all particles larger than 0.425 mm removed prior to testing for both the liquid and plastic limit tests. Secondly, the soil mixing operations should be very thorough. The soil should be mixed for at least ten minutes (up to 30 or 40 minutes for heavy clays). Mixing should continue for several minutes even after the disappearance of any wet or dry spots. For the liquid limit test it is not sufficient to add and mix soil or water to the sample while it is still in the curved dish. The sample should first be removed from the dish to allow mixing in a larger, more suitable container.

Stulz (Ref 2, Stulz 1983) suggests that "If you already know that you are going to add a stabiliser to your soil, then add the same proportion of stabiliser to your sample as you intend to use in your house". This is misleading as the term stabiliser is normally used to include cementitious compounds; cement, lime and pozzolanas etc. I believe that by "stabiliser" Stulz is referring to soil modifiers i.e. sand and clay rather than stabilisers. The modified soil should be tested but without the addition of cementitious stabilisers which will dramatically change the plasticity of the soil. In the case of cement the hydration reaction begins immediately the cement contacts water and initially progresses quickly. As a result the plasticity of the soil will change quickly with time and not allow any meaningful results to be obtained.

4.3.5 SHRINKAGE TEST

There is a large number of shrinkage-type tests which have been reported. The test which will be discussed here is a linear shrinkage test conducted on natural soil which has had particles larger than 6mm removed. This test has been included as a laboratory test because it requires a large mould and up to seven days of drying. The shrinkage test gives an idea of the gross behaviour of the soil on drying. The change in length of the soil sample may be considered to represent the expansion force which the soil stabiliser will have to resist when the final block becomes wet. In general the smaller the soil's contraction on drying the smaller the quantity of stabiliser required.

This test has been reported with two different but broadly similar experimental techniques. The method included here requires the soil mix to be at or near its liquid limit, while the other method frequently reported requires the soil to be at its optimum moisture content for maximum density moulding. The near-liquid-limit method has been chosen as this mixture of soil will contain more water and hence give slightly higher shrinkage values. The greater variation in liquid limit moisture content (between soils) compared to the more similar optimum moisture content will give a broader range of shrinkage values for different soils and hence will allow better discrimination. Again the recommended cement addition given by this test are only a guide and must be verified with trial block production.

The test has been calibrated by VITA for use with the Cinva Ram compacting machine (details are given with the test in appendix B) but not for other machines. Webb (Ref 5, Webb 1988) has suggested a very similar set of values for the Brepack machine which operates at five times the compaction pressure of the Cinva Ram, however it appears that the two sets of data are not comparable as the set given for the Brepack will produce blocks to a higher strength standard than that for the Cinva Ram. The cement saving appears small unless blocks of the same strength are compared. For instance, Webb cites blocks produced in Kenya from "Murram soil containing about 16 per cent clay stabilised with 4 per cent cement by weight under a compaction pressure of 10 MPa" and states that these "compared favourably with blocks made on a block press machine which used 18 per cent cement as a stabiliser. In this case the compacting pressure was 2 MPa". In this case the 18 per cent cement content used with low-pressure compaction was apparently equivalent to a 4 per cent content at high-pressure compaction. This is an extreme example but does illustrate the trend which is not apparent from the table included with the shrinkage test in Appendix B.

One final point to mention with respect to the cement content table from Webb is that for shrinkages of less than 15mm (in 600 mm) the soil should not be automatically rejected. It is not clear why Webb has chosen to reject this class of shrinkage. If the soil does have some plasticity, sufficient to allow adequate green strength for demoulding, then a low shrinkage soil should produce admirable blocks when compacted to high pressure. Lower shrinkage on drying will reflect the soil's potential to produce blocks which will be less prone to expansion on wetting and hence more durable. It is the requirement for green strength on demoulding which governs the minimum cohesion and hence shrinkage value. It would be expected that a high pressure machine should be able to handle soils with lower shrinkage than would a low pressure machine; from the VITA table the reverse would appear to be the case. A better guide would be that at either pressure soils with shrinkage down to a nominal value of 5mm should be investigated but zero shrinkage materials (0 - 5 mm) should be rejected.

This test is most useful where the scale of production does not justify the use of more elaborate tests or where it has been initially decided that soil modification will not be used. It does not give useful information for predictive soil modification but may be used to check the effectiveness of soil modification by trial.

5. COHERENT SOIL TESTING PLANS

In general the literature concerned with soil testing provides a number of suitable tests but does not provide a logical testing plan for their implementation. The following section discusses the soil-testing needs for differing project sizes and purposes. From this discussion it is hoped that the reader may be able to appreciate the need for different scales of soil testing. The large variation in scale of production, climatic conditions and use to which the final structure is put does not lend itself to specific recommendation, however certain generalisations are possible and would appear helpful as these are usually lacking elsewhere. The section is completed with an example of a coherent testing plan, comprising a testing tree for the field tests and a set of coherent laboratory tests, suitable for a medium scale producer.

In general there are two paths which may be followed by a soil-cement block producer, to use the available soil in its natural state or to use a modified soil (one produced by the combination of two less suitable soils). The decision whether to modify the natural soil is a complicated one. If the available soils are quite unsuitable for block production then either the soil must be modified or an alternative site must be found. Often however, although the available soil is acceptable for production in its natural condition, if it is modified blocks may be produced which are either of better quality or cheaper. The former is achieved by maintaining the cement content while improving the soil hence increasing block strength, the latter by maintaining the strength while reducing the cement content. The difference in cost or block properties resulting from modification depends on the degree of improvement which would be possible. The further away from the "ideal" soil the natural soil lies then the greater the improvement possible and hence the greater the justification for modification.

In small-scale block production, for example for a single building (self-built unit), the savings made through soil modification of an acceptable soil[5] are likely to be small. In this case the additional cost in terms of time and equipment required to perform all of the laboratory soil tests may not be justified. If the soil appears suitable from the field tests and the simple shrinkage box test, it would generally be more appropriate to use the natural soil, increasing the cement content if greater wet strength is required. If none of the available soils are suitable then modification will be necessary. In this case modification may be done by trial and error, checking the results with the simple shrinkage box test. This will then not require the grading or plasticity to be known but will take a significant time to perform adequately (the shrinkage test may take up to 12 days to complete). If the equipment is available it will always be beneficial to conduct the laboratory tests but adequate blocks may be produced without. The most fundamental piece of equipment required for laboratory testing is an accurate weighing balance, ideally capable of weighing to one thousandth of the sample weight.

In medium-scale block production, for example local village/community building programmes, the economies resulting from modification may be more significant and hence justify the increased testing costs resulting from a more complete laboratory testing program. Such a programme would include the determination of the soil's grading and plasticity characteristics. A more complete testing program enables faster more reliable modification processes to be used. The soil may be predictively modified to meet the criteria mentioned earlier in section 3.5, rather than imprecise modification by trial and error. The choice between modifying or not modifying should be based on the relative cost of the cement to that of the labour or machinery required to perform the additional soil blending

[5]. "acceptable soil" here means one which may be stabilised without modification even if quality improvement is possible through modification as opposed to an unacceptable soil which will not allow adequate stabilisation unless it is modified.

operation. If the relative cost of cement is high and significant cement saving is possible through modification, then in general it will be economically beneficial to modify such a soil to minimise its cement content. However if labour costs are high then it may be preferable to accept a high cement content and not modify the soil. Each case should be judged on its own merits.

For large-scale block production, involving considerable capital expenditure, then a full laboratory analysis including soil grading, plasticity and chemical composition may be justified. This type of test programme is not feasible without a well equipped, dedicated soil testing laboratory. (These are usually available through the government department dealing with road building). In this case several soil samples considered suitable from the field test selection process would be sent away to a soil laboratory to be tested, either so that the best can be identified or so that an optimum soil-blending formula can be devised. Even after full laboratory soil testing, trial block production testing must be carried out with the modified soil and local on-site laboratory testing is desirable to monitor the soil used throughout the project.

The above argument assumes that the final properties required of the soil-cement blocks are known. This is frequently not the case and deserves a brief consideration. Numerous standards have been developed for fired clay products and concrete blocks, especially in the developed world. However in general building material standards are much less advanced in under-developed countries and in the case of soil-cement blocks frequently non-existent. One draft specification for stabilised soil building blocks backed by the United Nations Commission for Human Settlements (UNCHS) in Nairobi, Kenya 1990, was based on a report presented by the Building Research Establishment (Ref 14, Webb 1991). This specification requires that water absorbtion after 24 hours of soaking should not exceed 15% of the original mass and that the minimum unconfined wet compressive strength after 24 hours immersion should not be less than 1.5 MPa (N/mm^2). It further suggests that the wet compressive strength should not be greater than 50% of the dry compressive strength. This specification may be used as an initial base standard for simple single storey buildings constructed with soil-cement blocks in arid or semi-arid regions. However it might be as well to remember that, provided enough strength is present to allow the wall to be self-supporting, durability is the factor which governs the building's life. A wet strength of 1.5 Mpa may be sufficient to prevent building collapse but might be inadequate for reasonable durability in less arid regions. The field of building standards relating to stabilised-soil building blocks is one which requires a large amount of further work. The wide variation in climatic conditions throughout the world necessitates regional or national building standards rather than global ones. At present these standards do not exist and a degree of judgement must be used when deciding the final block properties required. It would seem that the above specification can be taken as the minimum acceptable standard but that for areas with high rainfall the wet strength requirement should be increased to 2.8 Mpa or an external render applied to the wall. In such conditions any economic analysis carried out to asses the viability of soil modification should include due consideration of the cost of this external render or lack of it.

It may now be seen that the soil testing programme should be tailored to the scale of the project and the available testing equipment or testing funds. Soil testing is a supplement to reduce the number of trial blocks which need to be produced. A thorough testing plan should identify soils which are likely to be suitable and disqualify the unsuitable ones. All the above scales of production should utilise the basic field tests to reduce the number of soils to be subsequently considered. The simple laboratory tests will then further simplify the selection and modification of the soil. Full-scale laboratory testing will provide more accurate values for the grading and plasticity of the tested soils, although this accuracy improvement should be very minor if the simple laboratory tests are carried out correctly. Full-scale testing will also provide information on the chemical composition of the soil. The chemical composition may reveal the presence of soluble salts, primarily sulphates, which can attack the hardened cement's calcium silicate hydrate matrix and possibly lead to a reduction in strength with time. This reduction in strength with time may take several years to become apparent and therefore cannot be tested practically by trial block production.

The following sections show how the soil tests given in Appendices A and B may be used to provide a coherent soil test plan without undue duplication. Not every test mentioned in the Appendices need be conducted in every case; a number of the tests are alternatives which may be used according to the equipment available or can be used as cross checks if required.

5.1 PRELIMINARY ON-SITE SOIL TESTING PLAN

The initial field tests should be conducted on-site to assess the gross suitability of the available soils, arranging them into one of the categories listed below. Fines in this categorisation refers to the combined silt and clay content it should be noted that a soil containing clay-free fines regardless of the quantity of fines should be reported as very low clay and considered unsuitable.

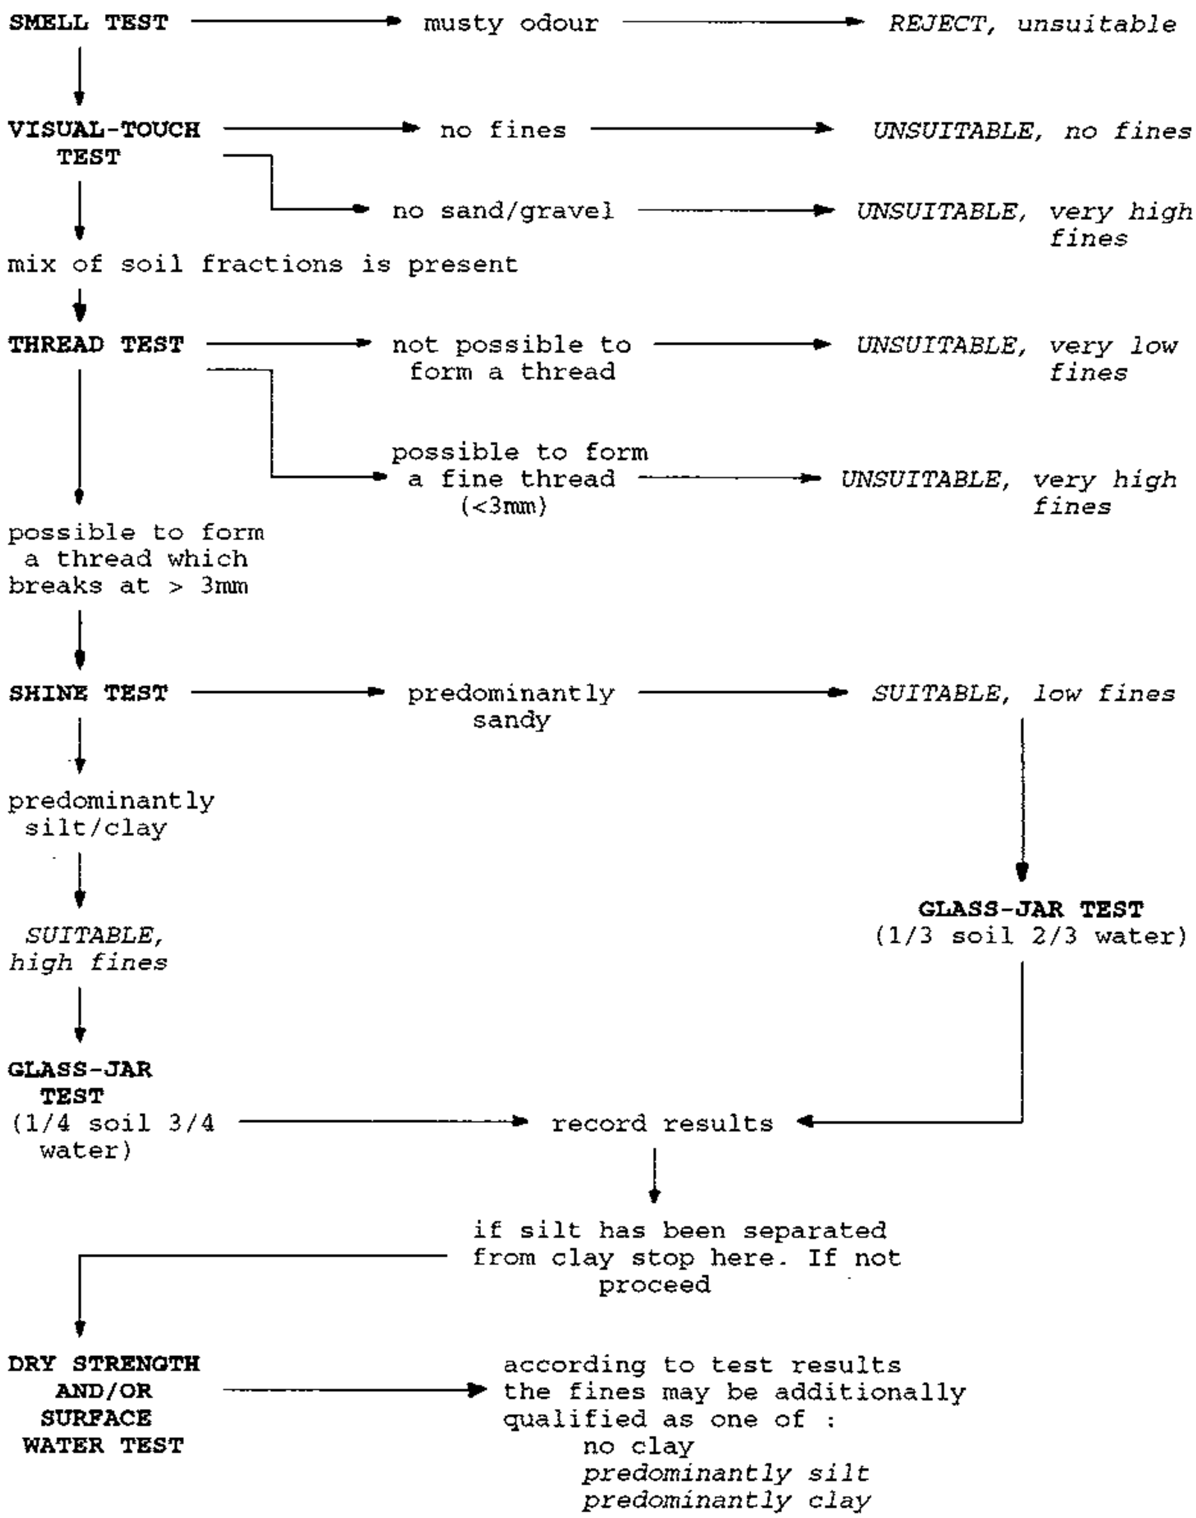
- *Organic..............Unsuitable.* REJECT.
- *Very low clay.........Unsuitable* unless clay added.
- *Very low/zero fines...Unsuitable* unless clay/silt added
- *Low fines............Suitable,* low cement content likely
- *High fines...........Suitable,* high cement content likely
- *Very high fines.......Unsuitable* unless sand added

Smell test. If musty smell is present record as organic and reject soil as unsuitable. If no smell proceed.

Visual-touch test.	To determine relative coarse/fine fraction present. If no fines are present record as unsuitable, no fines. If no sand/gravel present record as *unsuitable, very high fines* (proceed to shine and bite test to determine if fines are predominantly silt or clay for future reference). If a mixture of coarse and fine present proceed.
Thread test	To identify high plastic clay content and non-plastic soils. If a high plastic clay content present record as *unsuitable, very high fines.* If it is not possible to form a thread then non-plastic, record as *unsuitable, very low fines.* If neither proceed. (The ribbon test may be used as an alternative or for verification)
Shine test	To tentatively determine whether a combination soil is high or low fines. Predominantly sandy record as *suitable, low fines.* Predominantly silty or clayey record as *suitable, high fines.* Proceed with sedimentation test (use one third of a jar of soil if predominantly sandy and one quarter to one sixth if predominantly fines).
Sedimentation test	To give a rough analysis of relative sand/silt/clay composition. (Here the fines content may be further described by the recording the separate percentages of silt and clay not previously included in the above categorisation plan.) Less than fifty percent sand/gravel record as *unsuitable, very high fines.* Fifty to seventy percent sand record as *suitable, high fines.* Seventy to eighty percent sand record as *suitable, low fines.* Greater than eighty percent sand record as *unsuitable very low fines* (these are arbitrary boundaries and intended as a guide only). If no clay is present record as *unsuitable, very low clay.*
Dry strength and wet-shaking	These are additional mechanical tests on the fine soil fraction (< 0.425 mm.) and provide information on the clay content of the fines. These tests should be carried out if the glass-jar sedimentation test fails to discriminate silt from clay. If these tests show that no clay is present in the fines then the soil should be reported as *unsuitable, very low clay.*

Soils which are considered suitable from the on-site testing plan may then be more closely examined with the simple shrinkage box test and/or the following simple laboratory tests (dependant on the equipment and funds available). Such further testing will determine which soil is likely to produce the most acceptable blocks, remembering the points mentioned above in the consideration of suitable soils, section 3.4.

5.2 FIELD TESTING TREE TO ILLUSTRATE A COHERENT TEST PLAN



This field testing tree diagram illustrates one sequence in which the field tests may be carried out. This diagram does not include every possible field test but should illustrate that basic soil selection is possible if the tests are used coherently in a logical order.

5.3 LABORATORY TESTING PLANS

Laboratory tests will provide more precise detailed information on the soil's grading and plasticity. This information should be used to select the soil most likely to produce acceptable blocks based on the selection criteria given in sections 3.4 and 3.5. Laboratory test analysis for soils considered suitable on the basis of the above preliminary tests may be conducted using one of the following plans. Which plan is used depends on the resources available, Plan 1 requires accurate weighing equipment as the soil samples used for sedimentation and dry sieving are small. Plan 2 requires a moderately large supply of water for effective wet sieving. Plan 3 relies on representative soil samples being used. Other plans are of course possible.

If no single soil seems suitable or only barely suitable then a combination of two (or if justified more) soils may frequently produce a more successful material. For example a soil without fines may be improved (modified) by adding a suitable quantity of a clayey soil containing a high fines content. The grading information gained from the laboratory tests will enable the relative amounts of each soil type required to be provisionally calculated. Although the modified soil should be re-tested using the laboratory tests the modification process will be greatly simplified.

PLAN 1.

Sedimentation test (syphon)	Used to measure the clay fraction of the soil. The settled material may be subsequently dried and used in the dry sieve test.
Dry sieve test.	The settled material from above may be sieved dry to determine the gravel, sand and silt fractions.
Atterburg tests	Should be conducted using the original soil, suitably sieved, to determine the liquid/plastic limits and plasticity index.

PLAN 2.

Wet sieve test (fines retained)	Used to determine the gravel and sand fraction of the soil and to separate the silt/clay fraction for sedimentation.
Sedimentation test (syphon).	The material passing the 0.063 mm wet sieve may be separated into silt and clay fractions.
Atterburg tests	As above.

PLAN 3.

Wet sieve test (fines discarded)	Used to determine the gravel and sand fractions of the soil.
Sedimentation test (syphon)	A separate portion of the above sample is sedimented to determine the clay fraction. The silt fraction is found by adding the total measured soil percentages and taking this figure away from 100 %
Atterburg tests.	As above.

APPENDIX A : FIELD TESTS

Smell test

USE :	For determining the presence of organic material.
ACCURACY :	Medium to high.
TIME :	Fast.
LIMITATIONS :	This test does not determine the quantity of organic matter present.

EQUIPMENT: Minimal; small cooking stove or fire and a suitable pan.

METHOD: Take a representative sample of moist soil and smell it. If the soil smells musty then a significant quantity of organic matter is present (soil containing organic matter is unsuitable for building and should not be used). If a musty odour is not present, heat the soil in a pan and smell again. If there is now a musty odour then the soil again contains too much organic matter and should be discarded. If the soil does not smell musty at all then the soil is probably inorganic.

NOTE: Usually the top layer of soil will be organic but subsequent lower layers may be inorganic.

Visual-Touch test

USE:	For initial on-site examination of soil to determine the presence of gravel,sand, silt and clay.
ACCURACY:	Dependant on skill of tester.
TIME:	Fast.
LIMITATIONS:	Very difficult to tell silt from clay by a visual examination.

EQUIPMENT: None.

METHOD: Visual..Take a representative dry sample of soil. Breakdown any lumps or clods by rubbing between the fingers and examine to gain an idea of the proportion of different size particles. Particles larger than 2 mm are defined as gravel (BS1377) while those smaller than this but still visible to the naked eye form a continuum of coarse through medium to fine sand. The smallest grains visible to the naked eye are fine sand, approximately 0.06 mm. The conventional size boundaries are listed below. The dust which cannot be distinguished as single grains is a combination of silt and clay, normally called the fines.

Touch..The feel of the soil can also be an indicator of its basic components if rubbed both wet and dry. Sands are coarse particles which have a rough feel when rubbed between the fingers. They lack cohesion when wet, they do not stick together well. Dry silt has a similar but less pronounced feel to dry sand and shows limited signs of cohesion when wet. Dry clay usually forms hard but smooth clods. If these are broken down when dry the resulting powder has a smooth slippery feel. When wet, clay has a greasy or sticky feel and is very cohesive.

NOTE: This test is useful if it is used to gain a first broad idea of the soil constituents however unless the soil is a pure sand, silt or clay or the operator has considerable experience it is very difficult to assess the percentage composition. A no fines soil should be reported as *unsuitable, no fines*. Similarly a soil with little or no sand/gravel should be reported as *unsuitable, very high fines*. Further testing should be carried out if a mixture of sizes is observed.

British Standard and MIT definition of soil particle sizes:

Coarse gravel................	60 - 20 mm
Medium gravel................	20 - 6 mm
Fine gravel..................	6 - 2 mm
Coarse sand..................	2 - 0.6 mm
Medium sand..................	0.6 - 0.2 mm
Fine sand....................	0.2 - 0.06 mm
Silt.........................	0.06 - 0.002 mm
Clay.........................	> 0.002 mm

Thread test

USE: To test for the presence of a large quantity of plastic clay or pronounced lack of fines.
ACCURACY: Low.
TIME: Fast.
LIMITATIONS: Only gives a vague estimate as different clay types have different plasticity. Requires prior operator experience for successful interpretation.

EQUIPMENT: A smooth surface, a sheet of glass or similar.

METHOD: A small representative sample of moist, easily mouldable, soil should be formed into a cylinder about the same size as a thumb. This cylinder should then be lightly rolled with uniform pressure on a smooth flat surface by the outstretched fingers of one hand, forming a thread of soil (if it is not possible to form a thread report as *unsuitable, very low fines*). The thread will reduce in size until it breaks, either by snapping into shorter pieces or shearing along the length of the sample. The size at which the thread breaks gives an indication of the clay content. If the sample will easily form a 3 mm or lower diameter thread then there is probably a high plastic clay content. If the thread breaks at a larger diameter than 3 mm then there is either a moderate sand and silt fraction present or the clay is only slightly plastic. If the sample appears to have a high plastic clay content then it should be reported as unsuitable, very high fines.

NOTE: This is a simplified version of the Atterburg plastic limit. For the full test see the laboratory tests section.

Ribbon test

USE:	To test for the presence of a large quantity of plastic clay or pronounced lack of fines.
ACCURACY:	Low.
TIME:	Fast.
LIMITATIONS:	Only gives a vague estimate as different clay types have different plasticity. Requires prior operator experience for successful interpretation.

EQUIPMENT: none

METHOD: Take a representative sample of soil sufficient to form a roll about the diameter of the thumb but three times longer (A comfortable size to fit in the palm of the hand with the fingers rolled in to make a hollow fist). Wet this soil so that the sample is damp but not overly sticky. Hold the sample in the palm of the hand with the fingers rolled over and push the sample out from between the thumb and first finger, flattening it to form a ribbon 4 - 6 mm in thickness. Let the ribbon hang down from the hand, without supporting it, and see how long it gets before it breaks. Compare the length at which it breaks with the lengths given below.

.. 0 cm, no ribbon at all. This indicates that the soil contains very little or no clay and should be reported as *unsuitable, no clay*.

.. 4 - 10 cm, short ribbon. This indicates a soil containing a low to moderate quantity of clay and should be reported as provisionally suitable. The longer the ribbon then the larger the quantity of stabiliser which will be required for adequate stabilisation.

.. 25 cm and longer, long ribbon. This indicates a soil containing a high quantity of clay and should be reported as *unsuitable very high fines*. Such a soil would require an uneconomically high quantity of stabiliser for adequate durability.

NOTE: The lengths given above are not a set of rigid rules but should be treated as a set of guidelines. With experience of testing the local soils these lengths should be revised to improve the selection accuracy.

Shine test

USE: For determining the major soil components and identifying a silt or clay dominated soil.
ACCURACY: Low.
TIME: Very fast.
LIMITATIONS: This test determines which is the major soil component (sand, silt or clay). It does not determine the quantities present.

EQUIPMENT: Sharp knife (optional).

METHOD: Take a representative sample of soil. Moisten it and form into a ball. Cut the ball with sharp knife or polish a section of it with a fingernail. If the resulting surface is shiny the soil is predominantly clay. If the surface is dull and feels abrasive or harsh then the soil is predominantly sand or silt. Sand and silt may be distinguished by closely examining the surface. If the surface appears grainy then the soil is a sand. If grains cannot be seen the soil is silty.

Bite test

USE: For differentiating between silt and clay on-site.
ACCURACY: Dependant on skill of tester.
TIME: Very fast.
LIMITATIONS: Only useful for distinguishing on a presence/absence basis.

EQUIPMENT: None.

METHOD: Take a pinch of soil and lightly grind it between the front teeth. Any sand present will feel harsh or gritty and unpleasant. Silt will also feel gritty but much less unpleasant. Clay will feel smooth or flour-like.

Sedimentation test (glass jar)

USE: A simple test to give a rough numerical value to the percentage fraction of soil components.
ACCURACY: Medium to low.
TIME: Slow (up to 24 hours).
LIMITATIONS: The results from this test give an idea of the soil's component parts to a low accuracy. The low accuracy is due to the difficulty in discriminating the layer boundaries and the slow settling movement of these boundaries over time.

EQUIPMENT:
- 1 Wide transparent glass jar (> 65 mm diameter), straight sided and flat bottomed with a capacity greater than half a litre.
- 1 Bung for the glass jar (optional).
- 1 Stopwatch or clock.
- 1 Ruler long enough to measure the height of settled material.
- A supply of clean drinking water.

METHOD: A representative sample of soil is loosely placed in the glass jar up to one quarter of its depth for sandy soils or one quarter to one sixth of its depth for silty or clayey soils. Clear drinking water is placed into the jar to fill it almost to the top. The bung is then placed in the mouth of the jar and the jar left undisturbed until the soil is completely soaked with water. The jar is then shaken vigorously for one or two minutes and placed on a flat level surface to stand undisturbed for one hour. The jar is then reshaken for a further minute, replaced on the flat surface and the stopwatch started. The jar must now be left UNDISTURBED. After forty five minutes it should be possible to see a layer of sand settled at the bottom of the jar and a further layer of silt settled above. The cloudy suspension above the silt layer is the soil's clay content (If a pronounced clear layer is seen the soil has flocculated and should be treated with one of the chemical agents listed below). The clay settles out much more slowly than the sand or silt, settling at approximately 12 mm per hour. After a further twelve to twenty four hours the clay should also have settled. The different components can now be measured by measuring the height of the three layers. If the silt/clay boundary cannot be seen and the suspension has not flocculated then the experiment may be repeated using the timing system put forward by Norton (1986), the height of settled material is recorded after 1 minute, 30 minutes and 12 to 24 hours (depending on fineness of clay). The total depth of the sediment (not including the water remaining above) is taken as 100% of the soil. The height of each layer is then recorded as a percentage of the total depth. The three values then taken to be the sand, silt and clay content of the soil.

NOTE: This test has been in wide use for a long time but with some significantly different methods of application. The test is based upon Stoke's law of sedimentation which predicts the rate of settling for a spherical particle in free fall. This is only strictly valid for low concentrations of spherical particles. The jar test then has two sources of primary error in that the particle concentration is not low and the particles are not spherical, particularly so when considering the clay fraction, most clay particles being a plate-like shape. Results from this test should always be treated with caution.

This test frequently contains instructions to add a pinch of salt as a deflocculent. This is incorrect: salt should not be added except under special circumstances (for details see above, section 4.3.3 Sedimentation tests). Suitable deflocculents / dispersants are listed overleaf.

Deflocculents after Head (Ref 8, Head 1980):

sodium bicarbonate	starch
sodium carbonate	sodium silicate
sodium hexametaphosphate	tannic acid
sodium tetraphosphate	sodium hydroxide
sodium oxalate	trisodium phosphate | for laterites.
sodium tripolyphosphate	tetrasodium phosphate | for laterites.
sodium polyphosphate	

also: gum arabic (Ref 6, United Nations 1964)

Dry strength test

USE:	Additional test to estimate whether silt or clay predominate in the fines of a combination soil.
ACCURACY:	Low, dependant on operator judgement.
TIME:	Slow if sedimentation is used to prepare the sample, faster if dry sieved.
LIMITATIONS:	Only low accuracy without prior operator experience.

EQUIPMENT:

EITHER	1	Wide transparent glass jar (> 65 mm diameter), straight sided and capacity greater than half a litre.
	1	Syphon tube of suitable length approx 5 mm diameter.
	1	Separation disk with stem. A flat disk just smaller than the diameter of the glass jar attached to a suitable stem so that the disk may be lowered into the jar.
	1	Stopwatch to time thirty seconds.
	1	Wide dish to collect the syphoned liquid. Approx 150 mm diameter.
		A source of clean water (as clear as possible).
OR	1	0.06 mm. sieve and collector

SYPHONING METHOD: Place loose soil into the jar up to one quarter of its depth. Add water to nearly fill the jar, cover the mouth and shake vigorously. Leave to stand for one hour to allow the soil to soak.

Shake the jar vigorously for approx two minutes and stand on a solid flat surface. Time for thirty seconds from placing the jar on the flat surface.

Lower the separation disk quite quickly into the jar so that it covers (without disturbing) the sand settled after thirty seconds. Syphon off the liquid containing the remaining suspended matter into the wide dish. The easiest way of doing this is to tie one end of the syphon tube to the base of the separation disk's stem. This anchors the tube, preventing it from floating.

The particles will slowly settle out of the water in the wide dish leaving clear water. This water should then be decanted off, either by carefully pouring, without disturbing the settled material, or preferably by syphoning. Not all of the water should be removed like this as inevitably some material would be lost. The remaining water should be evaporated off.

DRY SIEVING METHOD: If a 0.06 mm sieve is available the silt and clay portion of the soil may be removed from the soil mass by dry sieving. A representative sample of soil should be dried and completely sieved through the 0.06 mm sieve. The material passing through the sieve should be collected and used for the test below. See section 4.3.2 for a discussion of sieving techniques.

The resulting material should then be well mixed with a little water to evenly distribute the particles and a representative sample should be formed into a 2 cm diameter ball. This ball should be soft but not sticky, (a dough-like consistency).

The ball should then be dried out either by gently heating or by leaving in the sun.

When dry the ball should be crushed between the first finger and thumb. The resistance of the ball to crushing gives an estimate of the type of fine predominating. If the ball falls apart when picked up then the soil either has a very low fines content or no clay and should be reported as *unsuitable, very low fines*. If the ball crushes easily the fines are very fine sand, inorganic silt or a combination of very fine sand, silt and a small quantity of clay. This reaction should be reported as *suitable, low fines*. If it crushes with moderate difficulty the fines are an organic clay, a silty clay or a sandy clay and should be reported as probably *suitable, high fines*. If the ball cannot be crushed or only with considerable difficulty the fines are an inorganic highly plastic clay and should be reported as probably *unsuitable, very high fines*.

Surface water test

USE:	Additional test to estimate whether silt or clay predominate in the fines of a combination soil.
ACCURACY:	Low to medium.
TIME:	Slow if sedimentation is used to prepare the sample, faster if dry sieved.
LIMITATIONS:	Requires careful observation.

EQUIPMENT: As for the dry strength test above.

METHOD: Follow the instructions for the dry strength test (above) to produce a soft 2 cm ball. The ball is then held in the palm of one hand and repeatedly jarred horizontally by striking against the other hand.

As the ball is jarred either a film of water may appear on the surface, characterised by a shiny appearance, or no change will occur. After noting the preceding reaction, squeeze the ball with the fingers of the other hand. Either the water will disappear from the surface, the mass hardening and eventually crumbling or the appearance will not change, the ball being deformed into a soft plastic mass.

Repeat the above shaking and squeezing steps several times to be sure of the reaction.

If water appears and disappears quickly, the ball hardening when squeezed then the fines are a very fine sand or an inorganic silt. Reported as *unsuitable, very low clay*.

If water appears and disappears slowly then the fines are a slightly plastic silt or a silt containing a small amount of clay. Reported as *suitable, low clay*.

If no water appears on shaking and the ball is deformed into a soft plastic mass on squeezing then the fines are predominantly clay. Reported as provisionally *unsuitable, very high clay*.

NOTE. If the sample is a silt containing some clay, water will appear on shaking but may only partially disappear on squeezing, the ball feeling slightly plastic. Reported as *suitable, high clay*.

APPENDIX B : LABORATORY TESTS

Dry Sieve Test

USE:	To separate grades of sand on a size basis and give a value for the total fines content (silt and clay) for low-cohesion soils.
ACCURACY:	High (providing the soil is sufficiently broken down).
TIME:	Medium/slow.
LIMITATIONS:	The results from this test usually give an accurate breakdown of the sand fractions but silt and clay are too fine to be easily separated by sieving. If the soil is not easily broken down into individual particles the wet sieve test should be used.

EQUIPMENT: Nesting sieves

6 mm	Coarse and medium gravel
2 mm	Fine gravel
0.6 mm	Coarse sand
0.2 mm	Medium sand
0.063 mm	Fine sand

Suitable sized collector to catch the combined silt and clay fraction passing the 0.063 mm sieve.
Mass measurement balance.

METHOD: The dry sieve test is very simple to conduct if suitable sized sieves are available or can be made. A large (2 Kg) representative sample of soil is taken and thoroughly dried either in a pan over a stove or by spreading the sample out and leaving it in strong direct sun. From the dry sample two accurately weighed sub samples of about 1 Kg are taken, (500 g is adequate if the soil is fine). The following procedure is then carried out on each and the results averaged. The sieves are stacked in order of decreasing size, the 6 mm sieve at the top of the stack and the collector at the bottom. The weighed soil sample is then broken down into individual particles either by hand or by light grinding in a pestle and mortar. Re-weigh the sample if any material is lost in grinding. Place the weighed sample in to the top sieve. The set of sieves is then shaken until no more material passes from one sieve to the next, this may take some time to complete, (15 minutes or more), as particles slightly larger than the sieve aperture size tend to jam in the holes and blind the sieve. If this occurs gentle brushing of the sieve with a soft brush will unblock these holes, but care must be taken not to force material through the holes as this would give a false value.

Once material transfer has stopped the soil particles lying on top of each sieve are carefully removed and weighed, remembering to brush the material from any blinded holes. The mass of the material on each sieve is converted to a percentage of the total mass hence giving a simple particle size analysis, but without distinguishing silt and clay. Soil loss during the experiment can be checked by comparing the initial mass with the sum of the mass of the separated fractions.

NOTE: This test may be carried out with the sediment from the syphon test (described below), the material in the collector should then be silt as the clay will have been removed but the smaller sample size requires more accurate mass measurement. If accurate mass measurement is available this will give a more reliable result than dry sieving as the clay fraction, which tends to adhere to larger particles when dry, will have been washed off.

Sedimentation test (syphon)

USE:	A more accurate version of the glass jar test enabling direct measurement of the clay fraction weight.
ACCURACY:	Medium to high.
TIME:	Slow.
LIMITATIONS:	The accuracy of the results depend on successfully separating the clay fraction (see comments above on flocculation).

EQUIPMENT:

- 1 Flat bottomed glass jar, approximately 65 mm internal diameter and 1 litre capacity (a rubber bung to close the end of the cylinder is useful but not essential).
- 1 Flat circular disk on a stem such that it may be lowered into the cylinder. The disk should be slightly smaller than the internal diameter of the cylinder with the stem 10 cm longer than the height of the cylinder.
- 1 Flexible rubber syphon tube to remove suspended material from the cylinder.
- 1 Stopwatch or clock.
- 1 Weighing balance accurate to at least 0.1 g preferably 0.01g.
- 1 Heat proof container to receive the syphoned suspension.
- A clean supply of water.

METHOD: Weigh out a representative 100 g sample of dry soil and place it in the cylinder. Add clean water to 200 mm, measuring the height from the internal cylinder base. Close the cylinder with the palm of one hand or a suitable sized rubber bung and shake it vigorously end over end to produce a uniform suspension of soil. This may take some time depending on the type of soil. If the soil does not appear to form a uniform suspension then leave it to soak for thirty minutes and reshake. Once a uniform suspension has been formed place the cylinder on a flat steady level surface and begin to time 20 minutes.

At the end of 20 minutes slowly lower the disk to cover the settled material, taking care not to disturb it. If the soil contains a high proportion of fines, it may not be possible to see the upper edge of the settled layer. If this is the case then repeat the experiment using a smaller soil sample. (The top layer of material is silt, if the disk is allowed to rest on the surface then some silt will be forced up around the edge of the disk. Any silt forced back into suspension will give a misleadingly high value for the clay fraction.) The remaining suspended material may now be syphoned off with the rubber syphon tube. The syphoning operation is more simple to perform if the tube is tied to the stem just above the upper face of the disk. This stops the tube from floating or curling.

The material syphoned off is then dried, weighed and recorded as the clay fraction. The purity of the dried clay fraction may be tested with the bite test above if silt contamination is suspected. The settled material should then be combined sand and silt, these should now be separated by sieving. The sieving may be done wet or dry. In this case, the soil having had the cohesive clay component removed, dry sieving is the more appropriate. The settled material should be dried and placed into the top of the set of sieves as described above for the dry sieve test. In this case the material passing the 0.063 mm sieve is the silt fraction.

NOTE: This test is also based on Stoke's law of sedimentation and hence open to the problems mentioned for the glass jar sedimentation test. In particular salt is not a suitable deflocculent, one of the reagents mentioned above (Glass-jar sedimentation test) should be used if required. Flocculation should always be avoided if possible as it results in significant "wipe down" of the clay fraction (see below) and frequently results in a semi-settled layer of combined silt and clay above the settled material, causing difficulty in determining the level for the disk.

The syphon test uses a less concentrated sample of soil than the glass jar test and hence is more accurate but it is still prone to "wipe down" whereby the larger soil particles carry the smaller particles down with them. These effects can be reduced by carrying out a second syphon test on the settled remains of the first test, subsequently combining the two clay fraction values to give a more accurate reading. However this does increase the time required for the test.

Wet sieve test

USE:	To separate sand from the fines, particularly for lateritic soils which are difficult to breakdown when dry and may contain clay trapped in particle fissures.
ACCURACY:	Medium to high.
TIME:	Slow, dependant on the drying time after wet washing.
LIMITATIONS:	Flushing the soil particles down through the set of sieves requires quite large quantities of water which must be subsequently dried off before weighing the sample. Care must be taken when handling this water to prevent loss.

EQUIPMENT: Nesting sieves

6 mm	Coarse and medium gravel
2 mm	Fine gravel
0.6 mm	Coarse sand
0.2 mm	Medium sand
0.063 mm	Fine sand

Two or more large sized collectors to catch the wash water carrying the combined silt and clay fraction passing the 0.063 mm sieve.
Mass measurement balance.
A clean supply of drinking water.

METHOD: A representative dry sample of soil is weighed out accurately, about 1 kg for fine soils and 2 kg for coarse soils. This sample is mixed in a suitable clean bowl with an excess of water and left to soak for 1 hour. If available a dispersant should be added to aid the particle separation. Suitable dispersants are listed above under the glass jar sedimentation test. After one hour the soil is remixed and poured into the nesting sieves making sure to rinse any soil residue into the sieves with more water. The soil is then washed through the sieves with more water until no further particle transfer occurs between sieves. This may be checked by judicious inspection. This will require a large quantity of water and hence the collector should be regularly checked and replaced when nearly full.

When washing has been completed the soil fractions on each sieve should be dried, weighed and recorded as a percentage of the initial mass.

The wash water should be left to stand undisturbed until clear. This clear water can then be removed by syphoning or carefully pouring off without allowing any material to be lost. The residue is then either dried, weighed and recorded as a percentage as above or further separated into silt and clay fractions by the Sedimentation test (syphon).

SIMPLIFIED METHOD: If the wash water is allowed to run to waste then the total fines content may be found by subtracting the combined collected masses from the initial mass. The clay fraction may then be found from a separate sedimentation test and the silt fraction would be assumed to be the difference between the combined sand and clay percentage and 100%.

Atterburg Limit tests

USE:	To provide an indication of the properties of the soil fraction finer than 0.425 mm.
ACCURACY:	Medium to high.
TIME:	Medium/slow.
LIMITATIONS:	Considerable difficulty may be experienced finding the plastic limit when the soil contains a low plasticity clay. Tests on the same sample may give different results if performed by different operators.

EQUIPMENT:

1	Curved dish approx 93 mm diameter, 27 mm deep at centre.
1	Grooving tool to form a 2 mm wide, minimum 8 mm deep groove with sides 60 degrees off horizontal, or a knife to cut the groove.
2	Water proof, air-tight containers one large enough to hold approx 250 g of soil the other large enough to hold approx 100 g of soil.
1	0.425 mm. sieve.
1	Flexible blade to mix the soil.
1	Smooth surface. eg. plate glass 200 x 200 mm.
1	3 mm diameter rod (optional).
1	Mass measurement balance.
	A supply of clean drinking water.

METHOD: Dry a representative sample of soil, grind it in a pestle and mortar to break up any agglomerations of particles and sieve it through the 0.425 mm sieve to give a sample of about 200 g. Place this sample into the larger air-tight container and seal it. The following two tests should be performed on this sieved sample.

Liquid Limit. Mix about 70 g of the soil sample with the drinking water to form a thick homogenous soil paste. The mixing operations should continue for about 10 minutes but if the soil contains a moderate to high quantity of clay then the mixing stages should be very thorough taking up to 30 or 40 minutes each. With the flexible blade, smooth this paste into the curved dish, taking care not to trap any air. The soil should be 8 mm deep at the centre of the dish and full height at the edge. Using the grooving tool (or a sharp knife), divide the paste in two across a diameter leaving a clean groove 2 mm wide with sides 60 degrees from the horizontal.

Solidly hold the dish level in one hand with the groove pointing away from the body. Gently tap the dish horizontally against the heel of the other hand by moving it 30-40 mm (keep the empty hand still). After 10 taps the groove should close so that the two portions of soil come into contact along the bottom of the groove over a continuous distance of 13 mm. If the groove closes before 10 taps then the soil is too wet. It should be removed from the dish and more dry soil mixed with it and the test repeated. If the groove does not close after 10 taps then the soil is too dry. It should be removed, mixed with more water and the test repeated.

When the groove just closes over 13 mm the soil is at its liquid limit, put the sample into a pre-weighed container, seal it and reweigh it. Then dry the sample and weigh it again The plastic limit is now found by calculating the mass of water in the sample as a percentage of the soils dry mass.

Plastic Limit. Take about 10 g of the sieved soil sample and mix it with water to form a thick paste which should be malleable but not sticky. Roll the soil into a ball with the hands until it begins to dry and crack slightly. Divide the ball into four roughly equal parts and follow the following procedure for each part.

Mould the soil into a cylinder about 6 mm diameter. Place it on the flat surface and roll it under the fingertips with an even light pressure to reduce its diameter to 3 mm (check with the 3 mm rod) after between five and ten back-and-forth movements, slightly more for heavy clays. It is important to maintain a uniform rolling pressure throughout (do not reduce the rolling pressure as the thread approaches 3mm). If the sample breaks into pieces by shearing longitudinally or laterally at 3 mm diameter it is at the plastic limit. If it breaks before 3 mm, slightly wet the sample and retest. If it does not break at 3 mm it is too dry. Roll the sample between the palms of the hands and retest. If the soil always breaks before 3 mm then it should be recorded as non plastic[6].

When the soil breaks at 3 mm, quickly gather the pieces together, place then into a pre-weighed air-tight container, seal the container and repeat the test with the next soil sample. When all samples have been tested weigh and record the sealed container's mass then dry the sample and reweigh. Calculate the percentage of water as a fraction of the dry weight. This percentage is the plastic limit.

Plasticity Index. The plasticity index is the numerical difference between the liquid and plastic limit recorded as the nearest whole number.

---

[6]. A non plastic soil may still be suitable for soil cement production provided that some clay is present. The plastic limit test is a standard reference and failure to produce a result does not automatically mean that the soil should be rejected. For soil with a low clay content or containing a clay of low plasticity considerable difficulty may be experienced in attaining a plastic limit despite the soil exhibiting some plasticity.

Shrinkage test

USE: To provide an indication of the cement content required for a given soil compacted with a low pressure moulding machine such as the Cinva Ram.

ACCURACY: Medium.

TIME: Slow (at least seven days drying time).

LIMITATIONS: Requires a large soil sample and mould. It may take seven days for the shrinkage to be complete. This test has been calibrated for use with particular presses and as such is not directly relevant to machines operating at different compaction pressures.

EQUIPMENT:
- rectangular mould box of internal dimensions 40x40x600 mm.
- 6 mm sieve.
- mixing container and mixing implements.
- a supply of clean water (drinking water).
- a ruler or tape measure.
- a lubricant, either silicone grease, mould release oil, used engine oil or grease.

METHOD: The internal length of the mould cavity is accurately measured and recorded. All of the internal mould faces are smeared with the available lubricant to reduce the tendency of the soil to adhere to the mould.

A representative damp soil sample is taken and sieved through the 6mm sieve. This soil is then thoroughly mixed with water until it has a wet pudding or porridge-like consistency (this should occur near the liquid limit, see above). The mould is then filled with this soil mixture, in three roughly equal layers. After the addition of each layer the mould box is tapped to remove any air trapped in the soil. When the final layer has been tapped the excess soil is removed from the top of the mould leaving a smooth flat soil surface. It is important that the soil does not extend beyond the internal edge of the mould wall as this will increase the soil drag as the sample dries.

The mould containing the soil sample is then placed in a shaded area to dry. Once the soil appears to be shrinking away from the box sides it may be moved into direct sunlight to speed the drying process. The mould should be protected from rain throughout the drying time.

When the drying is complete the length of the dry soil sample should be accurately measured and recorded. If the sample has cracked across its width and separated into several pieces these pieces should be pushed together and the combined length recorded. If the soil has hogged up out of the mould forming a crescent-shaped length, the length of both upper and lower faces should be measured and their average recorded as the dry length. Cracking indicates a soil containing a high sand/silt fraction while hogging indicates a high clay content.

The linear shrinkage on drying may then be found by subtracting the dry soil length from the length of the mould box. This shrinkage length may then be referred to the table given below after VITA for the low-pressure (2MPa) Cinva Ram machine and after Webb for the high-pressure (10MPa) Brepack machine (Ref 5, Webb 1988).

Measured Shrinkage (mm. per 600 mm)	Recommended* Cement percentage (for Cinva Ram)	Recommended* Cement percentage (for Brepack)
under 5	too difficult to handle when block making	
5 - 15	5.56	perhaps insufficient clay (see sect'4.3.5)
15 - 30	6.25	5.0
30 - 45	7.14	6.7
45 - 60	8.33	8.3
over 60	not suitable for use unless more sand is added	

* The Cinva Ram blocks are to meet a wet strength criteria of around 1MPa, while the Brepack blocks meet a criteria of around 2.8 MPa. If the same strength criteria were to be used the high-pressure Brepack blocks would probably require about 40% less cement that the low-pressure Cinva blocks.

Working Paper No. 39

The Performance Testing of Treadle Pumps

by Dr. T.H. Thomas

October 1993

Abstract:
A good treadle pump satisfies many user criteria including some that can be tested under laboratory conditions. The paper describes a set of laboratory tests and suggests performance thresholds that should be reached in them. The tests relate eitther to efficiency or to ease of priming. Under the description of priming tests there is included an analysis of the effect of any 'dead volume' of trapped air upon the maximum suction head of a pump during priming and during steady operation.

List of Variables

A	cross-sectional area of cylinder or equivalent cross sectional area of diaphragm
f	pump cadence in cycles per second
g	gravitational constant = 9.81 m/s^2
H	total head experienced by pump = pressure rise thro' pump / ρg $= H_d + H_s$
H_f	friction head loss
H_d	delivery head = delivery port pressure / ρg
H_p	(unaided) priming suction head
H_s	suction head = inlet port negative pressure / ρg
H_{sm}	maximum pumping suction head
L_d	piston stroke
Q	flow through pump in m^3/s (1 m^3 = 1000 litres)
Q_i	ideal flow (if no leakage)
Q_l	leakage (including internal leakages) flow
W_f	friction power loss (mechanical)
W_{in}	input power at treadles
W_{out}	output power = $Q\ H\ \rho g$
η_{erg}	ergonomic efficiency
η_{flow}	output flow/(output flow + leakage flow) = $Q/(Q + Q_l)$
η_{head}	output head/(output head + head loss) = $H/(H + H_f)$
η_{hyd}	hydraulic efficiency = $\eta_{head} \times \eta_{flow}$
η_{mech}	mechanical efficiency = $(W_{in} - W_f)/W_{in}$
η_{pump}	pump efficiency = output power/input power = $W_{out}/W_{in} = \eta_{hyd} \times \eta_{mech}$
ρ	density of water = 1000 kg/m^3

1. Introduction

Any good treadle pump must satisfy many criteria. It must be 'effective' or efficient, durable, portable, adaptable over a range of users and delivery heads, easy to clean and repair, easy to install and start. For the purpose of this paper we will restrict our interest to performance in the narrow sense of effectiveness in use, i.e. performance then can be measured in laboratory tests.

Treadle pumps are human operated. The amount of water that can be pumped depends on the pump's efficiency, on the total head and on the effort and physique of the operator. It is not practical to replace human operators for testing purposes by calibrated motors or engines, so any test procedure must accommodate the variability of a person as a power source. Indeed the extent to which the pump matches the operator (allowing him or her to deliver power with the least fatigue) is an important performance parameter.

Human-powered pumps are not used continually or very steadily. They start and stop. For test purposes we usually distinguish between two phases of use:

a) Start-up or 'priming' when a pump is first applied to a new site.

b) Steady pumping.

There is a transition from the first phase to the second which may take as little as 5 seconds or as much as 10 minutes. During this settling-down period leather pistons may swell to achieve better sealing, residual air may be washed out of pistons, lubricating oil may spread to reach rubbing parts. However the transition has ill-defined boundaries and it is normally adequate to simplify behaviour into just the two phases already mentioned.

Priming takes a certain time t_p which terminates when the pump output has reached (for a given effort) say 95% of its final or steady state value.

2. Performance Measures

There are many possible performance measures, some of a global nature and some describing the effectiveness of particular pump components. Common measures are:

Output flowrate - for a defined (typical?) operator at various total heads and various suction heads. A convenient representation is to plot flowrate Q versus total head H for each of several suction heads (H_s) spanning from 0 to (say) 8 meters. Clearly H must not be less than H_s. The weakness of this measure is the variability of operators. However by using an operator of defined physique (eg. health, age, sex and weight) in a defined duty (eg. a cycle of 10 minutes treadling followed by 5 minutes rest maintained for 1 hour), this variability can be limited. Output flowrate is an easy measure to interpret and especially useful when comparing different pumps tested by the same operator.

Suction head - this is the maximum depth from which the pump can suck water. There is a absolute limit of about 10 meters on this depth at 20°C at sea level (assuming atmospheric pressure is 1000 mbar) which diminishes by about 10% for each kilometer above sea level. In practice suction heads are usually much less than 10 meters. We need to distinguish between two solutions. H_p = *unaided priming suction head*, is the maximum depth from which some water can be raised in say 1 minute of treadling without the addition of any water from the top. H_{sm} = *maximum pumping suction head* is the maximum depth to which the intake of a steadily operating pump can be lowered before delivery flow ceases. Alternatively a *pumping suction head* may be defined as the depth at which output falls to say 50% of its no-suction-head value. *Pumping suction head* may be observed from the *output flowrate* characteristic; *priming suction head* cannot. A further measure connected with suction is t_{lop} = *loss of prime time*, the time that a pump can be left idle after use before the achievable suction falls from H_{sm} to H_p or more realistically falls from H_{sm} to ½ $(H_{sm} + H_p)$.

Friction loss - can be divided into fluid and mechanical components. H_f = *friction headloss* is a function of flow rate Q and varies approximately with Q^2.

W_F = *mechanical friction power loss* varies with pump cadence (treadling rate) and would be expressed in watts. It measures friction heat generated in bearings, inside ropes, in the rubbing of pistons against cylinder walls and in the take-up of slack in mechanisms. Both H_F and W_F affect efficiency as discussed below.

Efficiency in any device is the ratio of the performance actually obtainable to that 'ideally' obtainable. When energy is being passed along a chain of processes - for example from human muscle to lifted water - the efficiency of each process can be expressed as the useful energy out of it divided by the energy put in. There are several efficiencies of particular interest. The hardest to measure is

$$\eta_{erg} = \textit{ergonomic efficiency} = \frac{\text{energy given by the treadler}}{\text{energy the treadler ideally could have given}}$$

Obviously we must compare "like with like", so the two human outputs should be measured over the same time and correspond to the same level of human effort. A machine which is awkward to use, i.e. which doesn't make effective use of the treadler's muscles, will have a low ergonomic efficiency. An ergonomically ideal machine will have $\eta_{erg} = 1$. The basic justification for employing a treadle pump rather than a cheaper handpump is precisely because of its higher ergonomic efficiency, its use of leg muscles rather than arm muscles.

More straightforward for measurement is

$$\eta_{hyd} = \textit{hydraulic efficiency} = \underbrace{\frac{\text{output head}}{\text{output head and head loss}}}_{=\eta_{head}} \times \underbrace{\frac{\text{output flow}}{\text{output flow and flow loss}}}_{=\eta_{flow}}$$

Both = η_{head} and = η_{flow} vary with pump throughput. At low heads and high flows, η_{head} is sometimes too low. At high heads and low flows, the seriousness of any leakage increases and η_{flow} is sometimes too low.

$$\eta_{head} = \frac{H}{H + H_f} \qquad \eta_{flow} = \frac{Q}{Q + Q_l}$$

where H_f rises with Q^2 and leakage flow Q_l rises with H. The second component η_{flow} is sometimes called *volumetric efficiency* and is affected both by leakage *from* the pump and, more important, back leakage *within* the pump due to imperfect non-return valves.

Mechanical losses determine:

$$\eta_{mech} = \textit{mechanical efficiency} = \frac{\text{energy that reaches the water}}{\text{energy put into treadles}}$$

$$= \frac{W_{in} - W_f}{W_{in}} \text{ or } = \frac{W_{wat}}{W_{wat} + W_f}$$

3. Prediction, Measurement and Interpretation of Output and Efficiencies

We can visualise flowing through a pump as undergoing a series of transformations each with an efficiency less than than 1.0 (100%).

Potential human power	$\xrightarrow[\eta_{erg}]{}$	Power applied to treadles	$\xrightarrow[\eta_{mech}]{}$	Power applied to water	$\xrightarrow[\eta_{hyd}]{}$	Output (pumping) power

$$(\eta_{pump} = \eta_{mech} \times \eta_{head} \times \eta_{flow})$$

However our interest in "efficiency" is only secondary. Efficiencies tell how effective the individual transformations are and how much room there is for improvement. Users are only interested in output flow under particular circumstances of operator, head and so on, and how the relative output flows of rival pumps compare with their rival costs. In any human-operated device the 'energy' cost of operation is high (for equal energy outputs, in most countries human labour costs up to 50 times that of engine fuel), so efficiency is important. Unfortunately the situations that favour use of human energy are also those that require the capital cost of equipment to be very low. To some extent high efficiency and low cost are incompatible.

In the flow chart above the first efficiency shown is ergonomic efficiency. Although there is a large literature on this topic and specialised measurement techniques (eg. human oxygen consumption), for pump testing it is not usually practical to separately measure ergonomic efficiency. The design of most treadle pumps allow the operator to adjust her/his position on the treadles to get the most comfortable combination of stroke, cadence (cycle rate) and foot force. The scope for adjustment has limits, so that heavy operators in situations of very low lift or light operators in situations of high lift may not be able to find an optimum position.

In the absence of direct tests of ergonomic efficiency, some indirect tests of treadler 'comfort' can be made. The pump can be operated at a mid-range head (eg. 3 m or 4 m) with a large strong operator, a medium operator and a small weak one. The cadence and stroke they choose for sustained pumping should be noted. The medium operator should not be at either end of the range of possible foot positions along the treadle, nor should she/he be persistently hitting the treadle end stops. With a good pump these conditions should also not arise with the heavy or light operators either (at this medium head). No operator should find the handle position awkward or the treadle angles too steep for ankle comfort.

Repeating the trials with a minimum head (1.5 to 3 meters depending on pump type) and a maximum head (5 to 10 meters), the operator choosing new best positions, will show whether the 'medium' operator can maintain a similar cadence and stroke as before. A change in either of more than 50% indicates likely low ergonomic efficiency at one or other end of the head range. It is unlikely that the heaviest operator will be comfortable and efficient at the minimum head, or a child will be efficient at the maximum head.

In the absence of complex equipment, a simple guide to human effort is pulse rate. If, on two different occasions of sustained pumping trials, the same person has the same pulse rate, then his two efforts are likely to be similar. Therefore if one occasion (i.e. choice of pump and head) gives a higher output power than the other, one may assume the former has the higher overall efficiency (ergonomic and pump efficiencies combined).

The three component parts of pump efficiency are the mechanical, head and flow (or 'volumetric') efficiencies. These can be approximately measured in isolation as follows.

$$\eta_{mech},\ mechanical\ efficiency = \frac{W_{in} - W_f}{W_{in}}$$

and power W is force × speed. Since speed is the same for both useful forces and for friction forces.

$$\eta_{mech} = \frac{F_{in} - F_f}{F_{in}}$$

provided both input force and friction force are measured at the same place.

Input force F_{in} can be measured at any defined position along a treadle when that treadle is moved slowly, the pump being connected to a defined typical head. Friction force F_f is approximately the force at the same point to slowly move the treadle when the pump head is reduced to zero (inlet and outlet at the same height). η_{mech} measured in this way should exceed 0.95 in a new well-adjusted pump and still exceed 0.9 in a worn pump.

$\eta_{head} = H/(H + H_f)$ requires measurement of head, which is simple, and friction head loss which is not. Friction head loss for a given flow Q can be obtained by first measuring the reverse head H_r (i.e. the height the pump outlet pipe is held *lower* than its input) necessary to drive that flow through the pump.

$H_f = k_f H_r$ where k_f is at least 4 and typically between 5 and 7.

For a two-cylinder treadle pump, whether with piston or diaphragm, any delivery flow has passed through two valves in series in either one cylinder or the other. During the reverse-head test the total flow divides about equally between the two cylinders (it may be necessary to clamp the pistons during the test to keep them in their cylinders), whereas in normal use the flow alternates between cylinders. The reverse head test is therefore subjecting each valve to only half the peak flow it would normally experience - hence the correction factor of $k_f = 4$ ($=2^2$). The reverse head also uses steady flow, whereas treadle pumps produce a slightly pulsating flow. This difference raises the factor k_f from 4 to about 6. As H_f is proportional to Q^2 we should measure H_r at maximum normal flow, which occurs at full power and minimum normal head H_{min}. Using the resultant value $H_{r,\,max}$ and H_{min} will give a worst case head efficiency of

$$\eta_{head,\,min} = \frac{H_{min}}{H_{min} + k_f H_{r,\,max}}$$

which should not be lower than 0.5 (50%).

$$\eta_{flow} = Q/(Q + Q_l) = Q/Q_i$$

so we need to measure either Q_l (difficult) or to calculate the ideal flowrate $Q_i = Q + Q_l$. With a piston arrangement, Q_i = piston stroke × cylinder area × cadence × 2 = $2\ L_p\ A\ f$ in consistent units. This flow efficiency should not be below 0.9 (90%).

With a diaphragm it is necessary to calibrate the volume displacement for each stroke length, a calibration which may be significantly in error if the diaphragm distorts strongly with variation in water pressure. In fact, measurement of volumetric/flow efficiency is probably not worth undertaking with diaphragm pumps.

The measurement of overall pump efficiency η_{pump} ia impractical unless calibrated gymnastic equipment is available to measure the power output of the operator. If such equipment is available and its action is similar (ie. treadling) to that of the pump, it may be possible to relate operator pulse rate to operator power. In such cases using the pump at exactly the same operator power W_{in} as on the calibrated equipment will permit the calculation of

$$\eta_{pump} = \frac{\rho g\, Q\, H}{\text{operator power}}$$

Pump efficiency will generally be lowest at low heads (and hence high flows). A worst case efficiency of 50% might be just acceptable. Alternatively $\eta_{pump} = 0.5$ at full power can be used to define the minimum rated head H_{min}.

4. Start up, Suction and Priming

The measurement of (unaided) priming suction H_p, and maximum pumping suction head H_{sm} is fairly straight forward.

A dry pump can be operated with an open delivery port and a vertical suction pipe (of normal diameter) attached to its inlet port. Starting with 10 meters of suction (if available) the suction depth should be reduced until the pump delivers water. The suction should be reduced not faster than 1 meter every 2 minutes: this can be done either continuously or in half meter steps. When the suction head H_p at which delivery begins has been found, it should be checked that the pump will prime within say 1 minute from this depth even after the suction pipe is completely drained of water and left to dry for 30 minutes. Once the pump is running and kept running for at least 5 minutes at a suction of H_p or less, the suction point should be gradually lowered while treadling slowly until (at depth H_{sm}) the delivery flow stops. This test can be repeated several time, and the values of H_{sm} averaged, to give a more reliable measure.

Suggested values for H_p and H_{sm} are 2 meters and 6 meters. H_p is quite variable as it depends on treadling rate and can also be badly affected by leaks round pistons or through valves. A diaphragm pump should reach a better priming suction H_p than a piston pump.

An alternative approach to measuring priming and suction performance is to estimate them from indirect measurements. Failure to prime or failure to maintain prime occurs when the pumping flow rate is less than the leakage flowrate. This may be due to high leakage or low flowrate or both.

The suction side of a pump and the suction pipe are normally surrounded by air that will leak in through any fine cracks. During priming the piston-cylinder seal and the valves are also in air (not water as during normal pumping) and will therefore leak faster than when wetted. The simplest form of priming assistance is to somehow wet these components, for example by pouring water on top of the piston.

The flow efficiency of a pump is lowered by the presence of any air in the cylinders or diaphragm chambers, due to air being thousands of times more compressible than water.

Consider a cylinder that contains a 'dead' volume V_d of air at atmospheric pressure when the piston is in its lowest position. As the piston is raised the air volume expands and its pressure drops approximately according to the relation p. $V^{1.2}$ = constant. Only when the piston has moved a considerable distance will the pressure have dropped enough to be below the inlet pressure and hence open the inlet valve. Thereafter further piston movement will perform useful pumping, drawing air (and below it water) up the suction pipe. We can therefore calculate a flow efficiency which assumes perfect seals (no leaks) but expresses the effects of this residual air. This ideal flow efficiency depends upon the suction head (expressed as a fraction of the atmospheric head of 10 meters) and the ratio of volume swept by the piston V_s. So let us define two ratios, a normalised suction S and a cylinder ratio R.

R = dead volume / swept volume = V_d/V_s

Table Ideal volumetric efficiency of cylinder (as %)

	S = 0 (H_2 = 0	0.1 1	0.2 2	0.3 3	0.4 4	0.5 5	0.6 6	0.7 7	0.8 8	0.9 9 m)
R =0.0	100	100	100	100	100	100	100	100	100	100
0.2	100	98	94	93	89	84	77	65	44	0
0.4	100	96	92	86	79	69	54	31	0	0
0.6	100	94	88	79	68	53	31	0	0	0
0.8	100	93	84	72	58	37	08	0	0	0
1.0	100	91	80	65	47	22	0	0	0	0
1.5	100	86	69	48	20	0	0	0	0	0
2.0	100	82	59	31	0	0	0	0	0	0

During priming when the pump is dry, the ratio of dead air volume to swept volume can be quite high, over 2 for some diaphragm pumps and over 1 for piston pumps. These will therefore not self-prime for suctions over 3.5 meters suction and 5.5 meters suction respectively even with perfect seals. For good self priming R must be kept well below 1.

During steady use however, much of the dead volume at the bottom of cylinders/chambers will be occupied by water. The dead air volume V_D will be much reduced and R ratios of below 0.1 may be attainable.

Using the table above, and measuring the pump to ascertain the values of R when the pump is dry and again when it is working (but air can still be trapped above the delivery valve), it is possible to predict maximum values for priming suction H_p and pumping suction H_{sm}. Actual values will be less due to leakage, especially during start up.

Regardless of any leakage losses, an operational *volumetric efficiency* due to these compression effects of less than say 60% would be unacceptable. Such a pump would be "springy" and difficult to treadle.

5. Conclusion

Because it uses a human energy source of variable and unknown power, it is not normally practical to test the efficiency of a treadle pump. However a number of tests and measurements are possible to check that the ergonomic, mechanical and hydraulic efficiencies (defined in the paper) are tolerably high.

If it is the relative performance of two rival pumps, rather than the absolute performance of a single pump, that is required, then suitable tests are available. For example one such test in Zimbabwe in 1991, comparing treadle pumping with bucket-carrying, established that the former was three times as productive as the latter in a typical irrigation task.

The ease of priming of a treadle pump, and the limits of its ability to draw water from a source some meters below itself, can be readily tested and also roughly predicted from measurements of pump geometry. It is shown that a pump whose 'dead' air volume exceeds its piston swept volume can not achieve high suction.

Treadle pumps have a lower head limit below which their inefficiency becomes acceptably high. This limit is typically 2 meters. Although treadle pumps can be designed for high heads, ergonomic and size constraints make them inefficient to operate over a head range of more than about 5:1, and economics discourage their use for heads exceeding 10 meters.

Good performance depends on generously sized valves and passages (to reduce head losses), good seals and fast closing valves (to reduce internal and external leakage), correct gearing (to allow users to choose ergonomically efficient cadences and strokes) and smooth, well-lubricated linkages (to raise mechanical efficiency).

DTU. WORKING PAPER No. 40 November 1993

Quasi-static Compression Forming of Stabilised Soil-cement Building Blocks

by Dr.D.E.Gooding

ABSTRACT

This paper examines the quasi-static compression (slowly applied pressure) method of compacting stabilised soil-cement building blocks. It describes a self-contained piece of research which was conducted to enable the comparison of quasi-static compression with the alternative dynamic methods of soil compaction. It gives an initial over view of the process of soil stabilisation and outlines the roles which soil structure and block curing play in stabilisation. The alternative methods of block compaction are briefly described, followed by a discussion of the material factors which affect the compaction of stabilised soil. A number of simple theoretical models to describe the internal compaction mechanisms of quasi-static compaction are then given.

The results of an experimental investigation to asses the effect of double-sided compaction, mould wall roughness, mould wall taper and pressure cycling relative to the datum process of single-sided, single-cycle compaction are then discussed. This is followed by an experimental investigation to determine the relation between compaction pressure, cement content and seven day wet compressive strength. A formula relating cement content and compaction pressure to wet compressive strength is put forward as the best fit to the experimental data gathered. This formula is then used as the basis for a simple economic analysis of high and low pressure compaction machines.

CONTENTS

INTRODUCTION

The following paper has been produced as the result of an on-going research program to investigate the compaction process used in the production of soil-cement building blocks. It is concerned with the standard quasi-static compaction process. This is the form of compaction normally used in the field by machines such as the Cinva Ram and the Brepack.

The paper is organised into six main sections followed by four appendices containing a bibliography and experimental details. The first section gives an initial overview of the stabilised block technology and briefly describes the roles which various factors play in the final strength of the block. Section two briefly describes the alternative compaction mechanisms and puts this research in context as a reference base for future work to investigate impact and vibration compaction. The third section deals with the material factors which affect the compaction process. The fourth section gives a number of simple theoretical models to describe the compaction process. Section five examines moulding factors which affect the quasi-static compaction of soil-cement blocks. Mould taper, mould roughness, compaction pressure cycling and double sided compaction are examined relative to standard single-sided compaction (the datum process) by recording the pressure transmitted from the compacting soil to the mould walls with an LVDT-based pressure transducer. Section six examines the relationship between compaction pressure, cement content and seven day wet compressive strength. This relationship is then used in a simple economic analysis to asses the cost effectiveness of high and low pressure compaction machines.

1. STABILISED SOIL

Some form of soil covers virtually the whole land surface of the Earth. This soil is usually readily processed with simple hand tools into an easily mouldable material which possesses good compressive strength when dry. Given soil's widespread availability, it is not surprising that it was traditionally widely used as a building material.

The major drawback to building with soil in its natural condition is its susceptibility to water. A soil wall may be considered as a load bearing skeleton of silt and sand glued together by clay. This glue-like behaviour when dry is caused by micro-droplets of water which exist at clay particle interfaces. Clay particles are usually electrostatically charged as a result of surface ion substitution. The charge tightly bonds a thin adsorbed layer of water to the particle's surface. The bonding is sufficiently strong for some adsorbed water to remain even at oven drying temperatures (105-110°C). At the point of contact between two adjacent particles, a micro-droplet of water can exist where the two adsorbed water layers come into contact. These micro-droplets generate both surface and capillary tension forces which hold the clay particles together. However, when any significant quantity of water is absorbed into empty soil pores, the droplets increase in size and the capillary and surface tension forces reduce, causing the soil to quickly soften and subsequently swell. On repeated wetting and drying the outer surfaces of a soil wall expand and contract more quickly than the main body. In a comparatively short time this leads to cracking and spalling of the outer surfaces and low durability for the wall. Moreover, if the wall becomes saturated with water the compressive strength may fall sufficiently to allow complete collapse.

When a soil has been treated to reduce the effect of strength loss on water saturation to a low level, then it may be considered a permanent, durable building material and may be called stabilised soil.

1.1 THE PRINCIPLES AND PRACTICE OF SOIL STABILISATION

If a soil is to be used in any but the driest of climates, it should be stabilised against the weakening effect of water ingression if it is to be durable. There are three primary methods of stabilising a soil: by adding a chemical waterproofer to reduce the tendency of the soil to adsorb water, by adding a chemical binder to give a strength mechanism which persists even when the block is saturated, or by compressing the soil to increase its density, hence increasing its load bearing capacity and at the same time reducing its water permeability.

Under normal conditions the soil's density is increased by compaction to reduce the soil-pore void volume and hence its permeability. By reducing the permeability of the soil, the length of time for which a soil wall may be exposed to water without adverse effect will be extended. However, increased density will not stop the ultimate failure of a soil wall if it is allowed to become completely saturated. To maintain strength when completely saturated, the soil must have an additional strength mechanism.

The advantages of increased density complement those derived from the addition of chemical waterproofers and binders, such that it is normal practise to compact the soil block whenever an additional stabilising agent is to be employed. The reduced permeability reduces the speed of water ingress, while the reduction in soil-pore void volume results in a lower chemical requirement. Whether binder or waterproofer, the chemical additive extends throughout the soil-pore void structure. If the volume of the void structure is reduced, then the amount of stabiliser required to fill or bridge the voids is reduced and hence an increase in soil density will usually allow a reduction in stabiliser content for the same final block strength (see section six for more information on the pressure-cement trade off).

When adequately stabilised, a soil block should not collapse when saturated with water, even after several cycles of complete wetting and drying. A waterproofing agent such as bitumen cutback has two effects. It reduces the ability of water to wet individual soil grains and hence reduces the ingression of water. It also provides a secondary method of particle adhesion by weakly sticking particles together. A dry soil block which has been waterproofed with bitumen may be weaker than an unstabilised block as the adhesion power of bitumen is frequently less than that provided by the silt and clay fraction which it is supplementing. However, when subjected to water the unstabilised soil block will rapidly loose almost all of its strength while the waterproofed block will largely retain its lower strength.

A binding agent such as cement will also reduce the effect of water saturation. Again any compaction of the soil during production will reduce the permeability of the soil and reduce the soil pore-void volume. The addition of a chemical binding agent does not stop the ingression of water much beyond that provided by the increase in density. Instead the binder provides a secondary method of bonding the soil particles together which is independent of the soil's water content. In the case of cementitious binders, the stabiliser forms hard insoluble fibres throughout the soil pore-voids. These fibres then effectively form a rigid skeleton which continues to hold the soil particles together even when wet. The addition of cementitious binders to an appropriate soil will improve both the wet and dry strength of the final cured block. The following paper is centred on binder-type stabilisation and in particular the production of stabilised soil-cement blocks where the stabilising agent is ordinary portland cement. Other binders, such as lime, have been used to make successfully stabilised blocks; however cement is the most commonly used stabiliser and as such has been the subject of this research.

Regardless of the type of stabiliser used, the production process for stabilised-soil blocks is similar. Firstly the local area is surveyed to establish the location of a suitable soil type.[1] Having found a suitable soil or modified a less than suitable one, the soil is dug, sieved to remove any large particles (greater than 6mm) and break up any large lumps. It is then laid out to dry. A suitable quantity of stabiliser is mixed with the dry soil and a uniform mixture is produced. A suitable quantity of water is then mixed with the soil such that the resulting mix is at the optimum moisture content (see section 3.1) for compaction. This mixture is transferred to the block mould for compaction. After compaction the "green" block is ejected from the mould and transferred to a curing area, which should be flat, level and protected from rain. The block is left to cure before incorporation in a wall. The curing regime differs according to the type of stabilisation being used. The

[1]. The process of soil selection and the discussion of soil suitability is covered in an earlier paper, DTU WORKING PAPER No. 38 "Soil Testing for Soil-Cement Block Preparation."

curing requirements for cement stabilised blocks will be covered in section 1.3.

1.2 SOIL STRUCTURE

The soil structure plays a very important role in the stabilisation process. In general use the high cost of soil will dictate the stabilisation of natural local soil. Natural soil exists in layers of differing composition. The top most layer of soil is generally organic and hence unsuitable for stabilisation. The subsequent lower layers will normally be inorganic and contain differing fractions of gravel, sand, silt and clay, and may or may not be suitable for direct stabilisation. If the first inorganic layer is predominantly clayey it will be poor for stabilisation. However, if the second layer is more sandy, a soil more suitable for stabilisation may be produced by blending the two.

Any soil may be described by a particle grading curve and its plasticity or Atterburg limits. The particle grading curve details the proportions of gravel, sand, silt and clay present in the soil while the plasticity limits give information on the properties of the fine (silt and clay-size) components. The different size fractions play different roles within the stabilised block.

Particles of sand size and larger act as the main inert body of the block. These sand and gravel fractions should be present in correct proportions to allow the most dense packing arrangement. The theoretical optimum distribution of particle sizes is that given by the Fuller curve (Fig 1.2a).

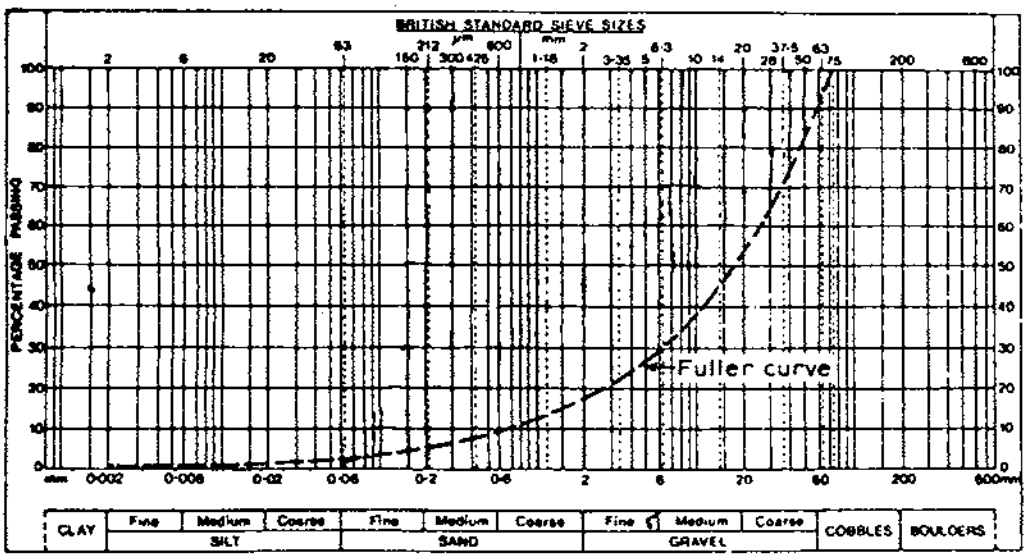

Figure 1.2a The Fuller Curve

The Fuller curve is based upon the assumption that all of the particles are spherical and that the largest particles just touch each other, while there are enough intermediate particles to fill the voids between the largest, but without holding them apart. The intermediate size particles are also similarly arranged with progressively finer particles filling the voids between larger ones. The Fuller distribution is an ideal model and never occurs naturally. However, a natural soil which has an even distribution of particle sizes, termed well-graded, is a good approximation and will ensure adequate packing.

The fine fraction of the soil may be considered as the active fraction. The coarse material is essentially inert, it does not change volume on wetting and does not play a significant role in particle bonding. The fine fraction is responsible for the dry cohesion of a soil. If this fraction is wetted it will expand. Clay consists of a large number of very small usually plate-like shaped particles. In a dry condition these particles pack closely together, held tightly in place by micro-droplets of water. On exposure to more water, capillary suction tends to draw water into the inter-particle fissures and separate the particles. This particle separation occurs simultaneously in three directions such that the clay expands.

The expansion of dry clay on wetting is the source of dimensional variations which can lead to cracking and spalling of a soil-cement block. For block durability, the extent to which the block expands and contracts on exposure to water should be minimised. A stabilised soil-cement block exhibits less dimensional variation than an equivalent unstabilised block. The force exerted by the expanding clay fraction must be resisted if the block is to remain intact over any significant length of time. In the case of soil-cement blocks this expansive force is largely resisted by the confining action of the insoluble cementitious matrix. Hence a large clay content soil will require a large quantity of cement to stabilise it. In order to minimise this expansion for a given water exposure level, and hence the amount of cement required, it is necessary to reduce the clay content of the block to a minimum.

However, the cohesive strength of damp clay is largely responsible for the green strength of the freshly formed block. Indeed a pure sand will exhibit negligible cohesion when dry and only slightly more when damp. It is most important to the economics of soil-cement block production that the fresh block can be ejected from the mould immediately after compaction rather than the cure-in-mould approach seen in conventional concrete work. To enable immediate ejection after compaction, the fresh block must have enough strength to allow at least careful handling without damage.

Hence it can be seen that the clay fraction is both a help and a hindrance to block production and a compromise must be reached. The extent of the compromise and the "optimum" clay content will be different for each particle grading and type of clay, montmorillonites for example exhibiting a much higher expansion on wetting than other types of clay. Moreover, the compaction pressure used to form the block also plays a role. At high compaction pressures the soil particles are forced into more intimate contact which increases the green strength of the block for a given clay content.

The sensitivity of the soil's Optimum Water Content (discussed in more detail below) also depends on the soil's structure. The enormous range in particle size from gravel (6mm) to clay (less than 0.002mm) results in a large difference in the specific surface area (SSA) of soils containing different proportions of different sized particles. When a soil is made up of predominantly fine material then the SSA of that soil is very large, when the soil contains larger fractions of more coarse material then the SSA is reduced. For a high SSA soil, a given change in water content will have a reduced effect on the compaction process as the area over which the water acts will be relatively large and result in only minor physical change. Conversely for a low SSA soil, the area over which the water acts is reduced and hence the physical effect on the soil is greater.

This effect is illustrated in figure 1.2b (Fig 1.2b). Dry density after compaction is plotted against moisture content at the time of compaction. Curve A shows the pattern for a well graded soil containing a range of particles from gravel to clay size, Curve B shows the pattern for a more narrowly graded soil containing particles from only fine sand to clay size. It can be easily seen that curve A has a more pronounced peak than curve B. It may also be noted that the density peak for curve B is shifted towards higher moisture contents and that the peak dry density is reduced. The increased optimum water content would be expected from the above discussion of SSA while the reduction in dry density would be expected from the discussion on particle grading.

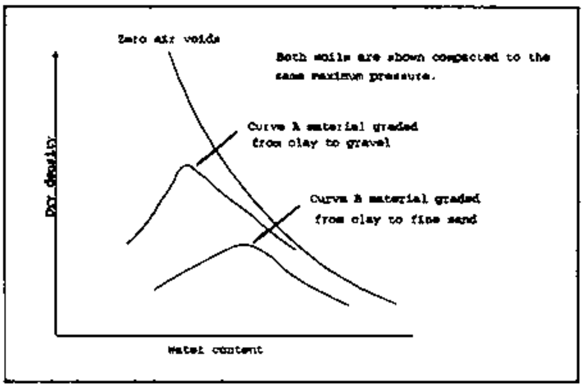

Figure 1.2b Dry density plotted against water content.

The factors affected by the structure of the soil may be summarised as follows:

GRADING The soil grading should be as close to the optimum Fuller curve as practical to enable the most dense packing of the soil particles. The more dense the packing of the soil particles then the lower the permeability of the soil and the higher its compressive strength. The larger the greatest size of particle the more care must be taken in controlling the moisture content.

PLASTICITY The soil should contain sufficient clay to allow adequate green strength on ejection from the mould. Too little clay and the breakage rate on ejection of the compacted block will be unacceptably high. Too much clay and the long term durability of the block will be adversely affected.

1.3 THE CURING PROCESS

The curing process described below refers to that required for blocks which have been stabilised with ordinary portland cement. The curing regime will be broadly similar for lime stabilised blocks but the length of time for curing should be doubled. For bitumen stabilised blocks, "curing" is the process of evaporation of the bitumen solvent and of the moisture content required for compaction. The bitumen curing process is primarily a drying operation while that for cement and lime is a period of time for the bulk of a chemical hydration reaction to occur.

In the case of bitumen stabilisation drying out of the block is desirable, provided that the drying is not sufficiently rapid to lead to warping of the block. For cement and lime stabilisation, drying out of the block will stop the cementitious hydration reaction and hence not allow the blocks to gain their full strength.

After ejection from the compaction mould the block should be carefully transported. The green blocks are weak until the chemical hydration reaction has occurred and any significant breakage rate will have an adverse effect on the economics of the project. The safest way to transport green blocks is to place them on individual boards and subsequently carrying the board to the curing site. The blocks may be placed onto and removed from the board by placing the palms of the hands flat against the largest sides of the block and squeezing the hands together just enough to grip the block to lift it.

The blocks should be taken to a flat level area which should be protected from direct sunlight and rain. Direct sunlight would cause the blocks to dry out too quickly, while rain would easily erode the fresh blocks at least until the cement has had time to hydrate. During the first four days the block should be kept damp to allow the chemical cement hydration reaction to occur. It is this hydration reaction which gives the soil-cement block its superior wet strength.

The exact mechanism by which a small content of cement may stabilise a large mass of soil is not fully understood. Ordinary Portland Cement is made up of 45% tricalcium silicate (C_3S)[2] and 27% dicalcium silicate (C_2S). In the presence of damp soil these

---

[2]. C and S represent Calcium and Silicon respectively, not carbon and sulphur. This is in keeping with most of the published concrete literature and is acceptable, allowing these simple equations to be given as illustrations instead of the more complicated fully balanced chemical equations.

components hydrate to form mono and di-calcium silicate hydrate gels (CSH and C_2SH, see equation below). These gels then slowly crystallise into an insoluble interlocking matrix throughout the soil voids binding the soil particles together. As the matrix is insoluble it gives a strength mechanism which works to restrain the softening and swelling of the unaffected soil, thereby dramatically reducing the weakening effect of water. The interlocking calcium silicate fibres may be seen when a cured soil cement sample is examined under an electron microscope. The hydration of the calcium silicate also results in the release of free lime (CH) according to the reaction:

$$C_3S + 2H = C_2SH + CH$$
$$C_2S + 2H = CSH + CH$$

The free lime then reacts further with the clay fraction (pozzolanic reaction) by the removal of silica from the clay minerals and subsequently forms more calcium silicate gel which also gradually crystallises.

2. BLOCK COMPACTION PROCESSES, THE ALTERNATIVES.

This paper examines the effects of various process and material factors on the production of soil-cement blocks by quasi-static pressure application. This work has been conducted as a self-contained piece of research but will be used as a reference datum for the future examination of alternative compaction mechanisms, the alternatives being dynamic force application by impact and vibration.

QUASI-STATIC COMPRESSION: Quasi-static or slowly applied compaction is the process used by the majority of soil-block making machines. The loose soil is compressed by slowly applying a large force. The magnitude of the pressure which is applied varies from machine to machine but is generally within the range of 1-8 MPa. The Cinva Ram is a well known low-pressure machine which uses force applied manually through a lever mechanism to produce a compaction pressure of about 2 MPa. The Brepack is an example of a high-pressure machine which applies between 8 and 10 MPa compaction. The Brepack uses a lever mechanism for the initial compaction and finishes with a manually operated hydraulic ram.

If a standard block's dimensions are assumed to be 290x140x100 mm then compaction pressures of 2 and 10 MPa equate to static loads of 8.3 and 41.4 metric tonnes. This is an appreciable loading for the structure of any machine to withstand.

DYNAMIC COMPACTION: Dynamic compaction is compaction by a mass which has a non-trivial velocity on impact, much like a hammer blow driving a nail into a piece of wood. Dynamic compaction requires far less massive machinery to generate large forces than quasi-static compaction does (to *push* a nail into a piece of wood requires a much greater static mass than that of the hammer). Dynamic compaction may also require less effort from the manual-machine operator.

A preliminary investigation into the efficiency of road compacting machines by the Transport and Road Research Laboratory (Williams and Maclean, 1950, Ref No.21) showed that slowly applied static loading may not be the most effective method of compaction for soil. It appears that dynamic compaction is more effective in terms of the depth of soil compacted.

Single impact and vibration are an extension of the same theme. Vibration may be thought of as a repeated light blow which, although requiring more complicated machinery to implement, does not involve the dropping of large and potentially dangerous weights.

3. MATERIAL FACTORS AFFECTING THE COMPACTION OF STABILISED-SOIL BLOCKS

3.1 MOISTURE CONTENT

Any soil placed in the mould for compaction should contain a known quantity of water. Earlier literature on the subject has suggested that there exists an optimum water content (OMC) at which the maximum density of the soil may be reached for a given compaction pressure. This is correct. By definition the resulting cured dry density will be highest for a block which has been compacted at its OMC. It should be forcefully noted that the OMC is not a parameter solely dependant on the soil, it varies considerably with the compaction pressure used to form the block. In general, as the compaction pressure increases so the OMC decreases. The content may be conveniently thought of as a lubricant which has adverse effects in excessive quantities. At higher compaction pressure the applied force is greater, the soil particles will move more readily and hence less lubricant (water) will be required.

The sensitivity of any particular soil to moisture depends on the soil's particular composition and has been discussed above with reference to specific surface area. Well-graded soils including a substantial fraction of large-size particles will be more sensitive to moisture content variation than soils with smaller fractions of large size material. The degree of sensitivity to change in moisture content is an important parameter to consider when producing blocks. If the soil material being used does contain a significant quantity of large size material then the control of the moisture content is more critical.

At the outset of this work a number of tests were conducted to establish the optimum moisture content for the soil used in the subsequent work (artificial *soil-A*). To this end a number of small cylinders were produced at varying water contents and at both 2 and 10 MPa. The soil used for the testing was well graded and the largest size fraction was coarse sand. This type of soil was found to have a low sensitivity to water (it contained a negligible proportion of gravel-size material), resulting in a flat moisture/density curve. However as a result of the low aspect ratio of the cylindrical mould used, the soil-strength required for successful demoulding was quite high. This emphasised the importance of green strength from an early stage in the experimental proceedings. The OMC at 10 MPa was found to be 8% and the cylinders became too weak to allow demoulding without the most careful and elaborate system at 10%! At lower moisture contents the green samples became progressively stronger. This follows readily from the strength mechanism described above for unstabilised soil.

Although the ultimate compressive strength of the block is important, so too is the green strength of the block. By lowering the moisture content at compaction, the green block produced will be stronger although the final cured strength will be lower. The extent to which the reduction in moisture content will reduce the final strength of the block depends on the nature of the soil. In general a more sensitive soil will show a larger drop in final strength as a result of the larger drop in compacted density. It is usually the case that compaction above[3] the optimum water content will result in a weak green compact. If this green compact is not sufficiently strong to allow handling on ejection then it is likely that the breakage rate both on ejection and subsequent transportation will be high.

Low green strength is one of the major problems for many block production systems. Indeed Dr. Lawson (1992, Ref No.22) found breakage rates to be as high as 50% for blocks produced on a Cinva Ram type machine in Nigeria. If an excessive green breakage rate is found then the water content should be reduced to increase the green strength. It should be remembered that any block which has been broken on ejection or during handling operations is lost. It may not be broken up and recompacted, as the cement hydration reaction will have progressed to such an extent that the amount of remaining unreacted cement would be too low for adequate stabilisation.

[3] With low clay content soils even compaction at the OMC may produce blocks with inadequate green strength.

The moisture content at the time of compaction also has an effect on the durability in terms of the blocks' permeability. It has been reported by CRAterre that compaction at moisture contents less than the optimum will result in a more permeable structure than compaction above optimum. A verification of this work will be carried out at The University of Warwick shortly. CRAterre use the concept of flocculated and dispersed microstructure to explain this phenomenon (Doat et al, 1979, Ref No.8). At low water contents the plate-shaped clay particles mutually attract each other. The outer edge of one plate electrostatically attracts the centre section of the neighbouring plates, leading to a flocculated clay structure (fig 3.1a). At high water contents, the surface charge of the clay plates is largely neutralised by the surrounding water dipoles and creates a pattern of mutually repelling particles or a dispersed structure (fig 3.1b). However at present the magnitude of this permeability change is not clear. In wet climates where water penetration is likely to be of importance then compaction slightly wet of the OMC may be appropriate to increase the blocks' resistance to water.

In summary, compaction at the OMC will produce the most dense blocks (by definition). Compaction wet of the OMC will produce blocks with a lower green strength on demoulding but possibly a lower permeability when cured. Compaction dry of the OMC will produce blocks with a higher green strength on demould and possibly a higher permeability.

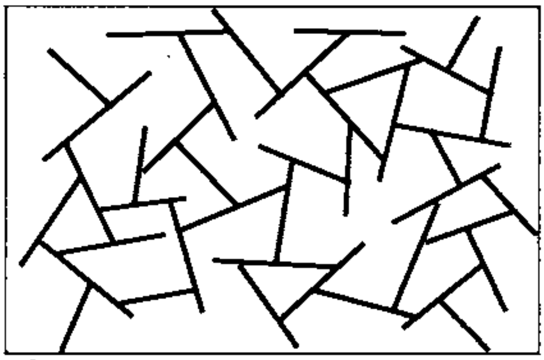

Figure 3.1a Flocculated

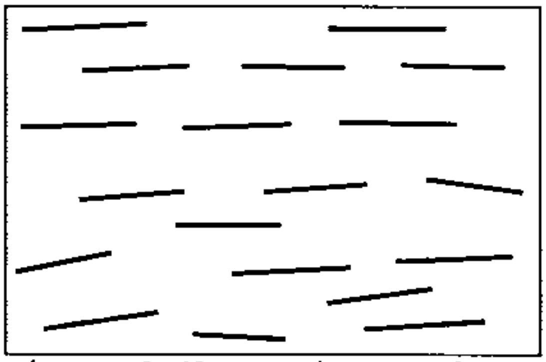

Figure 3.1b Dispersed

Compaction at the OMC is the best compromise. In dry climates and where low green strength has been seen to be a problem, the moisture content may be reduced. In wet climates were low green strength has not appeared as a problem then compaction at slightly increased moisture content may be considered. It should be remembered that the final cured strength of the block may be increased and the permeability reduced by increasing the cement content (although this may be costly) whereas the green strength may only be increased by improving the structure of the soil, compacting to higher pressure or reducing the compaction moisture content.

3.2 COMPACTION DELAY

The strength of the final cured block depends heavily on the adequate hydration of the cement. Cement is the most expensive ingredient in the production of stabilised soil blocks. Ordinary Portland Cement starts to react immediately on coming into contact with water. The reaction progresses quickly to begin with and progressively slows down over several weeks.

The hydration of the cement produces the insoluble calcium silicate hydrate skeleton which extends throughout the soil voids. This skeleton provides the restraining mechanism which gives soil cement its superior wet strength. The precipitation of these fibres begins as soon as the cement comes into contact with water. The fibres' effect is significantly reduced if they are deposited as discrete entities rather than as a continuous skeleton. Most of the fibres which form prior to the compaction of the soil cement mix will be broken during the pressing process and are then not as effective. The most effective precipitation occurs after the compaction process when the soil particles will remain undisturbed. As a result, the final strength of the stabilised block depends to a degree on the length of time for which the cement is exposed to water prior to compaction. Ingles and Metcalf (Ingles & Metcalf, 1972, Ref No.10) have reproduced a graph from G.West which indicates that over 50% of the final strength of cement stabilised soil may be lost by a delay of 2 hours (Fig 3.2a). Even after half an hour West indicates that between 30 and 40% of the strength is lost. A set of trials conducted at The University of Warwick on cylindrical test compacts has failed to convincingly reproduce such dramatic results. This may be because the short curing period used (seven days) was insufficient, not allowing the samples to cure for long enough to develop sufficient strength for adequate testing in the compression-test equipment available. However, a general trend was observed confirming some loss in (seven day) strength with increased delay between water addition and compaction. A 2 hour delay in compaction produced a strength loss of about 20%.

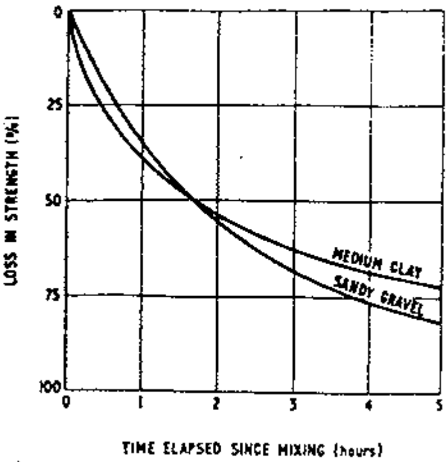

Figure 3.2a Cured strength loss due to compaction delay

4. MODELS TO DESCRIBE THE INTERNAL COMPACTION MECHANISM FOR COMPRESSED BLOCKS PRODUCED BY QUASI-STATIC COMPRESSION.

A number of simple models were initially postulated to describe the internal compaction mechanism; a simple hydrostatic fluid model, a pipe flow model, a solid model (based on Poisson's Ratio) and an elasto-plastic band compaction model.

4.1 Simple Hydrostatic Fluid Model.

The simplest model which might be used to describe the compaction process is the hydrostatic fluid model. This model assumes that the soil behaves like a contained fluid, namely that the pressure within the soil is the same in all lateral directions and increases in a downward vertical direction only as a result of the overburden pressure (weight of soil above the layer in question). This overburden pressure is insignificant compared to the external pressures applied to a block during moulding.

This model predicts that if a compaction pressure of 10MPa is applied to the top surface of the mould, both the mould walls and the base of the mould should also experience a transmitted pressure of 10 MPa. It further predicts that there will be no shear force between the soil and the mould walls.

4.2 Pipe Flow Model.

This model assumes that the soil is behaving like a viscous fluid flowing through a pipe. A viscous fluid may support a shear force while it is flowing. The more viscous the fluid, the longer it will take to flow and the larger the shear force it can maintain. This model predicts that if a pressure of 10 MPa is applied to the top surface of the mould the soil will "flow" downwards towards the bottom of the mould away from the source of high pressure. As some of the applied force is resisted by the mould wall shear force, the force on the bottom of the mould is reduced. As the distance from the compacting piston increases so the area for shear with the mould wall increases. As a result, progressively more force is transferred to the mould walls as a shear force or friction. This effectively reduces the driving force or pressure. The reduced driving pressure then results in a lower lateral pressure than that predicted by the simple hydrostatic model.

The above model is based on fluid pipe flow; flow through an open ended pipe. In the case of soil compaction one end of the mould is fixed and soil is forced towards it by the movement of the opposite end. According to fluid theory, when the velocity of flow reduces to zero, hydrostatic conditions should again prevail as a stationary fluid cannot support a shear force. As the flow of soil may be expected to stop when the compacting piston ceases to move this zero soil flow should result in equalised hydrostatic conditions, the mould wall pressure should equalise to the simple hydrostatic state mentioned above. If the mould wall pressure does not equalise then either the soil has become so viscous that its rate of flow is too slow to show this equalisation in the time available (typically 30 sec for block production) or that the soil may not be described as a fluid by the end of compaction. If the mould wall pressure does not equalise then the soil must be resisting internal shear forces, behaving as a solid.

4.3 Solid Model (Poisson's Ratio)

By applying a pressure to the top surface of a solid object, vertical strain is induced in the medium this results in a lateral stress which in turn causes lateral strain. The ratio of vertical compressive strain to lateral tensile strain is defined as the Poisson's Ratio of the medium and is constant within the elastic deformation regime. Typically, for most metals, Poisson's Ratio is around 0.3 (for a fluid it would be 0.5).

Poisson's Ratio is normally used to describe the deformation of unconfined solids when subjected to compressive or tensile stress. A simple unconfined example would be the compression of a steel cube. In such a simple case the Poisson's Ratio is relatively simple to define, the three axial strains being simple to measure and uncomplicated by constraint interference. In the case of soil block compaction this is not the case. Lateral strain is less than it would be when unconfined, as the movement is restrained by the mould walls. The applied stress results in a vertical strain, this producing a lateral stress resulting in a lateral strain. This lateral strain acts on the mould walls, as a result the mould walls deflect. The resistance of the mould walls to the soil deflection decreases the amount of lateral soil strain which can take place.

The mould walls restraining influence further complicates the model as the wall is not completely rigid. The wall elastically deflects as a result of the stress within the soil. The amount of deflection depends both on the stiffness of the wall and the soil stress acting on it. As the wall deflects it provides more resistance to movement as its effective rigidity increases, also as the soil expands so the soil stress is reduced. There should then exist a balanced condition where the restraining force exerted by the wall is equal to the residual soil stress. What effect this residual soil stress will have is unclear. The walls' restraining force may be considered as producing a lateral compressive force which in turn would produce a vertical stress opposing the initial compaction force.

The compaction may be described by this solid model provided that the soil's Poisson Ratio is assumed to change as the compaction cycle progresses. During the initial compaction stage (say up to 10% of the final compaction pressure) a large block height reduction takes place, typically 80-90% of the total height reduction, with almost no measurable lateral strain. This indicates largely plastic flow; on the removal of the compacting force only limited recovery takes place (typically 1-3 mm, 1/80th of the total deflection). As the block height reduces further the amount of relaxation expansion increases.

4.4 Elasto-plastic Band Compaction Model.

This model assumes that the compaction proceeds over a set of surfaces arranged roughly parallel with the moving compaction piston. As the compaction force is applied, so the top layer of soil plastically and, to a lesser extent, elastically compresses. As the soil plastically compresses it becomes stiffer and passes more of the applied force on to lower layers which are thus compressing at a slower rate. On decompression the plastic deformation is not recovered but the elastic compression reverses resulting in a degree of material expansion.

5. MOULDING FACTORS AFFECTING THE COMPACTION OF SOIL-CEMENT BLOCKS

Blocks are commonly moulded in a single cycle by moving a piston down into a parallel sided mould containing soil. The mould walls start with some roughness due to machining during manufacture, and this may increase due to soil abrasion during use. This process has been taken as a datum ("standard compaction"). Research was undertaken to better understand the standard compaction process and to investigate a number of variants to it. The pressure transmitted through the soil to the bottom of the mould was taken as a key variable that should correlate strongly with block density and subsequent cured block strength.

The following section examines the effect of the following moulding parameters:

Double Sided Compaction (instead of single sided)
Mould Wall Friction (high verses low)
Mould Wall Taper (instead of parallel-sided mould)
Pressure Cycling (instead of simple compression)

The effects of the changes in moulding parameters were observed by measuring the pressure transmitted to the mould wall through the compacting soil. The transmitted pressure was recorded by placing an LVDT-based pressure transducer (designed in-house) in seven separate locations in the mould wall and mould piston. The compacting pressure was applied in discrete increments up 2MPa or 10MPa. At each increase in load the block height, mould wall deflection and transmitted pressure were recorded. Details of the experimental method and the experimental instrumentation are included in appendices C and D.

The initial testing was conducted on blocks made without the use of cement such that the material could be reused and the testing procedure would be less time dependant. Moreover, without the addition of cement the soil mix has a higher internal friction[4] and therefore amplifies the effect of the changes in pressing parameters. It has been assumed that although the magnitude of the variation in the observed parameters will be different for cement mixes, the pattern of change will be similar. Any variation apparent in a non-cement mix is likely to be present in a mix containing cement, but to a lesser degree. Following the initial set of tests two further set of blocks were produced with the addition of cement, one set by the datum process and one by double-sided compaction. These soil-cement blocks were allowed to cure for seven days and then tested for wet compressive strength to asses the actual improvement in strength resulting from double-sided compaction.

All of the blocks produced were made from an artificial soil (*Soil-A*). This soil has been carefully tested both to BS1377 and by the methods given in the Development Technology Unit Working Paper (DTU) No.38 "Soil Testing for Soil-Cement Block Preparation". The soil is composed of Kaolin grade E powder and a poor quality building sand (high fines content). It has a low plasticity index and is well graded with particles from clay to coarse sand size. This soil has been used to allow repeatable experimentation for the duration of this work and if required the soil may be reconstructed at a later date. By using an artificial soil the large variation in properties of natural soil can be minimised. The details of this soil are included in appendix B.

5.1 SINGLE-SIDED COMPACTION - THE DATUM PROCESS

The first case which was examined was that for single-sided compaction. This is used as the datum against which to compare the other cases and as such it is examined in detail. Figure 5.1a shows the pressure variation as recorded by the LVDT transducers[5]. The pressure applied to the top face of the block, via the piston, was increased in small equal steps so as to achieve a uniform increase over time. It was then reduced at the same rate back to zero. After each step pressure and displacement readings were made, the applied pressure being held constant for long enough for these readings to stabilise (quasi-

---

4 The fine cement particles appear to act like a dry lubricant during compaction. Without cement the soil mix displays higher internal friction.

5 The detailed description of the performance, calibration and location of the LVDT transducers is given in appendix D

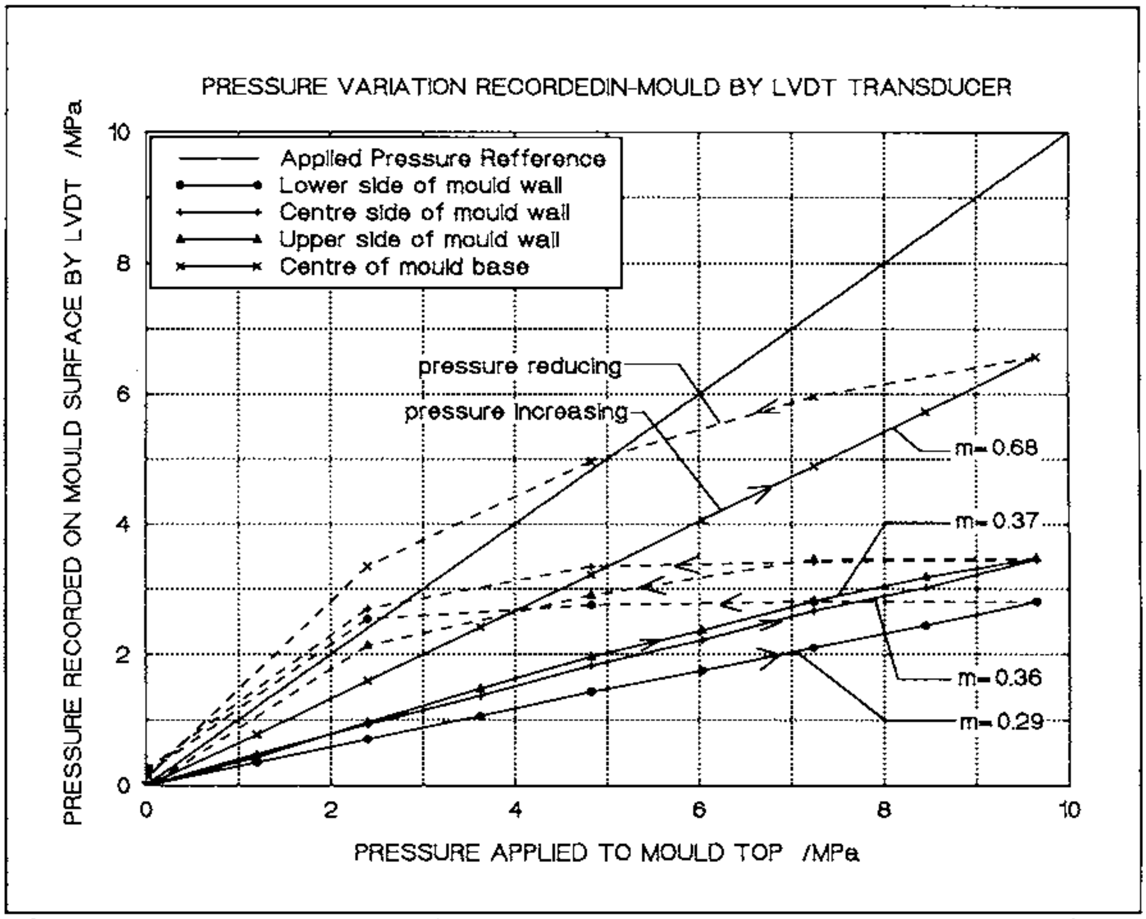

Figure 5.1a Compaction pressure plotted against transmitted pressure

static process). Pressure recorded on the block wall is plotted against pressure on the mould top (applied pressure calculated from the applied force and the known area of the mould surface). Only one transducer was initially used and hence the traces in figure 5.1a are actually the amalgamation of six separate block pressings, each trace being the average of two presses.

The maximum pressure readings agreed surprisingly well between pairs of blocks, averaging an agreement within ± 0.25 MPa (± 4% for base pressure). The applied pressure plot has been included in the figures for ease of comparison and plots as a straight line with a maximum of 9.66MPa (40 tonnes applied to the largest block face). In general the internal pressure throughout the mould increases linearly with the applied pressure but with differing rates of gain around the block (Table 5.1).

The transducer on the mould base recorded the highest pressure gain of 68%, rising to a maximum of 6.7 MPa compared to the applied 9.7 MPa, a loss of 3 MPa.

The transducers located at the upper and central regions of the mould-side wall both gave recorded maximum pressures of 3.5MPa (3.5 for the upper region and 3.48MPa for the central region i.e gain = 37% and 36% respectively). The pressure distribution along the length of the block at mid-height was also recorded. The pressure recorded at one third the length along the mould side wall was also 3.5 MPa (gain = 37%), while the pressure recorded at the end of the mould wall was 3.9 MPa (gain = 40%), slightly higher than at the centre.

The lower centre side wall transducer recorded a maximum pressure of 2.8MPa.

Table 5.1 Average Transmitted Pressure Recorded by LVDTs

Location of LVDT	Average Max Pressure /MPa	95% Confidence bounds	Pressure Gain %
Base	6.67	6.40..6.94	68
Upper Side	3.50	N/A	37
Centre Side	3.48	3.14..3.83	36
Lower Side	2.80	2.75..2.86	29

If the increase in pressure in the upper region of the mould wall (Fig 5.1a) is examined, it can be seen that this rise decreases slightly with increasing applied pressure and may be tending towards a maximum. This trend is not apparent for the remaining traces.

This pattern does not fit any obvious simple model and the only firm conclusion which may be drawn is that the soil condition is far from a simple hydrostatic fluid model.

The pattern of quasi-static pressure reduction was also recorded. The mould base pressure begins to drop off as soon as the applied pressure is reduced and continues to reduce at an increasing rate. At approximately 5MPa the base pressure is the same as the applied pressure. Below 5MPa the base pressure continues to decrease but remains higher than the reducing applied pressure.

The mould wall pressures also fall back as log curves. There is a lag period between when the applied pressure is reduced and when the mould wall pressures begin to drop significantly. This lag is least for the upper regions of the mould and increases for the central and lower regions respectively.

The material inside the mould under full (9.7MPa) compression will have undergone both plastic and elastic deformation. Large plastic deformation is evident from the significant volume reduction, typically 1.5:1. Elastic deformation is also apparent, although less pronounced, by the increase in block height as the applied load is removed (see Fig 5.1b, block height during compaction).

The pattern of mould pressure fall may indicate a pattern of vertical and horizontal stress reduction. As the applied pressure is reduced so those regions of the block nearest to the moving piston begin to decompress. In the upper regions of the block this decompression takes place initially in the vertical direction, the direction of movement. The resulting elastic expansion of the material is largely vertical as the mould maintains a lateral constraint. The vertical expansion reduces the lateral stress which is being applied to the mould-side walls, according to a poisson-type relation. As the upper lateral stress reduces so does the frictional shear stress with the mould wall. The reduction in mould wall shear stress effectively reduces the vertical constraining force, allowing the lower regions of the block to decompress. As the applied pressure is reduced further so the region of elastic expansion moves downward.

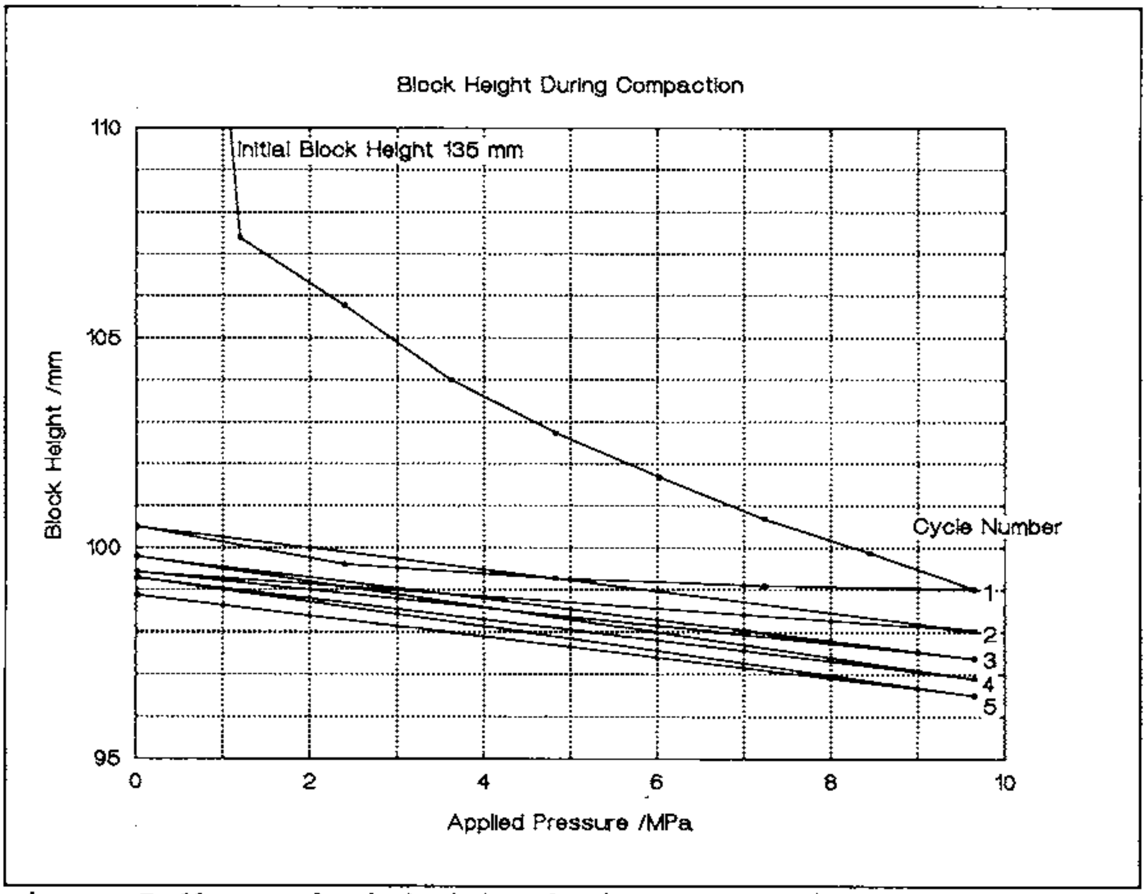

Figure 5.1b Block height during compaction.

The upper region of the block, being the nearest to the moving piston during compaction, would be expected to be in the most stressed/compacted state (closest to a hydrostatic condition). Therefore it could be assumed that this region would exhibit the largest elastic recovery and consequently the most rapid rate of reduction in side wall pressure. The central region of the block would be in a similar condition but could not begin to significantly decompress until the upper layer's vertical restraining influence had diminished sufficiently. This would then result in an effective lag in lateral decompression which would increase with distance from the moving piston i.e. towards the lower regions. Fig 5.1a (above) illustrates this progressive decompression. If the lateral and base pressures are examined at an applied pressure of 2.4MPa, it can be seen that the base pressure is the largest, greater than that applied but reducing the most rapidly. The upper region transducer shows that the lateral pressure in this band is the lowest and reducing quickly but not as fast as the base pressure. The central region has just begun to decompress significantly but remains higher than either the lower or upper regions and the lowest region is yet to begin dropping significantly.

In summary, as the applied pressure is raised to a maximum of 9.7MPa, the base pressure as recorded by the LVDT rises to 68% of this value and the mould side pressures to only 37%, 36% and 29% (upper, central and lower regions of the block respectively). On compression the bottom and side pressures rise linearly with applied (top) pressure. On decompression however, they fall back more slowly than the applied pressure, showing a strong hysteresis pattern.

5.2 DOUBLE-SIDED COMPACTION

There are various ways of applying "double-sided" pressure. The one used here was to fix the base plate, move the top plate (piston) and to let the sidewalls of the mould "float". An exact equality of top and bottom pressures was not achieved, as it might have been with mechanically linked top and bottom pistons. Perfect double-sided compression might have raised the sidewall pressure a little higher, probably to about 50% of the applied piston pressure.

The plot of applied pressure against recorded pressure is shown as Fig 5.2. The arrangement of the double sided compaction rig was such that only the central side wall and base pressures were recorded. Both of the recorded pressures were seen to be significantly higher than for single sided, 7.9MPa and 4.4.Mpa for the base and centre-side respectively. This represents a 12% increase in mould base pressure and a 9% increase in mould sidewall pressure (to 81% and 45% respectively).

This would appear to clearly indicate that double sided compaction was more effective in compressing the block. However, although significant in terms of pressure transmission for a high internal friction mix (no cement) when 5% cement was added to the mix, the pressure difference between single sided and double sided reduced to 10% and 5% for base and centre respectively.

Furthermore, when these blocks were tested for wet compressive strength after seven days of damp curing, the single

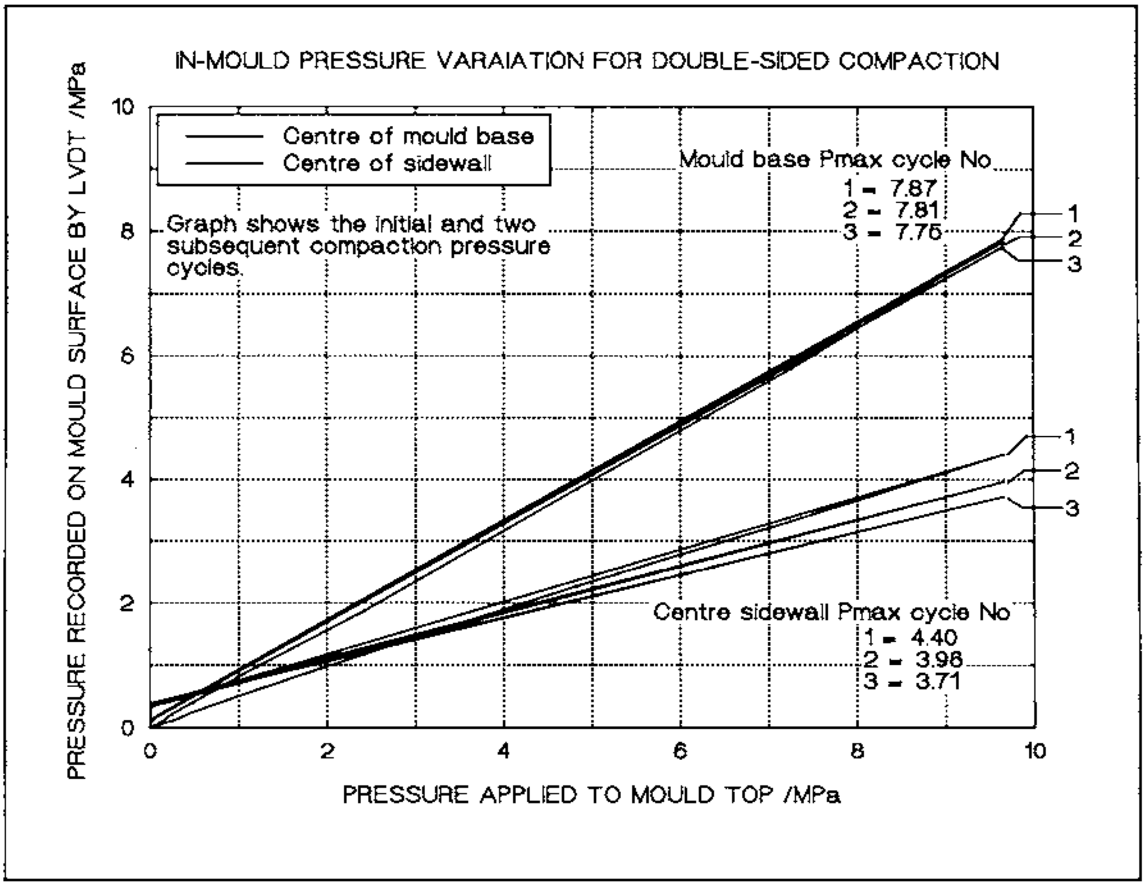

Figure 5.2a Pressure transmission for double-sided compaction

sided ones gave an average of 2.84 MPa (std 0.076) while the double sided ones gave an average of 3.03 MPa (std 0.087). This represents only a 7% increase in wet compressive strength, although this difference is likely to increase marginally with additional curing time.

Having initially stated that by using a soil mix without cement the internal friction would be higher, the difference between the above cases with and without cement should be expected. The apparently large increase in transmitted pressure for the no-cement blocks translates into only a small increase for the cement blocks.

If it is assumed that density is proportional to strength as has been suggested by other authors (Ingles & Metcalf, 1972, Ref No.10 & Webb, 1991, Ref No.20) then it might be expected that double sided compaction would produce a more uniform internal density distribution. If the compacted sintered bearing is taken as an example; single sided compaction produces a compact which is demonstrably more dense in the region nearest to the compacting piston. When compaction is double-sided the compact density is improved throughout but with a reduced improvement in the central region. If this is related to stabilised block strength then this would suggest that double-sided compaction should produce blocks which have more uniform internal density distribution and hence a more uniform strength distribution through their height.

Double sided compaction is more effective than single sided compaction which is clearly shown by the increase in both base and mould wall pressures. However, this increase only results in a 7% increase in seven day wet strength. As such the additional mechanical complexity and associated cost required to produce a commercial double sided block press would appear unwarranted.

5.3 REDUCTION IN MOULD WALL FRICTION

The effect of reducing mould wall friction was examined by lining the mould with a twin thickness of plastic sheeting, separated by a lubricating oil film. Figure 5.3 shows the plot of applied pressure against the recorded pressures. Lining the mould with plastic was used as an experimental technique to assess the effect of mould wall friction and would not be recommended for field use. During compaction the inner layer of plastic was dragged down with the compacting soil and forced to ruck into the body of the block thus producing flawed blocks. However, this should not invalidate the pressure transmission data gathered.

Both the base pressure and all of the recorded mould wall pressure were seen to rise significantly compared with the much rougher datum model. The base pressure rose to 7.6MPa whilst the upper and lower mould wall regions rose to 4.1 and 3.6 MPa respectively. This represents a 13% increase in base pressure and a 17% and 29% increase in upper and lower pressures. Again it would be expected that this would translate into a reduced effect in the final wet strength of the blocks but it does show that mould wall friction plays an important role in determining the effectiveness of the applied pressure in block compaction. It would be recommended that the mould should be as smooth as possible and that any machining marks etc should be orientated in the direction of the soil material movement during compaction i.e. perpendicular to the compaction piston.

5.4 MOULD WALL TAPER

Mould wall taper was investigated by angling the mould side walls to 1° and 5° from the vertical. This was done by separating the mould walls and bolting them in place with tapering sets of shim steel to produce the desired angles. The mould was arranged such that compaction was from the larger side of the taper. Figure 5.4 shows the plot of applied pressure against recorded pressure. The base pressure was seen to rise slightly to 6.9MPa but this was believed to be a function of the experimental method. The same dry mass of soil was used to produce each block throughout the set of tests and as a result

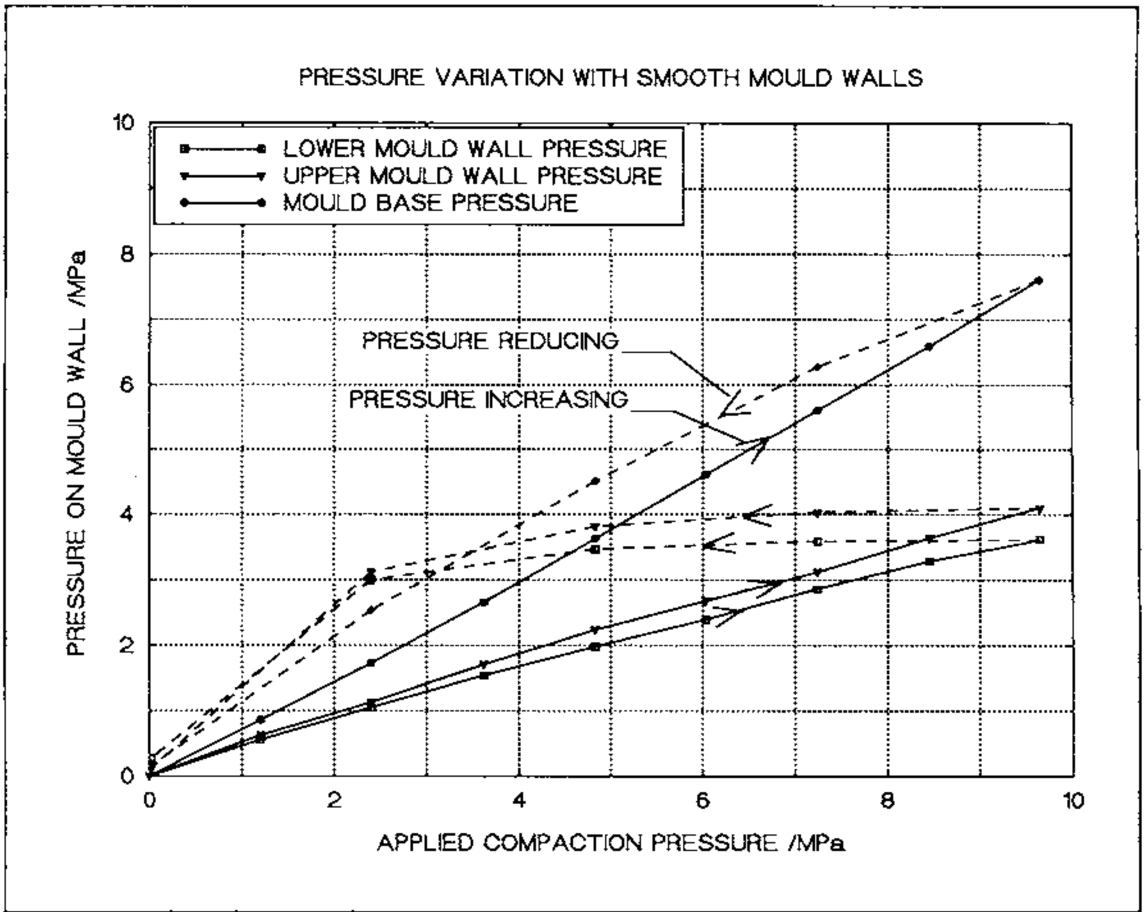

Figure 5.3 Pressure transmission with smooth mould walls

of the manner in which the mould was tapered, the final block height was reduced. Therefore some increase in base pressure would be expected as the height through which the applied pressure was acting was reduced. The mould side wall pressures were also recorded. The upper region pressure was significantly lower than that for the standard mould configuration but this was again a result of the manner in which the mould was tapered, the reduced block height and increased separation between the compacting piston and the mould wall effectively placed the upper transducer above the top of the block. The central and lower region pressure were slightly increased at 4.2 and 2.9MPa but not above what might be expected as a result of the increase in projected area seen by the compacting material. The 5° taper mould produced similar results; the base pressure increased to 7.5MPa while the central pressure increased to 4.4MPa.

In conclusion, mould taper does not have any apparent beneficial effect on pressure transmission. The block ejection cycle however required much lower forces which had to be sustained for a much shorter period of time. Taper may be used to ease ejection but the somewhat awkward shape of the blocks does not seem to justify the improved ease of ejection. Taper would not be recommended for incorporation into block production machines.

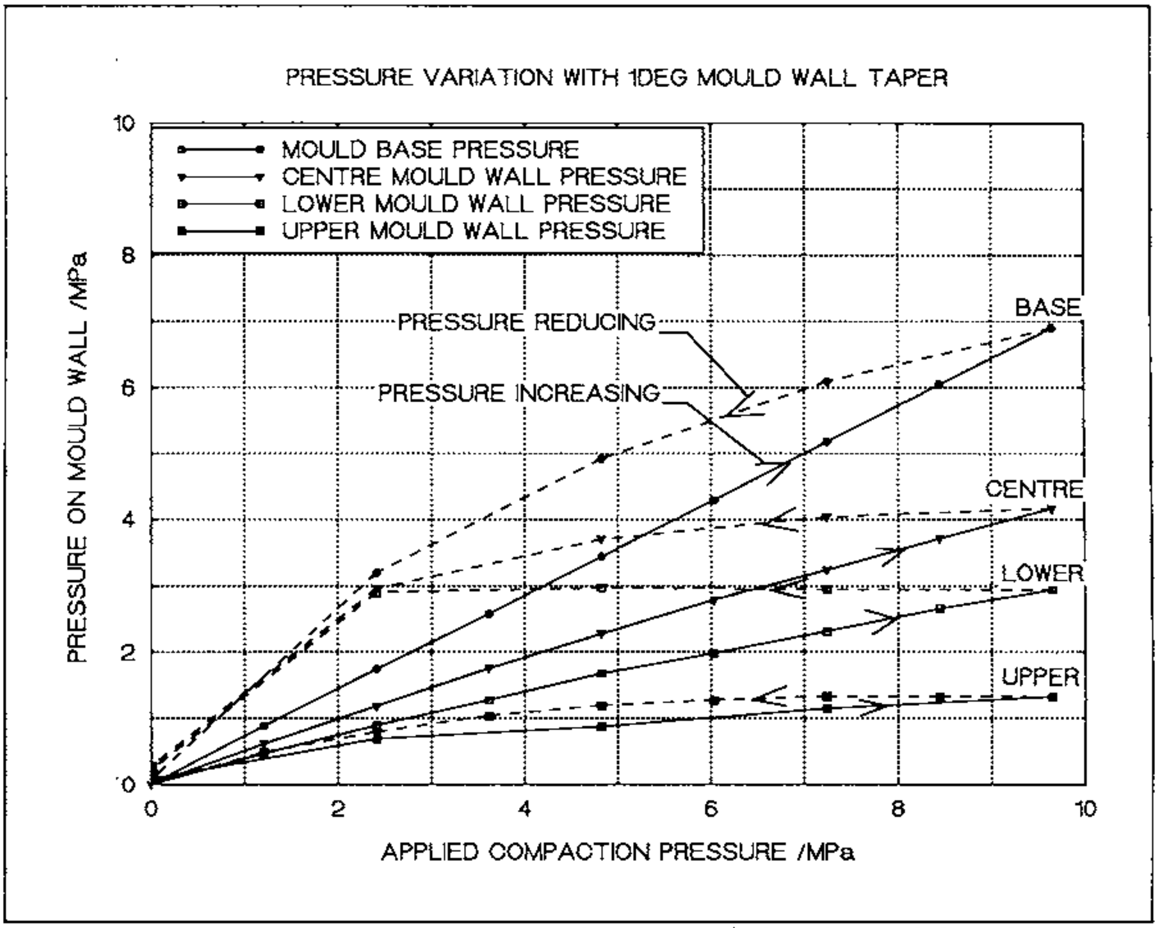

Figure 5.4 Pressure transmission with 1° mould wall taper

5.5 PRESSURE CYCLING

Here the term pressure cycling is used to imply the decompression of a fully compacted block to various levels of pressure and the subsequent recompression back to the original fully compacted applied pressure.

The manner in which a soil block would respond to applied pressure cycling was unclear. Three possible effects were expected prior to experimentation. The cycling would have no effect on the transmitted pressure, the transducers recording the same value of pressure as that recorded for the initial cycle. The cycling would progressively increase the transmitted pressure to a limiting maximum, independent of the magnitude of the cycle. The cycling would increase the transmitted pressure to a limiting maximum value depending on the magnitude of the cycle.

Table 5.5a Pressure transmission on full-pressure cycling

Cycle No	Maximum applied pressure /MPa	Maximum mould base pressure /MPa	Maximum upper mould wall pressure /MPa	Maximum centre mould wall pressure /MPa	Maximum lower mould wall pressure /MPa
1	9.65	6.72	3.48	3.55	2.84
2	9.65	6.85	2.55	3.38	2.26
3	9.65	6.93	2.14	3.20	2.04
4	9.65	6.92	1.87	3.18	1.89
5	9.65	6.92	1.69	3.13	1.81

Table 5.5a shows the pattern of pressure change in the mould side wall for cycling from 9.7 to 0.1 MPa for standard single sided compaction. It can be seen that the base pressure remains almost constant, in general rising slightly with successive cycles but not significantly (the LVDT hysteresis will account for an increase of 0.1MPa per cycle when cycling from 0 to 7 MPa). The mould side wall pressure appears to drop significantly with each cycle, dropping less with successive cycles.

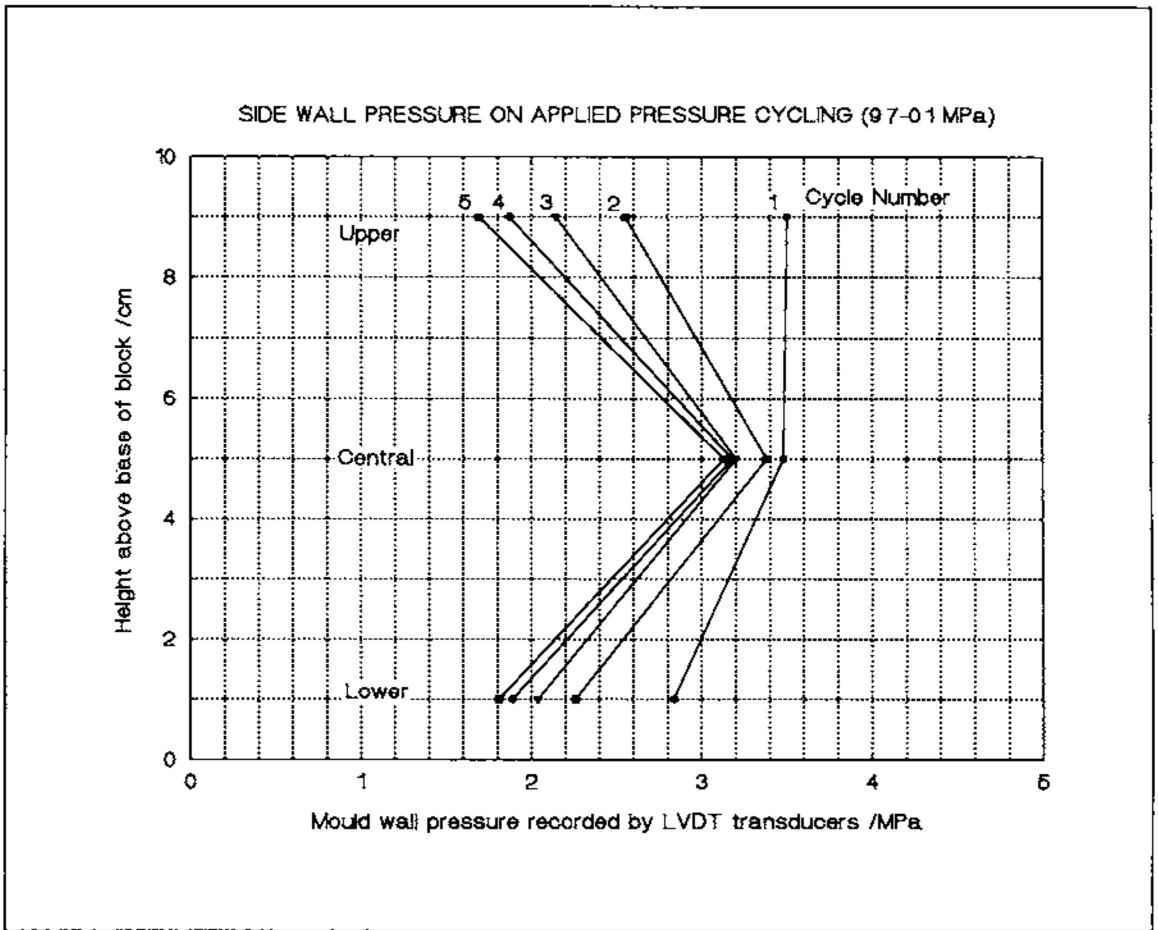

Figure 5.5a Recorded pressure on mould walls (upper, central and lower regions) with successive pressure cycles

Figure 5.5a shows the pattern of pressure reduction with successive cycles plotted with height of the transducer from the base of the block. This appears to indicate that the cycling action reduces the upper and lower side wall pressure at a greater rate than that for the central region. It might be argued that the reduction in upper side wall pressure is a result of the reduction in block height (see below). However, the reduction in the central and lower regions could not be accounted for on this basis.

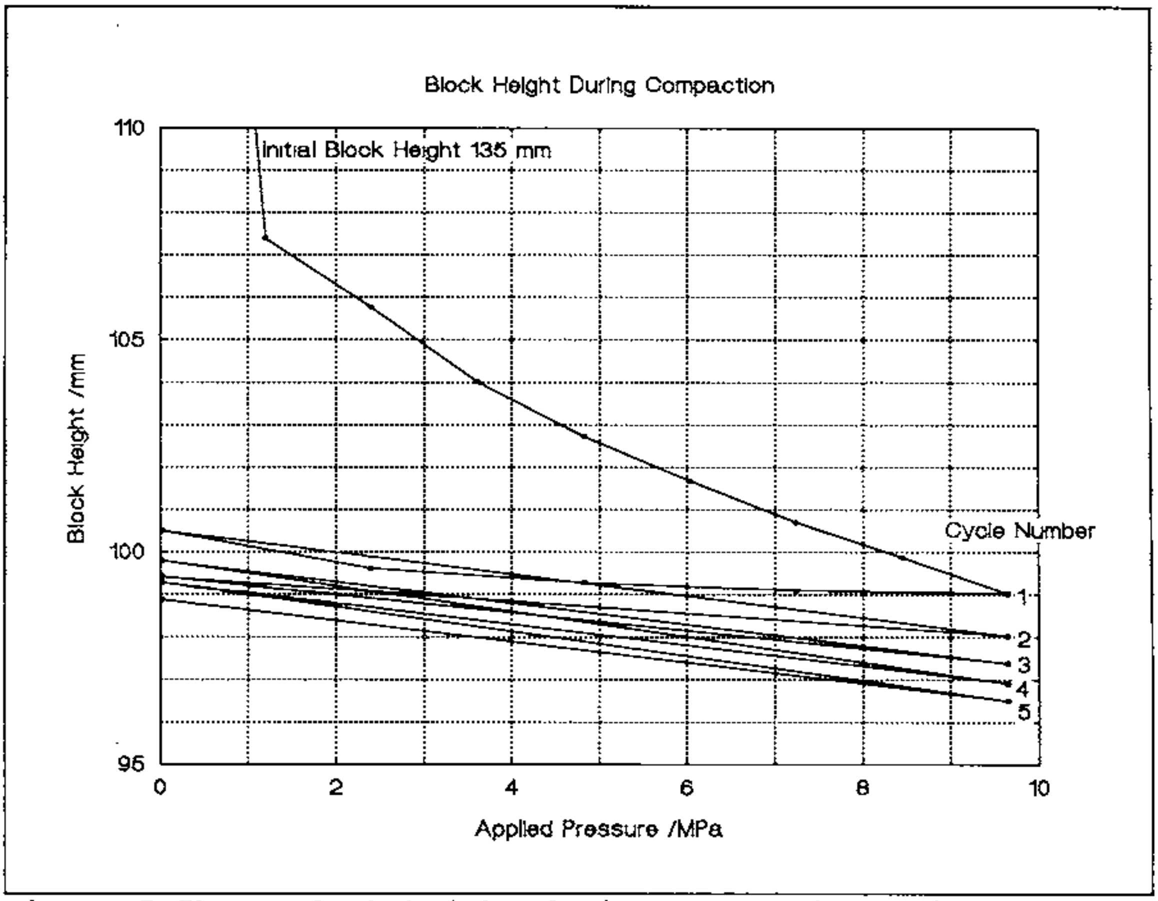

Figure 5.5b Block height during compaction and decompression.

If Figure 5.5b is examined then it can be seen that the block height reduces to 96.5 mm under full pressure after 5 cycles. The upper transducer's centre line is 90 mm above the base of the block and the active face is 5mm in radius. The transducer is therefore recording the upper side wall pressure from 3.9-13.9 mm below the upper surface for the first cycle and from 1.5-11.5 mm below the surface for the fifth cycle. The pressure reduction might then be accounted for if it is assumed that the edge region of the compaction piston is at atmospheric pressure (0 MPa on the LVDT scale) and that a region of transition from 0 to 3.5 MPa (max side wall pressure on the first cycle) exists. As the upper face of the block moves downward approaching the upper LVDT then it might be expected that the recorded pressure would drop. However without including a pore pressure type concept, it appears more difficult to explain the fall in the lower side wall pressure. No satisfactory explanation has yet been formulated.

Partial pressure cycling (cycling from full compaction pressure to a lesser pressure greater than zero) is shown as Figure 5.5c. Table 5.5b shows the numerical values for the maximum and minimum cycled pressure values for each cycle. This plot of applied pressure against recorded pressure is from one of the blocks which were used to determine the effect

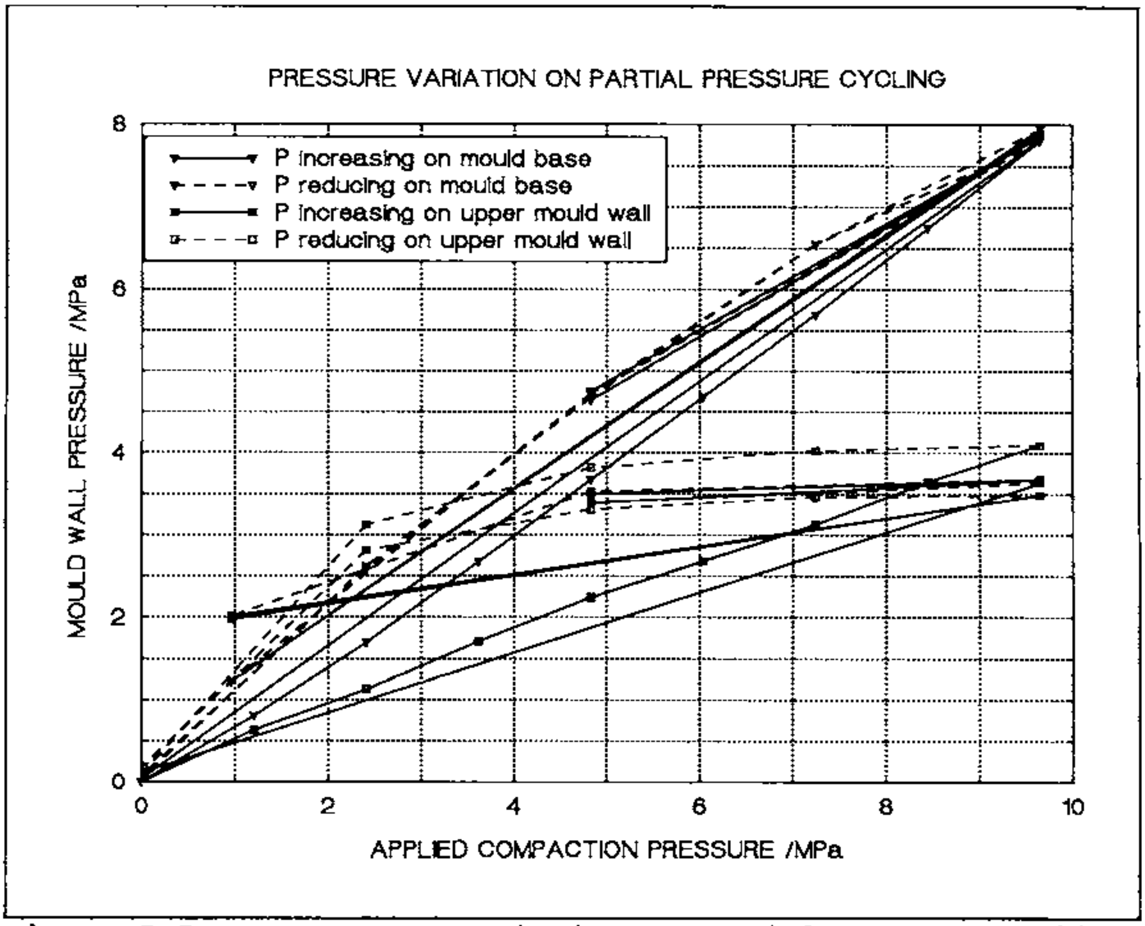

Figure 5.5c Pressure variation on partial pressure cycling

Table 5.5b Pressure values relating to figure 5.5c

Cycle No	Applied pressure /MPa	Mould base pressure /MPa	upper mould wall pressure /MPa
1	0.00 → 9.66	0.00 → 7.80	0.00 → 4.10
2	0.20 → 9.66	0.05 → 7.82	0.12 → 3.63
3	4.83 → 9.66	4.64 → 7.86	3.39 → 3.67
4	4.83 → 9.66	4.75 → 7.87	3.49 → 3.68
5	0.97 → 9.66	1.22 → 7.91	2.01 → 3.48
6	0.97 → 9.66	1.22 → 7.95	1.97 → 3.48
End	0.02	0.10	0.19

of reduced friction but this trace shows the effect of residual wall shear forces well. The block was initially compacted to 10 MPa and then cycled down to 0.1MPa. On repressurising the mould wall side pressure dropped significantly. The block was then cycled from full pressure to half pressure twice and showed no

This appears to suggest that pressure cycling has little or no effect on a region unless the pressure is dropped back to significantly less than the lag period pressure mentioned above (section 5.1).

5.6 Summary

From the work outlined above it may be concluded that the internal compaction state of the soil material within the mould is not hydrostatic. It would appear unlikely that the side mould walls, under datum conditions, will ever exceed 50% of the applied pressure and normally be less than 40%. This being the case, significant material savings in mould wall thickness would appear possible. A significant reduction in the pressure applied to the compacting piston is apparent in the base plate which may be assumed to be indicative of internal shear and inter-particle, particle-mould-wall friction. The mould wall shear is significant and may be reduced by smoothing/lubricating the mould walls. Taper has little or no beneficial effect on the compaction proses but does reduce the ejection load and the time for which the load must be applied. Double sided compaction does have a significant beneficial effect on compaction but this benefit would be small compared to the cost of the extra mechanical complexity entailed.

6. THE PRESSURE-CEMENT-COMPRESSIVE STRENGTH RELATION

6.1 INTRODUCTION

The compaction pressure and the cement content used in the manufacture of stabilised soil blocks are, for a given soil, the prime determinants of the block's final cured strength. Compaction pressure and cement content may be traded against each other for a given final cured strength. The compaction pressure used in field production will depend on the type of compaction machinery selected at the project outset and so may be considered a capital cost for the process while the cement content used may be considered a running cost. As high pressure compaction machines are more expensive to purchase than low pressure machines it is useful to examine the relative effect of both compaction pressure and cement content on cured strength.

M.G.Lunt of the UK Building Research Establishment (Building Research Establishment, 1980, Ref No.4) conducted a series of tests on two Ghanaian soils (both with high fines content, 49.0 and 56.0%) to assess the effect of increased compaction pressure on the blocks' performance when stabilised with 6% lime by dry weight. He concluded that "Improved performance can be achieved by increasing the compaction pressure although the degree of improvement diminishes as this pressure is increased. It is suggested that presses operating in the range 8 to 16 MPa could give satisfactory and economical results." This work thus suggests that there may be some economic advantage in using a high pressure compaction machine. However, increasing the compaction pressure is only one way to improve the final compressive strength of a block. Although it is generally accepted that the performance of a block will be improved both by raising the compaction pressure and by increasing the stabiliser content, the relative effect of these two changes appears to be uncharted. For example, does a doubling of compaction pressure give the same improvement in strength as a doubling of cement content? The following section examines the effect of both compaction pressure and stabiliser (cement) content on the final (seven day) wet compressive strength of the *soil-A* used for the above tests.

6.2 EXPERIMENTAL INVESTIGATION

A number of soil-cement cylinders were produced for a range of compaction pressures from 1 to 10 MPa and a range of cement contents from 3% to 11%. For each combination of pressure and cement three cylinders were produced, the average value of the wet compressive (seven day) strength was used in subsequent comparisons. The *soil-A* used is described in appendix B. This soil was selected as one which should be suitable for stabilisation based on previous authors' reports (United Nations, 1964, Ref No.17). Although the numerical values given below are unlikely to be correct for other soil types, it is expected that the trends exhibited will be, provided that the other soils fall within the range of suitable soils as defined in DTU Working Paper No.38.

The mould used was that specified in BS1924 (British Standards Institution, 1975, Ref No.3). A constant water content of 8% was used throughout the set of experiments[1]. The mould was filled with a constant mass (± 0.2%) of stabilised mixture regardless of the cement content. The cylinders produced were between 110mm and 125mm high, depending on the compaction pressure used, each having a nominal diameter of 50mm. The compacted green cylinders were sealed inside plastic bags in a damp atmosphere in batches of three and left to cure for seven days before complete immersion in water prior to wet compressive strength testing.

The results of the testing showed that both an increase in cement and an increase in compaction pressure increases the seven day wet strength, however the relative influence of each is different. Figure 6.3a and 6.4a respectively show the rate of gain in strength when either cement or compaction pressure is held constant. On each graph the data points connected by dashed lines are the average of three experimental results. The error bars associated with the data points represent a statistical confidence level of 90%, the length of the bars giving an indication of the scatter in results.

In order to relate cement percentage and compaction pressure, the raw experimental data (compaction pressure, cement percent and cured strength) was used as the input for a PC-based modelling package SPSS. A number of models were tried of which a natural log against natural log type plot was found to be the best. The solid lines on the figures given below represent the best fit to the data generated by SPSS;

$$\ln(str) = (0.315 \times \ln(pr)) + (1.216 \times \ln(cem)) - 2.178)$$

Where; str = compressive strength in MPa
pr = compaction pressure in MPa
cem = cement content percentage.

This model gave an adjusted R square measure of fit of 98.2% (Multiple R 99.1%)

---

[1] The optimum water content at the time of compaction should strictly have been found for each compaction pressure and cement content. However the *soil-A* used has a low sensitivity to moisture content and as such the effect on the experimental data should be minimal.

6.3 THE EFFECT OF COMPACTION PRESSURE AND ENERGY ON SEVEN DAY WET STRENGTH

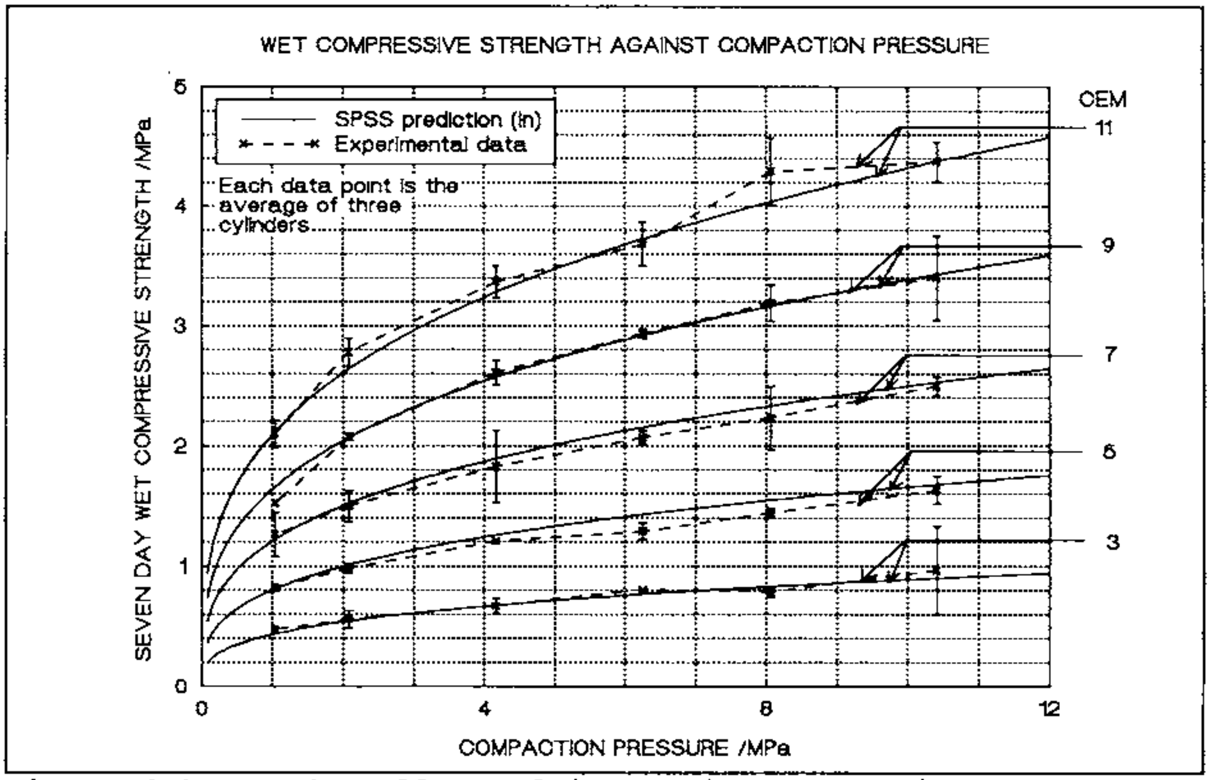

Figure 6.3a The effect of increasing compaction pressure on seven day wet compressive strength

For a given cement content (Fig 6.3a) strength increases with increased compaction pressure. Below 2 MPa this increase is rapid while above this the rate of increase reduces, tending towards a maximum strength as previously reported by Lunt (in Building Research Establishment, 1980, Ref No.4). Table 6.5 (below) shows the effect of doubling compaction pressure on the wet compressive strength. The figure given is the fractional increase in absolute strength resulting from doubling the respective variable. It can be seen that although the absolute rate of gain in strength is higher for high cement contents, the fractional increase in strength is fairly constant. A doubling of compaction pressure results in roughly 23% increase in wet compressive strength throughout the range.

Figure 6.3a shows that a given change in the compaction pressure of low pressure machines will have a large effect on the cured strength. A poorly operated or poorly maintained Cinva Ram may only operate at 1MPa, instead of the 2MPa usually quoted. This would result in a cured block strength 25% lower than that for a well operated/maintained machine.

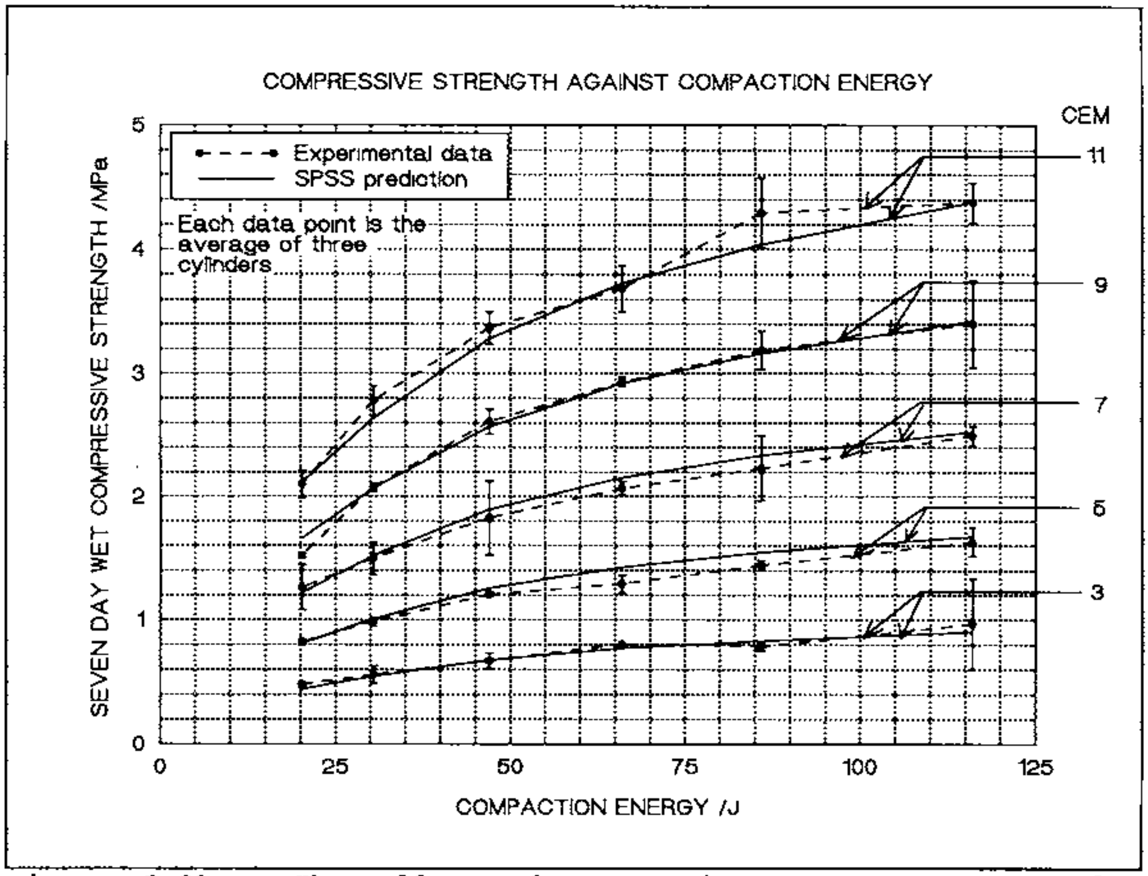

Figure 6.3b The effect of compaction energy on seven day wet compressive strength

Figure 6.3b is a plot of compressive strength against compaction energy. This graph is similar to 6.3a but shows the compaction process in terms of the energy expended in compacting the samples[2]. If the 3% cement trace is examined then it can be seen that by doubling the compaction energy from 25 to 50J the compressive strength increases by 37%, but doubling the energy from 50J to 100J only increased it by 22.9%. This is in keeping with the results shown in figure 6.3a as the energy required to increase the compaction pressure one unit is greater at higher pressures than at lower ones and hence the diminishing return.

---

2. The energy values are based on those found when quasi-statically compacting full-size blocks and were not directly recorded for the cylinders.

6.4 THE EFFECT OF CEMENT CONTENT ON SEVEN DAY WET STRENGTH

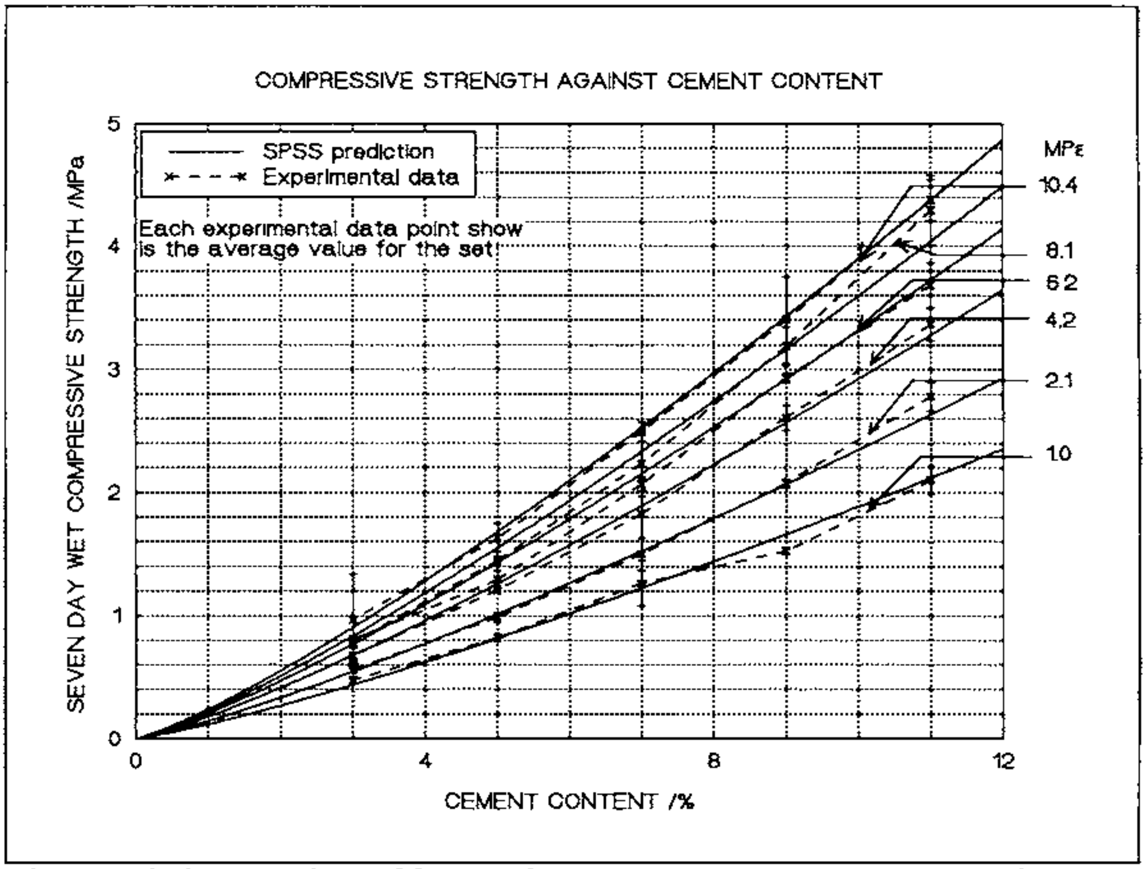

Figure 6.4a The effect of cement content on seven day wet compressive strength

If figure 6.4a is examined it can be seen that for a given pressure the rate of increase in absolute strength increases with increasing cement content. However, if table 6.5 (below) is examined it can be seen that the fractional increase in strength remains approximately the same, reducing slightly at higher cement contents. A doubling of cement content from 3 to 6% at a compaction pressure of 1.0 MPa produces a strength increase of 140% while a doubling of cement from 6 to 12[3]% produces an increase of 133%.

[3] The values for 12% cement used here are based on the SPSS model and represent an extrapolation above the maximum experimental value of 11%.

6.5 THE PRESSURE-CEMENT-STRENGTH RELATIONSHIP

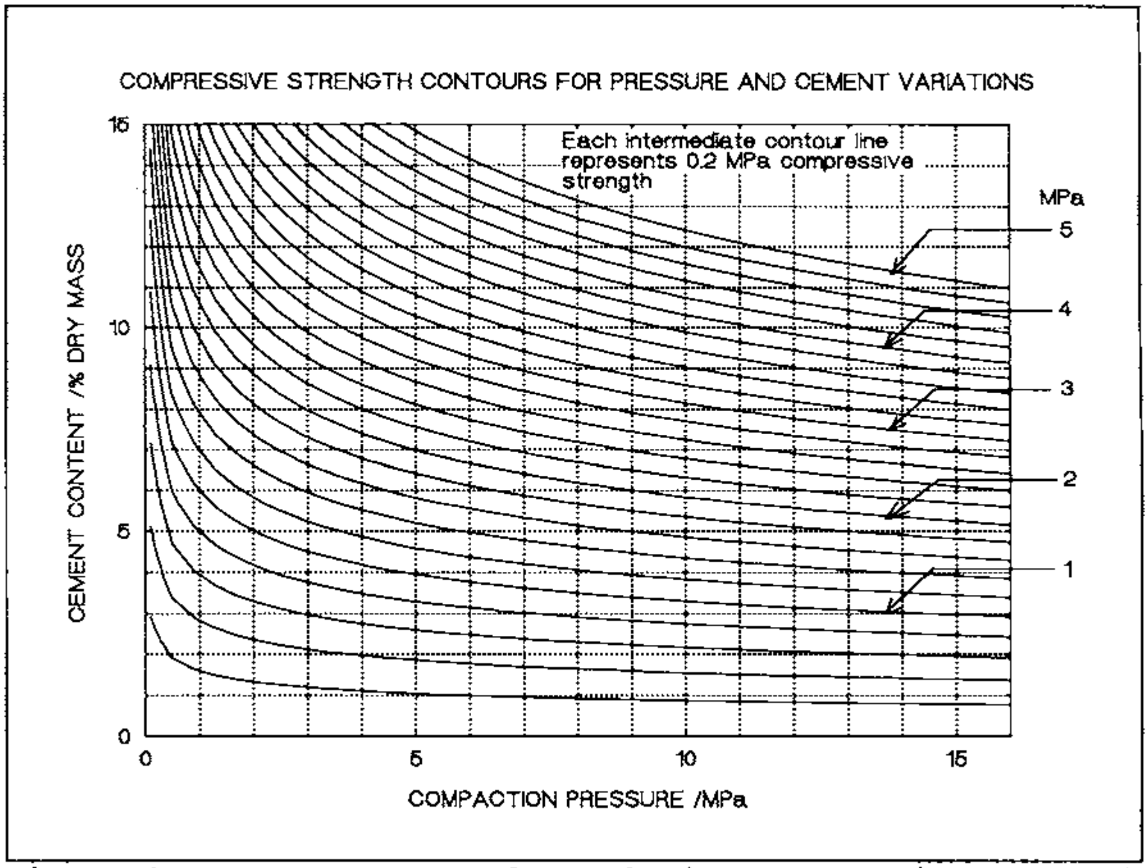

Figure 6.5a A contour plot relating compressive strength to cement content and compaction pressure

Figure 6.5a and 6.5b show the combined picture. Figure 6.5a is a contour plot showing lines of constant wet strength in relation to cement content and compaction pressure. Figure 6.5b is a three dimensional representation of the strength equation produced by SPSS from the experimental data. It can be seen from these figures that increasing the cement content of a stabilised block will in general provide a more effective method of increasing strength than increasing compaction pressure. Two standard wet strength values are normally quoted, either 1.4 MPa (Fitzmaurice 1958) or 2.8MPa (Webb 1988)[4]. The relative effect of cement and compaction pressure may be examined by regarding the reduction in cement content required when changing production from a 2MPa compaction machine to a 10 MPa machine at each of these two strength standards. Figure 6.5a shows that for a wet strength of 1.4 MPa and a compaction pressure of 2 MPa a cement

[4] Strength standards for soil-cement blocks are now becoming more widespread and vary from country to country to reflect the differing climates.

content of 6.6% would be required, while for a compaction pressure of 10MPa a cement content of 4.3% would be needed. In effect, for this soil, increasing the compaction pressure five times produces only a 35% reduction in cement demand. If the 2.8 MPa strength standard is considered, the same five fold increase in compaction pressure again results in a cement saving of only 35%.

Table 6.5 The relative effects of pressure and cement

Doubled Parameter	Strength Increase Compaction 2 → 4 MPa Energy 25 → 50 J Cement 3 → 6 %	Strength Increase Compaction 4 → 8 MPa Energy 50 → 100 J Cement 6 → 12 %
Compaction Pressure Doubled (11%cem)	2.59 → 3.23 MPa + 24.7%	3.23 → 4.03 MPa + 24.7%
(3%cem)	0.54 → 0.67 MPa + 24.1%	0.67 → 0.82 MPa + 22.4%
Compaction Energy Doubled (11%cem)	2.38 → 3.35 MPa + 40.7%	3.35 → 4.20 MPa + 25.0%
(3%cem)	0.49 → 0.70 MPa + 37.0%	0.70 → 0.86 MPa + 22.9%
Cement Content Doubled (10.4MPa)	0.90 → 2.10 MPa + 133.3%	2.10 → 4.89 MPa + 132.9%
(1.0MPa)	0.42 → 1.01 MPa + 140.5%	1.01 → 2.35 MPa + 132.7%

The trend which emerges from this study is that the final wet strength achieved by the block is much more sensitive to changes in the cement content than in the compaction pressure. By increasing the compaction pressure 400% the cement saving resulting is 35%. In order to interpret these figures, a simple economic model was constructed to compare the cost effectiveness of a 2MPa Cinva Ram and a 10MPa Brepack when producing blocks of 1.4 and 2.8 MPa wet compressive strength. This model is presented in the following section, 6.6.

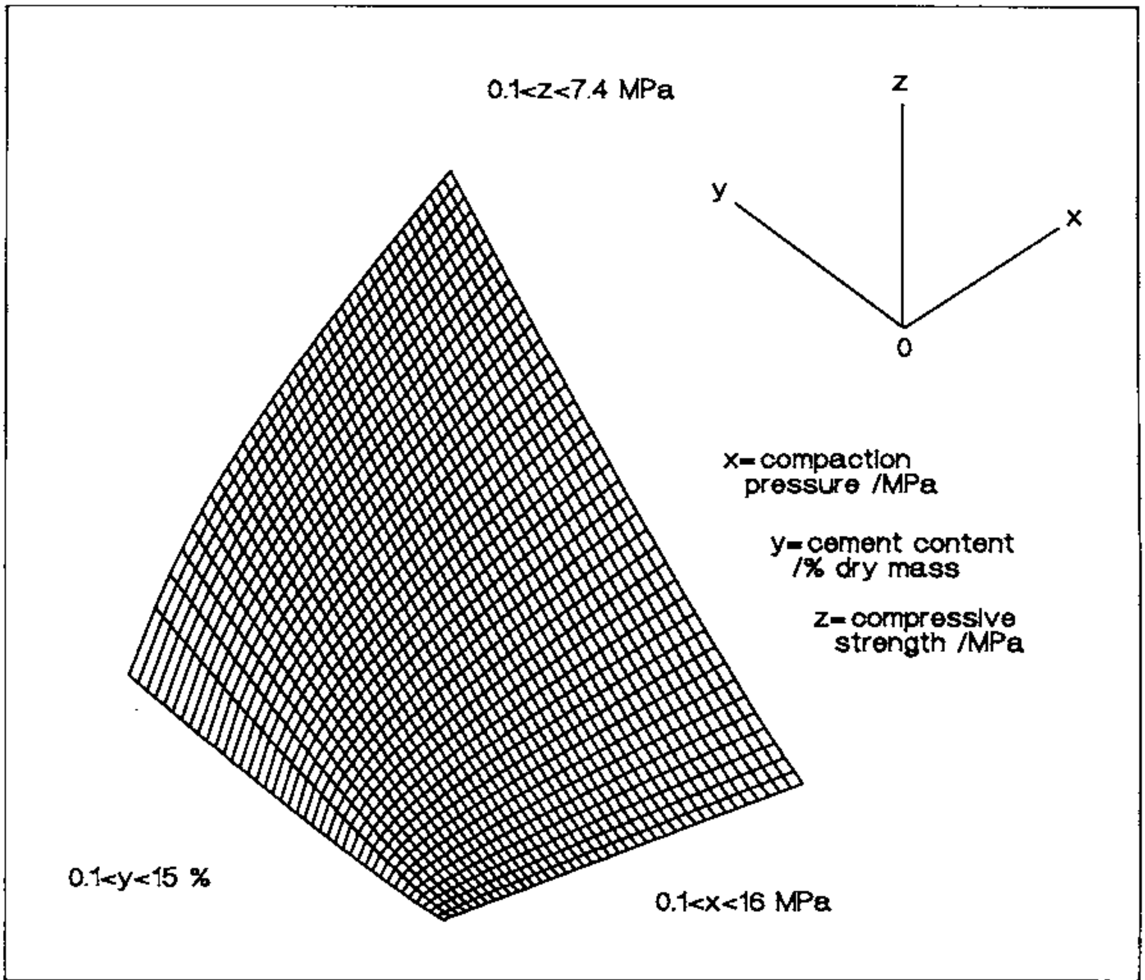

Figure 6.5b A three dimensional representation of the relationship between compaction pressure, cement content and compressive strength

6.6 SIMPLE ECONOMIC COMPARISON BETWEEN MACHINES GIVING RESPECTIVELY 2 AND 10MPa COMPACTION

The following model uses the 2MPa compaction pressure Cinva Ram and 10MPa Brepack machines for comparison. Two comparisons are made, one for blocks of 1.4 MPa wet compressive strength and one for blocks having 2.8MPa wet compressive strength.

It is assumed that both machines are operating in the same country with the same cost for cement and labour; £3.00 per 50 kg bag and £3.50 per man day (the costs quoted are those for Sri Lanka in 1993). Both machines use the same *soil-A*, as used in the above experimentation, compacted at 8% water content, both produce blocks of 290x140x100mm.

Both of the machines are manually operated toggle lever mechanisms. The Brepack generates higher pressure by the incorporation of a hydraulic ram which is operated after initial compaction by toggle lever has occurred. As large variations in the actual and quoted production outputs of each of these machines is common (production output depends heavily on the experience and dedication of the operators), it has been assumed that the maximum Cinva Ram output, quoted by the machine manufacturers, of 300 blocks per 8 hour day will be achieved and will be taken as the datum from which to extrapolate a comparable production figure for the Brepack. The maximum Cinva Ram production rate equates to the production of one block every 96 seconds. It will be assumed that the additional time taken to operate the Brepack hydraulic system is 20 seconds giving the Brepack a production rate of one block every 116 seconds or 248 blocks per 8 hour day.

The labour requirement for the Brepack may also be based on that for the Cinva Ram. The machines produce different numbers of blocks of different density; 300 blocks per day (see above) of 1980 kg/m^3 for the Cinva and 248 blocks per day of 2130 kg/m^3 for the Brepack. Hence the labour required, per day or per block, for soil winning and block compaction is different. If the labour distribution shown below is assumed for the Cinva Ram when producing blocks of 1.4 MPa wet compressive strength (requiring 2,084.4 kg of soil per 300 blocks) then soil winning/processing labour costs may be calculated per kg of soil required. Similarly the labour cost of compaction and stacking may be calculated per block, 16 man hours are required to compact 300 Cinva Ram blocks (a labour cost of £0.023 per block) while 16 man hours are required to produce 248 Brepack blocks (£0.028 per block).

It is assumed that the soil used is free and the only cost is then the cost of winning which is included in the labour cost.

It is assumed that the working life of a Cinva Ram is 3 years at full production resulting in 270,000 blocks when working for 6 days per week and 50 weeks per year. The life of the Brepack is also assumed to be 270,000 blocks.

It is assumed that the initial capital will be recouped with 30% interest within the working life of the machine assuming a 60% utilisation i.e. in five years for the Cinva Ram and six years for the Brepack. This results in a discount factor of 2.436 for the Cinva Ram and 2.643 for the Brepack.

LABOUR COSTS

Labour per day for a Cinva Ram producing 300 blocks (1.4 MPa wet compressive strength) per 8 hour day

soil winning	2 men to dig the soil, spread it out for drying and crush/sieve the dried material.
soil winning	1 man to mix the material and prepare batches for compaction.

block pressing	2 men to operate the machine and stack the green blocks for curing.

Assuming the above labour distribution for a Cinva Ram production unit then the cost of labour per kg of soil used may be found.

Soil required per block (see data)	6.948 kg
No of blocks produced per day	300
Total mass of soil required	2,084.4 kg
Labour cost per man per day	£3.50
Labour required to win/process soil	3 man days
Total soil winning labour cost	£10.50
Soil winning labour cost per kg	£0.0050

Labour cost for block pressing (Cinva Ram)	£0.0233 per block
Labour cost for block pressing (Brepack)	£0.0282 per block

CEMENT COST

Cement cost per 50kg bag	£3.000
Cement cost per kg	£0.060

CINVA RAM DATA (prices in Pounds Sterling 1993)

Purchase cost of machine £382.88 (1988 cost reported by Webb (1988) inflated by 5% pa)
Total freshly demoulded weight of one block 8.0kg (demould density 1980kg/m^3, volume 290x140x100mm)

1.4MPa wet compressive strength

Cement percentage required for 1.4MPa wet strength 6.6% (based on figure 6.5a)

Mass of soil per block	6.948 kg
Mass of cement per block	0.459 kg
Mass of water per block	0.593 kg

2.8MPa wet compressive strength

Cement percentage required for 2.8MPa wet strength 11.7% (based on figure 6.5a)

Mass of soil per block	6.631 kg
Mass of cement per block	0.776 kg
Mass of water per block	0.593 kg

CINVA RAM ANALYSIS FOR 1.4MPa WET COMPRESSIVE STRENGTH

Cost of cement per block 0.459 kg cement per block @ £0.060 per kg	£0.0275
Cost of soil winning labour per block 6.948 kg soil per block @ £0.0050 per kg	£0.0347
Cost of soil pressing labour per block (for Cinva Ram)	£0.0233
Cost of machine depreciation per block £382.88 ÷ 2.436 x 5 ÷ 270,000	£0.0029
Total cost per block	£0.0884

CINVA RAM ANALYSIS FOR 2.8MPa WET COMPRESSIVE STRENGTH

Cost of cement per block 0.776 kg cement per block @ £0.060 per kg	£0.0466
Cost of soil winning labour per block 6.631 kg soil per block @ £0.0050 per kg	£0.0332
Cost of soil pressing labour per block (for Cinva Ram)	£0.0233
Cost of machine depreciation per block £382.88 ÷ 2.436 x 5 ÷ 270,000	£0.0029
Total cost per block	£0.1060

BREPACK DATA (prices in Pounds Sterling 1993)

Purchase cost of machine £3828.80 (1988 cost reported by Webb (1988) inflated by 5% pa)
Total freshly demoulded weight of one block 8.65kg (demould density 2130 kg/m^3, volume 290x140x100mm)

1.4MPa wet compressive strength

Cement percentage required for 1.4MPa wet strength 4.3%

Mass of soil	7.679 kg
Mass of cement	0.330 kg
Mass of water	0.640 kg

2.8MPa wet compressive strength

Cement percentage required for 2.8MPa wet strength 7.6%

Mass of soil	7.444 kg
Mass of cement	0.566 kg
Mass of water	0.640 kg

BREPACK ANALYSIS FOR 1.4MPa WET COMPRESSIVE STRENGTH

Cost of cement per block 0.330 kg cement per block @ £0.060 per kg	£0.0198
Cost of soil winning labour per block 7.679 kg soil per block @ £0.0050 per kg	£0.0384
Cost of soil pressing labour per block (for Brepack)	£0.0282
Cost of machine depreciation per block £3828.80 ÷ 2.643 x 6 ÷ 270,000	£0.0322
Total cost per block	£0.1180

BREPACK ANALYSIS FOR 2.8MPa WET COMPRESSIVE STRENGTH

Cost of cement per block 0.566 kg cement per block @ £0.060 per kg	£0.0340
Cost of soil winning labour per block 7.444 kg soil per block @ £0.0050 per kg	£0.0372
Cost of soil pressing labour per block (for Brepack)	£0.0282
Cost of machine depreciation per block £3828.80 ÷ 2.643 x 6 ÷ 270,000	£0.0322
Total cost per block	£0.1316

The data given above is summarised in table 6.6 below. It can be seen from this simple analysis that for a final wet strength of 1.4 MPa and 2.8 MPa, high pressure compaction is 33.5% and 24.1% more expensive respectively.

The above model assumes a 30% interest rate and hence penalises the Brepack as a result of its higher capital cost. However this high capital cost is not the only penalty.

The Brepack compaction process must take longer than the Cinva Ram as an additional hydraulic circuit must be pressurised and hence the compaction cost in terms of operator labour is higher as the productivity is reduced.

Table 6.6a Block production cost comparison (Sri Lanka)

Cost per Block	wet strength 1.4 MPa	wet strength 2.8 MPa
Cinva Ram 2 MPa compaction	£0.088	£0.106
Brepack 10 MPa compaction	£0.118 +33.5% over 2 MPa	£0.132 +24.1% over 2 MPa

Compaction at higher pressure produces denser blocks which use less cement but more soil. Hence the costs associated with the soil are increased. In the above model it was assumed that the soil would be available free of charge except for the labour cost involved in winning it. If a secondary cost must be paid for the soil, land rental or a purchase price, then the high pressure compaction route is further disadvantaged.

Table 6.6b Percentage breakdown of block costs (Sri Lanka).

Cost Parameter	Cinva Ram 1.4 MPa strength	Brepack 1.4 MPa strength	Cinva Ram 2.8 MPa strength	Brepack 2.8 MPa strength
cement	31.1%	16.6%	44.0%	25.8%
soil winning labour	39.2%	32.4%	31.3%	28.3%
pressing labour	26.4%	23.8%	22.0%	21.4%
machine depreciation	3.3%	27.2%	2.7%	24.5%
total	100%	100%	100%	100%

Table 6.6b shows the percentage cost breakdown for the four blocks produced. It can be seen that although the high pressure compaction machine does reduce the cement demand, both the machine depreciation and the labour costs counteract this benefit.

For these machines using this soil type, increasing the cement content appears to be more economic than increasing the compaction pressure. Even if the life of the high pressure machine is doubled high pressure compaction remains the more costly. However what is not clear from this analysis is the quality of the final blocks. Although both machines should produce blocks with the same wet compressive strength, their densities will be different. Ultimate bearing strength when wet is not the only valid measure of performance but the most expedient to test and numerically quantify. The blocks' durability may be different as a result of their differing density. Work is currently under way at The University of Warwick to investigate this.

The above analysis is only valid for the cement and labour rates quoted for Sri Lanka. In other areas the relative cost of cement and labour may be completely different. For example in rural Zimbabwe the cost of cement is increased to £3.50 per 50kg bag while the wage rate is reduced to £0.80 per man per day. The effect of this shown in tables 6.6c and 6.6d

Table 6.6c Block production cost comparison (rural Zimbabwe)

Cost per Block	wet strength 1.4 MPa	wet strength 2.8 MPa
Cinva Ram 2 MPa compaction	£0.0479	£0.0698
Brepack 10 MPa compaction	£0.0701 +46.3% over 2 MPa	£0.0864 +23.8% over 2 MPa

It can be seen that even for a rural environment, where the daily wage rate is much lower than the cost of a bag of cement, high pressure compaction remains the more expensive option. For this case it is primarily the machine depreciation cost which dominates the analysis as the labour costs are greatly reduced.

Table 6.6d percentage breakdown of block costs (Zimbabwe)

Cost Parameter	Cinva Ram 1.4 MPa strength	Brepack 1.4 MPa strength	Cinva Ram 2.8 MPa strength	Brepack 2.8 MPa strength
cement	67.0%	32.9%	77.8%	45.9%
soil winning labour	15.8%	12.1%	10.4%	9.5%
pressing labour	11.1%	9.1%	7.6%	7.3%
machine depreciation	6.1%	45.9%	4.2%	37.3%
total	100%	100%	100%	100%

If the cement cost were increased to £6.00 per 50kg bag while the labour cost remained at the Sri Lankan value of £3.50 per man per day then the high pressure compaction route still remains the more expensive although the margin of difference is reduced (table 6.6e) to 18.8% and 8.5% for 1.4 MPa and 2.8MPa strength standards respectively.

Table 6.6e Block production cost comparison (if £6.00 per 50 kg of cement in Sri Lanka)

Cost per Block	wet strength 1.4 MPa	wet strength 2.8 MPa
Cinva Ram 2 MPa compaction	£0.1160	£0.1525
Brepack 10 MPa compaction	£0.1378 +18.8% over 2 MPa	£0.1655 + 8.5% over 2 MPa

The above analysis is not able to cover differences in the production efficiency and adaptability. Compaction to high pressure produces blocks which have a higher freshly demoulded (green) strength as a result of their higher density. This reduces the risk of block breakage during ejection and transportation to the curing area which has been reported by Lawson (Lawson, 1992, Ref No.22) to be as high as 50% in some extreme cases.

Moreover, because of the increased green block density the range of soil which can be used for production is larger for the high pressure machines. Green strength depends on the soil particle grading and the block density. If the green block density is reduced then for the same green strength or handleability the soil's clay content must be increased. i.e. high pressure compaction allows the use of soils with lower clay contents than those acceptable for low pressure compaction.

In conclusion, in most situations low pressure compaction will be more economic than high pressure compaction, provided that the block breakage rate is acceptably low, i.e. a moderate to high[5] clay content soil is used. If the cost of high pressure machines can be significantly reduced, while keeping the production rate similar to that of the low pressure machines, then high pressure compaction may prove to be more economic. Moreover if high pressure compaction is found to increase block durability then a small cost premium may be acceptable.

[5] Moderate and high clay contents within the acceptable clay content bounds of 10 - 30%.

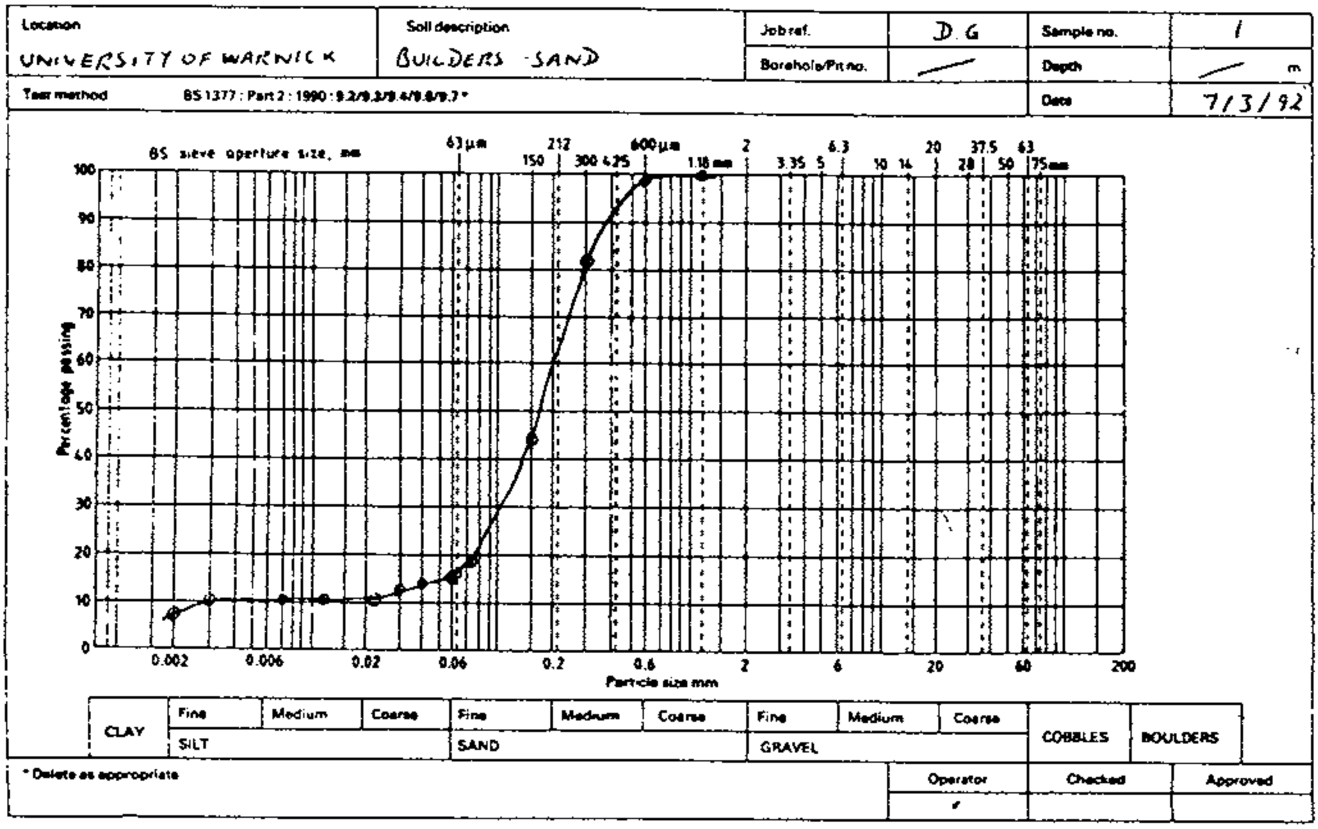
APPENDIX B SOIL-A DETAILS

Soil-A is an artificial soil produced at the University of Warwick by blending building sand with grade E kaoline powder. This soil was used for all experimentation to aid repeatability and allow a consistent soil composition throughout the course of the current research work. The soil was blended such that it fell within the ideal specification for soil-cement given by United Nations (1964, Ref No.17). This states that the optimum soil composition is; 75% sand, 25% silt and clay, of which more than 10% is clay.

Building Sand:

Grading:	Sand	84.2%
	Silt	8.8%
	Clay	7.0%

Grading curve:



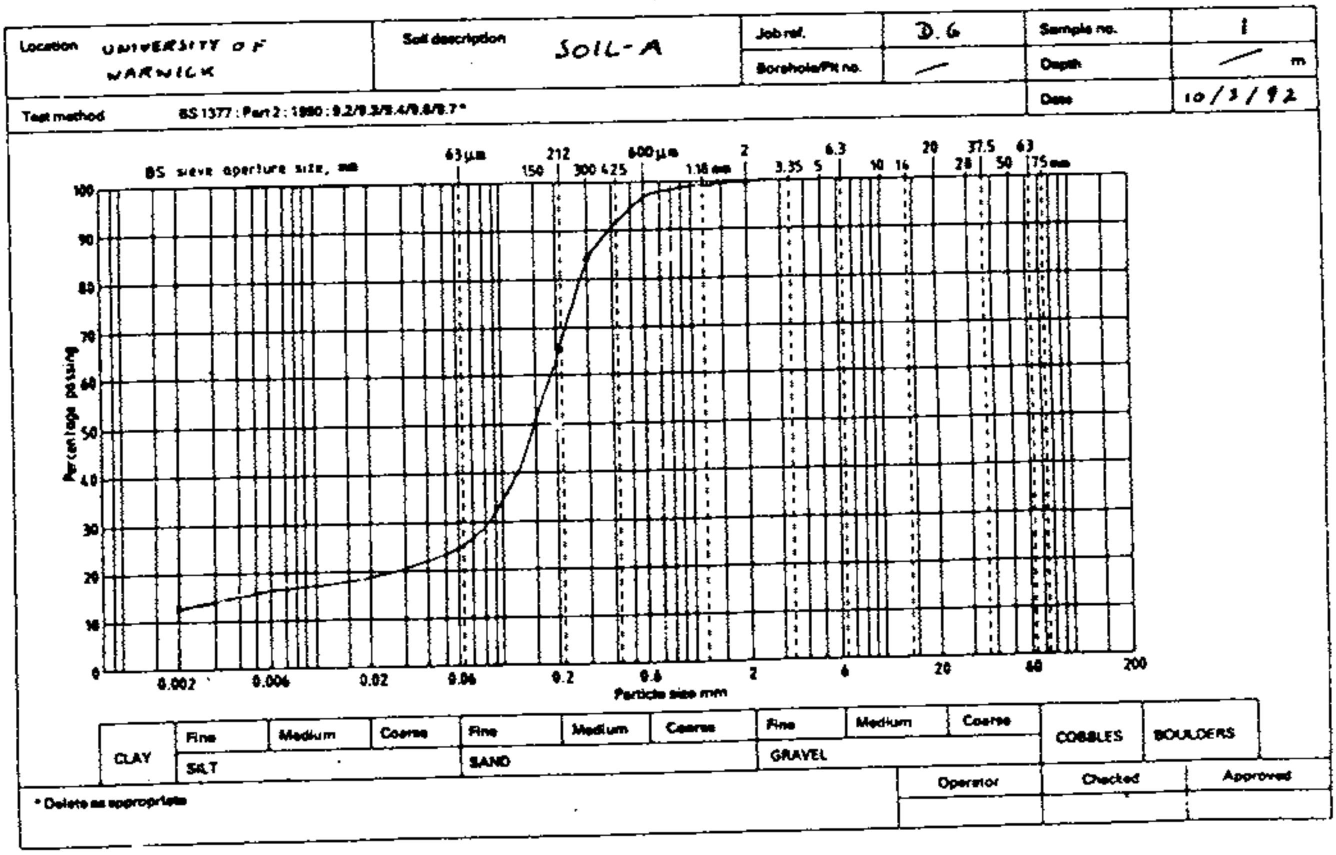
Kaoline Grade E powder:

Specific gravity	2.6
Specific Surface Area	8.0 M^2/g
Water soluble salts	0.15 %
SiO_2	50 %
Al_2O_3	35 %
Ph	5 ± 0.5

Soil-A mix proportions:	Building Sand	9 parts	(7.2 kg)
	Kaoline	1 parts	(0.8 kg)

Soil-A grading	76.5%	Sand
	8.0%	Silt
	15.5%	Clay

Soil-A grading curve:



APPENDIX C : EXPERIMENTAL METHOD

UNSTABILISED BLOCK PRODUCTION (290X140X100mm)

For each block a batch of *Soil-A* was manufactured and mixed for 5 minutes with distilled water to give a moisture content of 4% (for batch proportions see below). This batch was then left overnight to homogenise before remixing to 8% moisture content. All batch proportions were weighed to ±0.05g. All mixing was mechanical, using a large Hobart soil mixer.

The material to fill the mould was weighed out as three equal quantities into three plastic bags and sealed.

After oiling the mould with a release agent (engine oil), the soil was placed in the mould. The contents of each bag was lightly tamped before adding the next. The mould top was then placed on the soil and its height above the compression machine bed measured and recorded. A dial gauge was then positioned such that the block height during compaction could be measured.

The block was then compressed in 5 tonne force increments up to 40 tonnes. After each force increment the applied force was held constant long enough for the block height and both LVDT readings to stabilise and be recorded (typically 1 minute). The block was then decompressed in a similar manner.

The compressed block was ejected from the mould by pressing the mould walls down over the lower piston. The green block was then transferred to a wooden base plate and its final dimensions recorded.

UNSTABILISED MIX PROPORTIONS

7.200kg builders sand (0.5% moisture content)
0.800kg kaoline grade E powder (0.7% moisture content)
0.277kg distilled water (for 4% homogenisation)
0.318kg distilled water (8% moisture content for compaction)

Mass of 8% moisture content *soil-A* for block compaction 8.532kg

STABILISED BLOCK PRODUCTION (290X140X100mm)

For stabilised block production the above method was used but after homogenisation at 4% moisture content, 0.398kg of cement and 0.350kg of distilled water were added.

On ejection from the mould the green blocks were transferred to a plastic bag containing a damp tissue and sealed. The blocks were then left to cure for six days before immersion in water for the final 24 hours. Curing temperature was 22-24°C. After seven days the blocks were tested for wet compressive strength. Both the upper and lower block faces were capped with fibre board before compressive strength testing in a Denison concrete testing machine.

STABILISED SOIL-CEMENT CYLINDERS (ϕ 50mm, height 100mm)

The method given below is a copy of that used during manufacture. Six days after compaction each sample was soaked for 24 hours. On the seventh day after compaction the samples were capped with fibre board and tested for compressive strength in a Denison concrete testing machine. Although the Denison machine was operating below its range of grade 1 calibration (± 1 %) it had been recently recalibrated by an authorised testing house who indicated that the largest error given by the machine would be ± 3 % of the recorded value.

1. Measure out all ingredients for required batch. The water should be weighed into a pre-wetted container to allow for the quantity which remains in the container.

2. Place the 4% homogenised soil in the mixer. Sprinkle the cement onto the soil and note the time. Mix for 2 to 3 minutes or until the mixture looks uniform in colour, place a large plastic bag around the top of the mixer's bowl to reduce the evaporation of the water. Sprinkle in the weighed water, try not to pour the water onto the sides or the mixing paddle. Mix for a further 3 to 4 minutes or at least until the mixture looks uniform.

3. Weigh out 453.6g of the mixture, leaving the mixing bowl covered with a large plastic bag to reduce the moisture loss.

4. Oil the mould with the release oil and assemble for filling. Place approx one third of the mixture into the mould using the paper funnel. Take care not to spill any soil. Tamp the soil down with the steel bar. Repeat this for the next two thirds of the mix. Place the mould piston on top and try to centralise the main body between the end pistons.

5. Place the mould, red ring down, in the centre of the compression machine plated and compress to the required force twice (forces listed below).

6. Lift off the compression machine. Remove top and bottom pistons. Place the ejection ram in the base and the collars on top of the mould. Lower the compression machine to eject the sample. If you try and rotate the mould while compressing, it will be apparent when the sample has been ejected far enough for final removal by hand. Note the time that the sample was ejected.

7. Write the identification number on the top face and place it into a plastic bag. Repeat the above for the next two cylinders and then weigh and measure the length of each. Finally place them inside a plastic bag with one moist tissue and seal the bag.

Compaction forces:

1 MPa	= 1.960 kN	use 2.0 kN	(1.018 MPa)
2 MPa	= 3.93 kN	use 4.0 kN	(2.037 MPa)
4 MPa	= 7.85 kN	use 8.0 kN	(4.074 MPa)
6 MPa	= 11.78 kN	use 12.0 kN	(6.112 MPa)
8 MPa	= 15.71 kN	use 16.0 kN	(8.149 MPa)
10 MPa	= 19.63 kN	use 20.0 kN	(10.186 MPa)

ORDER:

Start with 10 MPa compression and 11% cement. Follow with 10 MPa 9% etc. This should minimise confusion with the compression machine!

BATCH PROPORTIONS:

All cylinders are to be compacted at eight percent water content and a dry mass of soil + cement of 420g, giving a fill mass per cylinder of 453.6g .

The figures below relate to batch mass measures. Each batch should contain enough material to make 3 cylinders with some material left over, approx 225g.

It is important to remember to note the time when the cement is added to the 4% moisture content soil.

BATCH TO MIX UP AND STAND OVERNIGHT:

(measure all mass to ± 0.05g)

9kg	lab-dry soil
1kg	kaolin from bag
0.347kg	distilled water

3% CEMENT BATCH:

1484.4g	4% homogenised soil
42.7g	cement
60.6g	distilled water

5% CEMENT BATCH:

1456.0g	4% homogenised soil
70g	cement
61.7g	distilled water

7% CEMENT BATCH:

1428.7g	4% homogenised soil
96.3g	cement
62.7g	distilled water

9% CEMENT BATCH:

1402.5g	4%homogenised soil
121.5g	cement
63.8g	distilled water

11% CEMENT BATCH:

1377.3g	4% homogenised soil
145.6g	cement
64.8g	distilled water

APPENDIX D : EXPERIMENTAL INSTRUMENTATION

THE LVDT TRANSDUCER

The LVDT transducer (see figures D1, D2 and D3) was designed to flush-mount in the mould walls. The main body of the transducer is machined from EN24T steel to form a circular spring. The thickness and shape of the spring are such that it will remain well inside the elastic region of the steel such that deflection is proportional to the applied load. The spring is deflected by a cylindrical piston mounted in a tubular guide. Both the outer faces of the tubular guide and of the cylindrical piston are flush with the spring body face and mould wall under conditions of no load.

The LVDT plunger is screwed into the rear spring boss. The LVDT body is clamped inside the transducer by the olive ring. Any deflection of the spring is sensed by the LVDT and converted into a voltage signal. The voltage output from the LVDT is fed into a conditioner and finally displayed on a digital voltmeter. The LVDT transducers and conditioners are both made by Schlumberger Industries and were supplied by RS Components Ltd, catalogue No 646-527 and No. 646-599 respectively. The Schlumberger Part numbers are LVDT SM1 and type OD3 911040 transducer conditioner.

Initially quite large hysteresis was observed on unloading. This was found to be caused by an air lock between the piston and the spring body. The design was subsequently modified by including a 1.5mm diameter vent hole. Two such transducers were manufactured and used during the experimentation.

Figures D4 and D5 show the calibration plots for transducer No.1 and No.2 respectively. Minor machining differences led to each unit having a different spring constant and hence a different gain. The gain of each unit was found to be constant over time and constant within normal laboratory temperatures. The zero offset was found to vary with time, typically 1mV per 30 minutes. The zero load voltage was recorded immediately before each experiment so that the zero offset could be determined, this offset was assumed to remain constant for the duration of each test (20 minutes). The transducers' hysteresis lead to a 0.1MPa over reading after four full cycles.

The pressure transmitted to the mould wall was found by entering the recorded voltage into the transducer equation:

$$y = mx + c$$

where y = transmitted pressure /MPa

m = transducer gain (found from calibration curves) /MPa/mV

x = recorded voltage /mV

c = zero offset correction (found by $c = -mx$ at zero load)

Figure D6 shows the possible locations for the transducers in the mould side wall.

Testing Machine Details:

All wet compressive strength tests were made on a Denison Concrete test machine 7229/T91081, max load 100kN. Certified to grade 1 calibration at time of testing.

All soil-cement cylinders were compacted on a Monsanto Tensometer Type E (No. N120-79) with a 25kN load cell (No. 263). Certified to grade 1 calibration at time of testing.

All soil-cement blocks were compacted on an Amsler compression machine (No. ES1120), max load 40 tonnes. Certified to grade 1 calibration at time of testing.

Working Paper No. 41

Algebraic Modelling of the Behaviour of Hydraulic Ram-Pumps

by Dr. T.H. Thomas

January 1994

Abstract:
The mathematical analysis of hydraulic ram-pumps began soon after their invention in the late 18th century. However simple models of adequate accuracy for use by system designers, pump manufacturers, installers and operators are still not available. This paper describes algebraic models of varying complexity for use by system and pump designers and by those involved in training installers and users. It argues that a pump plus drivepipe, rather than pump alone is the natural unit for modelling and for characterising performance in applications literature. Behaviour is shown to depend primarily upon three parameters. The first is λ, the ratio of peak drive flow (which depends upon tuning) to the pump's maximum flow with its impulse valve locked open. The second is μ, the ratio of peak drive flow to the 'Joukowski' flow just sufficient to achieve the system delivery head. The third is R, the ratio of delivery head to drive head. The analysis shows some of the trade-offs entailed in tuning, indicates the optimum choice of drivepipe and explains certain forms of malfunction observable in the field. Several 'rules of thumb' are derived. The paper also indicates areas where the greater precision of computer simulation over algebraic modelling is desirable.

CONTENTS

1. INTRODUCTION

This paper describes a number of analytic models, of varying degrees of complexity, for representing hydraulic ram pumps. It examines how such models can be used to optimise tuning, explain anomalous behaviour, aid system design and help in the design of better pumps.

The hydraulic ram pump, a water-powered water-lifting device, is of some antiquity, having been developed by Whitehurst, Montgolfier and others during the eighteenth century. Although its heyday was the late 19th century, there are over twenty manufacturers worldwide still producing machines. The ram pump performs the same role as a low-head high-flow turbine driving a high-head low-flow pump; it is however much simpler than a turbine-pump set as it contains only two moving parts, each a type of valve. The ram pump is mainly used to lift drinking water from small streams in locations where electricity is not available and engine-driven pumps would be costly to operate. The ram pump operates continuously but usually at a low power level (typically 50 to 200 watts), higher-powered pumping being more easily achieved by other means.

There is currently a revival of interest in ram pumps in developing countries and (due to changing tariff structures following privatisation of water supplies) in some industrialised countries too. Renewable energy devices in general are experiencing a come-back usually accompanied by design improvements resulting from new materials or new understanding. Ram pumps, not withstanding their simple construction, have also undergone some design changes affecting their cost and performance. More important to their wider use have been organisational changes (reducing the communication difficulties between manufacturers, installers and potential users). In developing countries population growth is causing expansion of rural settlements located higher than spring lines and intensification of agriculture through irrigation. Both of these increase the demand for water-powered pumping. The revival of interest has been reflected in several new publications (SKAT, Jeffery 1992, Knol 1992) and some transfer of manufacture to S. America and Africa from other continents.

The modelling of ram pump behaviour also has a considerable history (e.g. Eytelwein 1805, Lorenz 1910, O'Brien & Gosling 1933, Krol 1951, Rennie & Bunt 1981, Glover & Boldy 1990), although there is little evidence of such improvements in understanding affecting pump design or installation practice in the past. Two fairly recent developments have facilitated the devising of better models - improvements in instrumentation have made it easier to observe the complex movement of shock waves in actual systems, and the dramatic drop in computation costs have permitted the use of simulation models using short time steps (e.g. 0.1 millisec).

This paper arises from the work of the Development Technology Unit at Warwick University over nearly ten years on the identification of social and technical constraints to ram pump use, on the development of low-cost pumps for local manufacture in areas of use and on the transfer of system-installation skills into ten developing countries. Out of that work the need for, and the limitations of, modelling have become clearer.

2. REPRESENTING SYSTEM PERFORMANCE

The key components of a ram-pump system are shown in Figure 1. All of these have properties that affect system performance. There are some complex interactions between these components, so that little meaning that can be attached to the "performance" of the pump in isolation. When analysing the operation of a more conventional motorised pump it is possible to characterise the pump and the rest of the hydraulic circuit separately and to then combine these characterisations. The behaviour of a ram-pump is so strongly influenced by the nature of its drive pipe that this sort of analytic separation of system parts is not helpful.

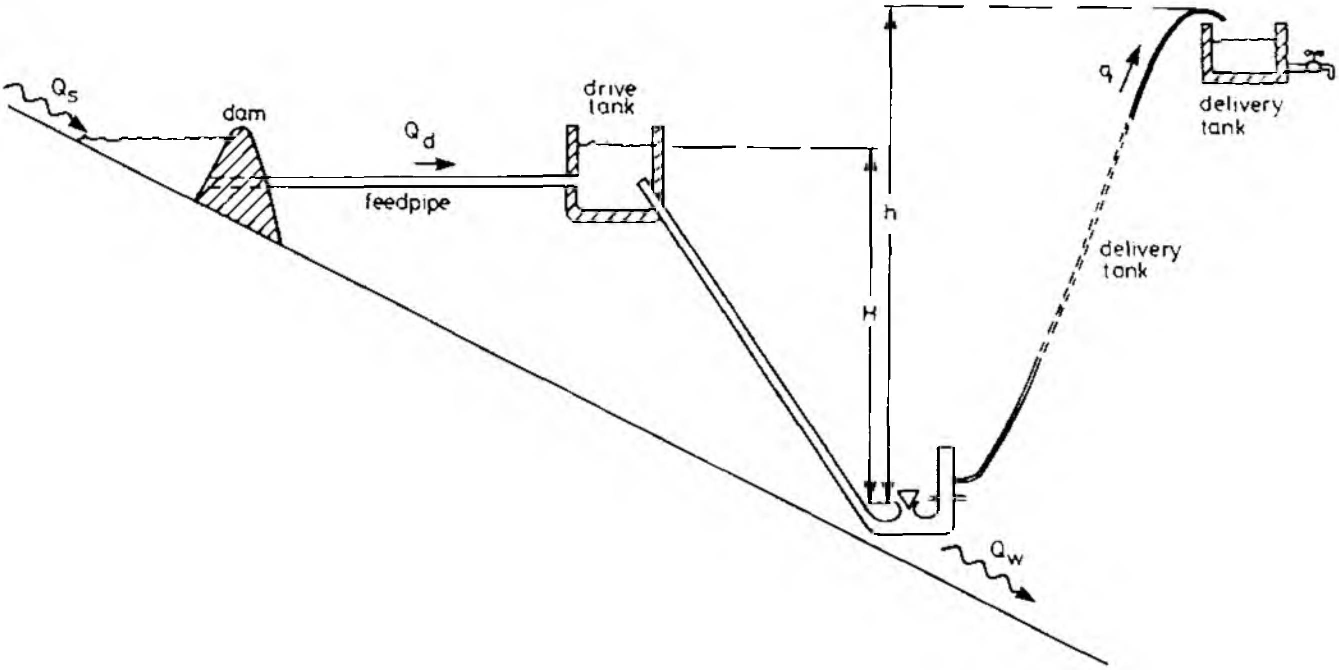

Fig. 1 Components of a ram-pump system

The components of the system have the following general characteristics that influence overall performance.

Feed pipe .. this has a *head loss* (dependent upon its length, diameter, roughness and the mean flow Q_d) which can be readily calculated independently of other system components.

Drive tank .. this is usually of sufficiently large surface area that it has negligible effect on system output and once sized can be left out of any further analysis.

Drive pipe ... this has a *drop* (H) that enters into even the crudest of performance equations, a *slope* (S) that primarily determines the water acceleration during the acceleration phase of pumping, an overall *friction factor* (relating friction head loss to instantaneous water flowrate) and an *area* (A) that relates velocity to flowrate.

Pump .... this has a *tuning control* that determines the driveflow Q_{vc} at the onset of impulse valve closure, an *impulse valve* whose inertia and fluid drag determines speed of closure once initiated and whose aperture when open detemines friction and kinetic energy losses during the acceleration phase, a *delivery valve* whose friction when open and whose inertia when opening and closing help determine pumping efficiency and finally a *flow-smoothing device* (e.g. pressure vessel) which if adequately sized has little effect on system performance.

Delivery ...... this comprises a *delivery pipe* carrying a steady flow (q) whose friction head loss is readily and separately calculable using standard formulae, and a *storage tank* which once sized (e.g. for 12 hours storage) has little effect on mean system performance. The *delivery height* (h) of course determines the outlet pressure at the pump.

When we come to characterise the performance of a system having a given site, pump, drive pipe etc. we normally treat the following as output (dependent) variables:

(i) delivery flow q

(ii) mean driveflow Q_d, taken as an average over many cycles

(iii) beatrate/(cadence) b, pump cycles per second
(iv) efficiency η, of the pump alone (not an easily defined entity), of the pump plus drive pipe or of the whole system. Efficiency is treated as a known constant (independent variable) in crude models and as a dependent variable in more elaborate models.

The normally determinable independent variables are
(i) delivery head h, or a higher head h' that includes friction head loss in the delivery pipe
(ii) drive head H, usually measured from the drive tank and hence already allowing for feedpipe friction head loss
(iii) drive pipe effective slope S, defined as drive head H divided by drive pipe length L (S has a somewhat more direct influence on performance than L)
(iv) pump setting Q_{cc}, the flow at which the impulse valve has been tuned to commence closing; this in combination with other variables determines the peak driveflow Q_p occurring during each cycle (a key variable in most analytic models)
(v) drive pipe area A
(vi) drive pipe type, and hence firstly its friction coefficient and secondly its wall stiffness that determines the velocity of sound in the water within it
(vii) pump type, and hence its internal frictions, exhaust velocity for a given driveflow and impulse valve-closure speed.

We have thus a plethora of independent variables whose number is tolerable for entry to a computerised model but is intolerably high if we intend to prepare graphs or tables to be used by a system designer in the field. (Indeed for a designer even the heads H and h are iterative variables since system design includes selecting between alternative water sources and pumphouse sites).

The list of variables above does not include feed pipe or delivery pipe characteristics and for the rest of the paper these will be assumed to be reflected in the values used for drive head H and effective delivery head h'. In practice these pipes will be sized, taking into account their probably large contribution to system cost, to give hydraulic 'efficiencies' of around 95% or even 90% for each: thus H might only be 90% of the drop from source to pumphouse and $h' = h/0.90$. In all our models we will be representing only that part of the system between the entry to the drive pipe and the entry to the delivery pipe.

Of the seven independent variables listed earlier, we might combine the last three for purposes of display output characteristics, producing graphs or tables for a particular combination of pump and drive pipe type (e.g. pump XYZ when used with a 110 mm OD, 10 bar, PVC drive pipe). This leaves for independent variables, two more than can be handled by a single readily readable graph or table. It is useful therefore to identify the degree of influence of these input variables upon the main output variables. Table 1 shows such an influence chart. The entries in the chart are based on experienced estimates of (the modulus of) sensitivity $|E|$

$$\text{where } \left|E_{yx}\right| = \frac{|\partial y / \partial x|}{y / x}$$

with y being regarded as the dependent variable. To emphasise the sensitivities, delivery head h' and head ratio $R = h'/H$ are used rather than h' and H.

Sensitivities $\left|E_{yx}\right|$ of each output variable to each input variable (acting alone) are allocated into four categories:

H = high sensitivity	$\|E\| > 0.8$	over most of both variables' ranges
M = medium sensitivity	$0.3 < \|E\| < 0.8$	" " " "
L = low sensitivity	$0.1 < \|E\| < 0.3$	" " " "
VL = very low sensitivity	$\|E\| < 0.1$	" " " "

Table 1: Influence of Independent Variables on Performance

Input variable (x)	Output Variable (y): Delivery flow q	Driveflow Q_d	Beatrate b	Efficiency η
Pump setting Q_{cc}	H	H	H	M
Head ratio R	H	VL	L	L
Delivery head h'	M	L	VL	M
Drivepipe slope S	VL	L	H	VL

Of these output variables, beatrate b is of no fundamental importance but may be used as a tuning indicator by operators. Mean driveflow Q_d may be constrained by the available source flow Q_s and hence should be known. Delivery flow is of primary interest to the system designer and knowledge of efficiency is useful when choosing between models of pumps. Of the independent variables, pump setting Q_{cc} and head ratio R are the main determinants of behaviour, with delivery head h' having a strong influence near the top of its range. Figure 2 illustrates the form of the relationship between inputs Q_{cc} and R and the outputs q and Q_d.

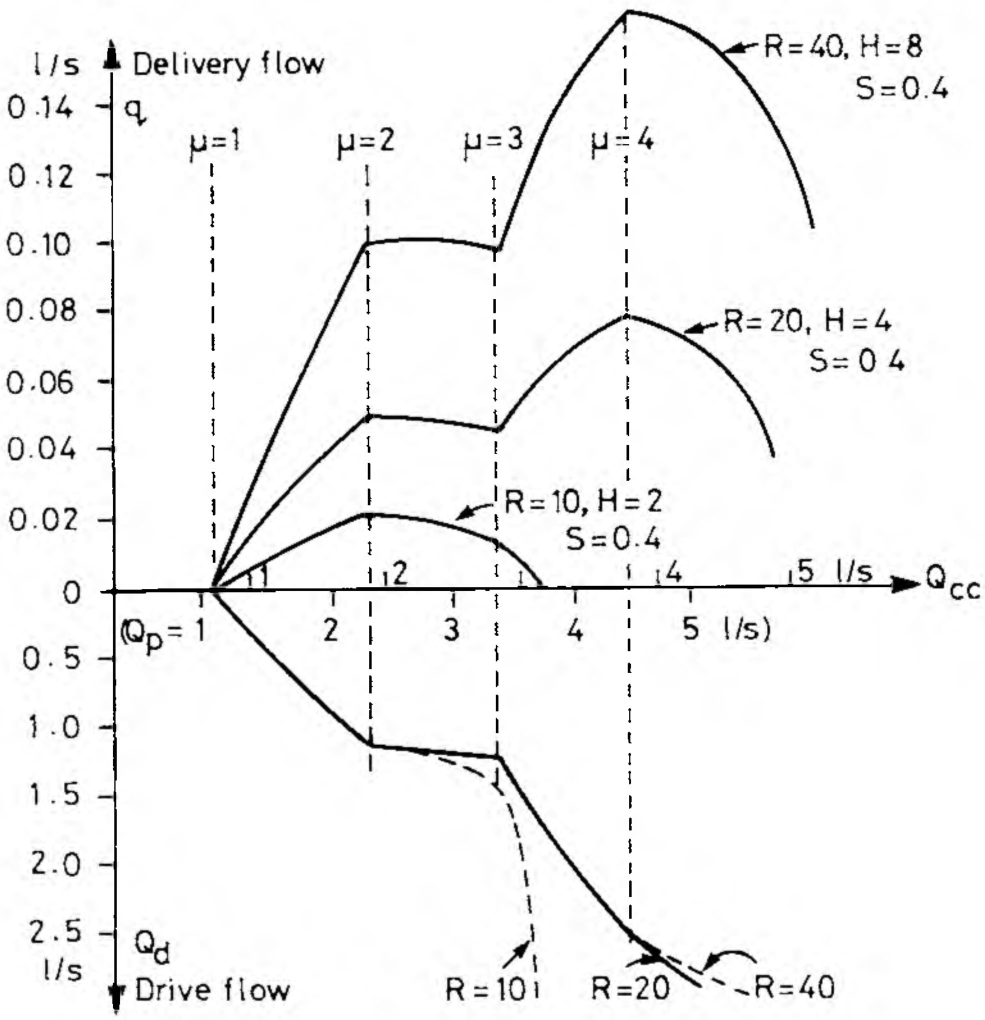

Fig. 2 Characteristic for pump type M8 with 50 mm drive pipe when tuning (Q_{cc}) is varied (delivery head of h' = 80m, drive pipe slope S = 0.4, drive head H = 2, 4 or 8 m)

3. MODELS

3.1 Algebraic and Simulation Models Compared

Algebraic models, invariable entailing the use of approximations to keep them manageable, are suited to application by 'hand' or by small computer to a range of activities - education, system design, pump selection and pump design. Because it is difficult to solve some of the equations, such models are often employed iteratively to indicate the performance, for example of a guessed-at system design, and how it might be improved by a change in parameters.

Users of ram-pumps are not, generally specialist engineers. Some installers have little education and cannot understand any algebraic notation. A major use of models therefore is to prepare design information even at the level of "rules of thumb". In fact three levels of model complexity can usefully be distinguished. Simple models are those operable by (some) water technicians. Standard models are usable by machine or system design engineers, by manufacturers to prepare charts and tables and for training demonstrations. Research models are primarily for pump designers. The Third World bias in ram-pump usage makes it particularly difficult to communicate and support models in the form of computer software.

Time-step (or-event-step) simulation models, usually based on the method of characteristics to represent transient flows in the drive pipe, have been developed for ram pumps (Glover). They are powerful but so costly of computing power that they are primarily useful for aiding pump design or explaining system phenomena rather than calculating routine performance graphs. Like all numerical techniques, these simulations deal with the particular - the influence of a particular variable can only be explored by repeated simulation 'runs' in which different values of that variable are used. With small computers, even with 486 processors, time-step simulations of ram-pump systems run at only a small fraction (e.g. 1%) of real time.

This paper restricts itself to 'simple' and 'standard' algebraic models and their use.

3.2 Simple Models

The simplest model of a ram-pump employs the concept of power balance and efficiency to give:

output power = input power × efficiency

$$\rho g\, q\, h' = \rho g\, Q_d\, H \times \eta$$

$$q = \eta\, Q_d / R \qquad \text{where head-ratio } R = h'/H \qquad [1]$$

The efficiency η so defined varies widely with operating conditions, falling to zero if Q_d is too small or R is too large. Manufacturers tables are however usually based on an assumed *constant* efficiency and users are often advised of constraints outside which they should not stray. Equation [1] probably represents the highest level of mathematical complexity one can expect any field worker or water technician to handle.

A model that can be employed in the teaching of field staff is the 'lumped-system' one whereby the pump cycle is broken into two phases. During an acceleration phase the water in the drive pipe accelerates under the drive head H, that is at rate $a = gH/L = gS$. During the deceleration phase the water decelerates under a reverse head of $h' - H$ giving $a = g\,(H - h')/L = gS(1 - R)$. This model neglects friction or the kinetic energy in the exhaust water; it also treats the water in the drive pipe as incompressible and hence fails to predict the negative pressures during end-of-cycle rebound that are important for pump operation. However this lumped-system model has several simple virtues that are not seriously affected by the rather drastic approximations inherent in it.

The velocity profile that the model generates is shown in Figure 3 superimposed upon a more realistic one.

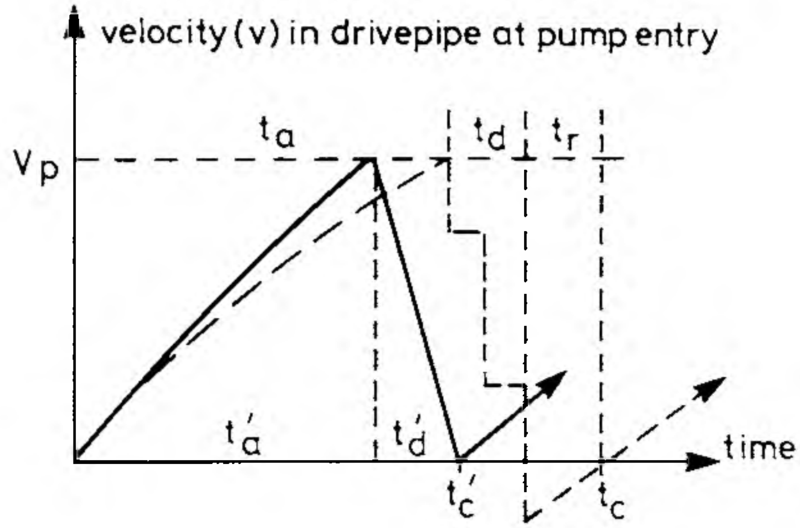

Fig. 3 Velocity profile predicted by frictionless lumped-system model
(Actual profile shown dashed)

The approximations result in predictions of acceleration phase time t_a a little shorter than reality t_a, a delivery phase of about the right duration ($t_d = t_d$) and no rebound time ($t_r = 0$). However in normal operation the drivepipe friction causing t_a to exceed t_a will be fairly small and the rebound phase may be short. Within about 10% accuracy this model correctly indicates the following.

(i) The cycle time is dominated by the acceleration phase.

(ii) For high head ratios ($R > 10$ so $t_c = t_a$),

peak velocity $v_p = g\,S\,t_c$ (t_c is cycle time) [2]
mean drive flowrate $Q_d = 0.5\ A\ v_p$

(iii) The shape of the driveflow-versus-time plot, Fig. 4 will be roughly a sawtooth (since $Q = A\ v$) for which the friction correction factor is

$$CF \equiv \frac{\text{average head loss with sawtooth flow pattern}}{\text{head loss at same } Q_d \text{ but flowing steadily}} = 2 \qquad [3]$$

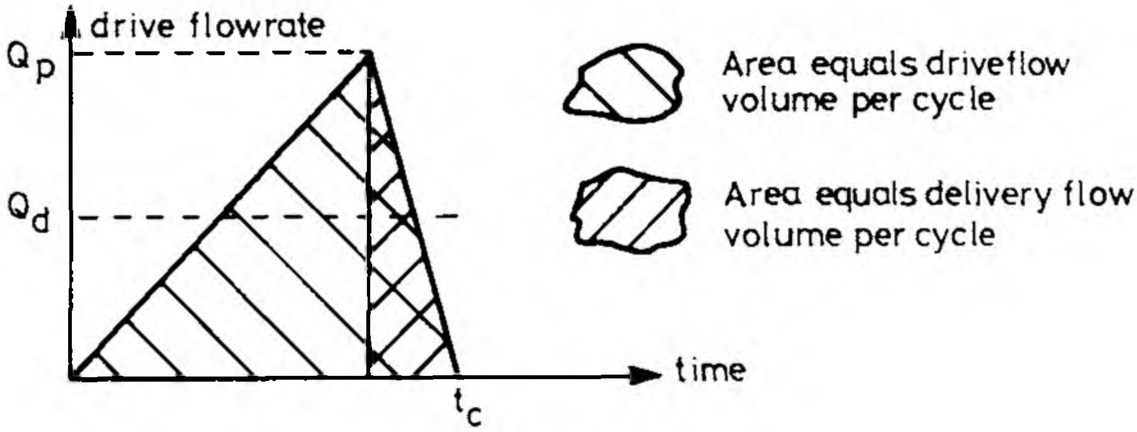

Fig. 4 Flowrate versus time predicted by frictionless lumped-system model

Thus drive pipe and exhaust kinetic energy losses can be first calculated assuming Q_d flows constantly and then doubled to allow for the waveform. Derived from this and the assumption that neither pipe friction loss nor waterflow kinetic energy should exceed, say, 10% of input energy gives two rules-of-thumb:

ROT.1 "Drive pipe size should be such that its headloss when carrying steady *flow Q_d does not exceed 5% of H".*

ROT.2 "The maximum height to which exhaust water sprays above the impulse valve (just before the latter closes) should not exceed 20% of H" (Height assumed proportional to KE, maximum flow rate Q_p assumed to be twice Q_d).

For any specific tuning, the pump manufacturer could describe the pump's friction and kinetic losses by specifying an equivalent length of (standard diameter) drive pipe L_{pe}. Drivepipe plus pump can be replaced by a simple but longer drivepipe (length $L + L_{pe}$), enabling a designer with access to pipe friction tables to apply:

ROT.3 "The headloss through drivepipe and pump together when carrying steady *flow Q_d should not exceed 10% of H".*

3.3 Acceleration Phase Models

The acceleration phase model above neglects various important effects, most noticeably factors which retard the gravitational acceleration. More accurate models were developed long ago but are not usually of a form convenient for a system designer.

The acceleration phase can be deemed to start when the water in the drive pipe starts to move downwards again (following its upwards recoil movement at the end of the previous cycle). Although shock waves may still be travelling up and down the water in the drive pipe, their amplitude should be small enough that the whole water column can be treated as having a single, initially zero, velocity.

It can readily be shown that the instantaneous acceleration of the drive pipe water satisfies

$$\frac{dv}{dt} = g\,S\,(1 - kv^2) \qquad [4]$$

So that acceleration terminates when

$$v = v_\infty = k^{-\frac{1}{2}} \qquad [5]$$

The retardation factor k reflects the headloss at drive pipe entry, plus that due to drive pipe friction, that caused by friction within the pump and the velocity head 'thrown away' in the waste water. The head loss due to all these factors can be expressed as a multiple of the velocity head in the pipe

$$H_{loss} = C \times \frac{v^2}{2g} \quad (\text{where } C = 2gH \times k) \qquad [6]$$

and $$C = C_1 + C_2 + C_3 + C_4 \qquad [7]$$

where C_1 is pipe inlet loss coefficient, typically 0.2 to 0.5

C_2 is pipe friction coefficient fL/D and f is typically 0.02

C_3 is pump loss coefficient, typically 1.5 but may be much higher

$C_4 = A^2/A_e^2$ where A is the pipe's cross-sectional area and A_e is the effective area of the discharge aperture of the impulse valve.

The first of these coefficients is usually negligible compared to the others, especially if the drive pipe inlet has a bell mouth. For practical purposes:

$$k = k_d + k_p \qquad [8]$$

where k_d (representing the drive pipe) equals $C_2/2gH$ and k_p (representing the pump) equals $(C_3 + C_4)/2gH$.

For the pump designer the minimisation of k_p is an objective, especially by maximising A_e to keep C_4 small and having large internal channels to keep C_3 small. k_p varies with pump tuning. For the system designer maximum economy comes from matching drive pipe to pump so that k_d is neither much greater than k_p nor much less. This fixing a pump (with impulse valve jammed open) onto a previously open-ended drive pipe should not reduce the flow through it by a factor more than 1.7 (implying $k_p < 2\,k_d$) or less than 1.22 (implying $k_p > k_d/2$). A rule-of-thumb that arises out of this analysis is:

ROT.4 "The area of the impulse valve's exhaust aperture should not be much smaller than the drive pipe's cross-sectional area".

Returning to equations [4] and [5], solving and relating all velocities to the maximum velocity attainable, gives

$$\text{normalised velocity, } \lambda = v / v_\infty = \frac{e^{2\tau} - 1}{e^{2\tau} + 1} \qquad [9]$$

where normalised time, $\tau = t / t_o$ (and where $\lambda = \lambda_p$ $\tau = \tau_m = t_a / t_o$)

and reference time, $t_o = v_\infty / gS$ (time to reach the velocity v_∞ were there no retarding influences)

The relationship is plotted in Figure 5 where the normalisation is also illustrated.

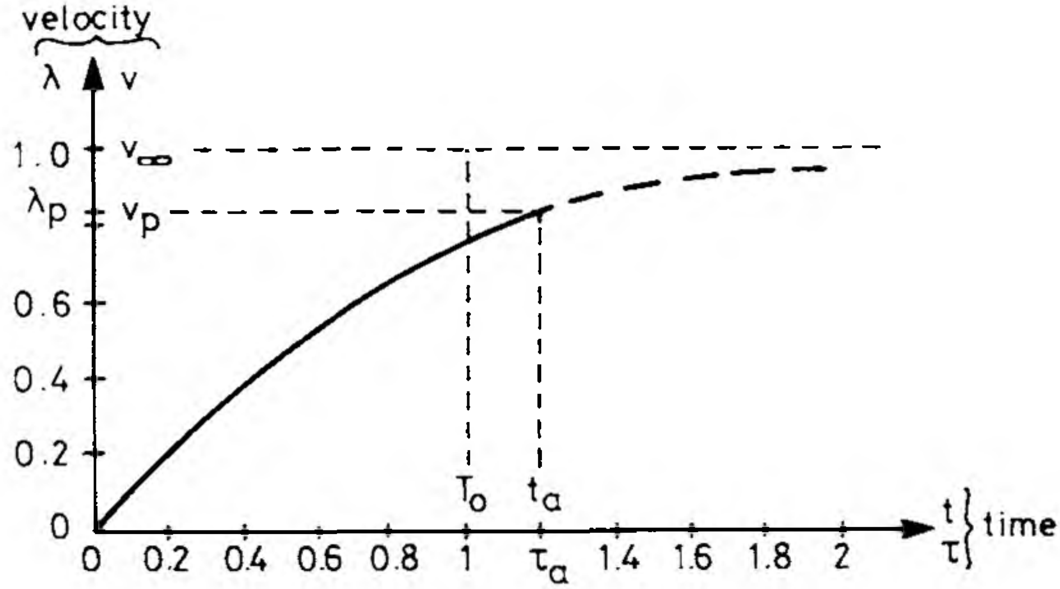

Fig. 5 Variation of water velocity during the acceleration phase
($\lambda = v / v_\infty$ and $\tau = t / T_o$ **are normalised values)**

This model is helpful discussing pump tuning. Tuning indirectly determines the peak velocity v_p at which acceleration terminates. As the purpose of the acceleration phase is to convert potential energy (height) into kinetic energy, we are interested in efficiency and power (rate of forming KE). Both of these are functions of v_p.

Figure 6 shows the efficiency and the normalised power of the acceleration phase as a whole, as functions of the normalised peak velocity at impulse valve closure ($\lambda_p = v_p/v_\infty = Q_p/Q_\infty$). The relevant algebraic expressions are:

$$\eta_a = -\lambda_p^2 / \ell n(1-\lambda_p^2)$$

$$P_a = \rho AL.\ \frac{gH}{2}.v_\infty \times \frac{\lambda_p^2}{\tau_\infty} \qquad [10]$$

$$t_a = \tau_a\, t_o = \tfrac{1}{2}\ \ell n\left(\frac{1+\lambda_p}{1-\lambda_p}\right) v_\infty / gS$$

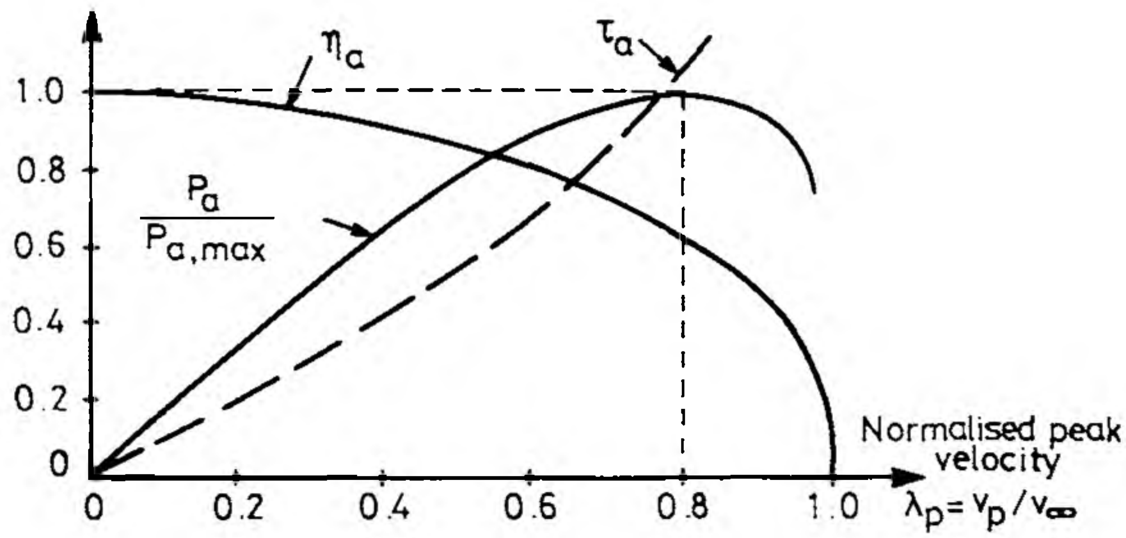

Fig. 6 Efficiency and power of the acceleration phase
(v_p is velocity at the end of the phase)

During the acceleration period the average velocity is about half the peak (final) velocity. The average and peak flows are similarly related. The acceleration time is close to $v_p/g\,S$ being actually:

$$t_a = \frac{v_p}{g\,S} \cdot \frac{\ln\{(1+\lambda_p)/(1-\lambda_p)\}}{2\lambda_p}$$

and the average velocity during acceleration is given by:

$$\frac{\bar{v}_a}{v_p} = \frac{\overline{Q_a}}{Q_p} = \frac{-\ln(1-\lambda_p^2)}{\lambda_p \ln\{(1+\lambda_p)/(1-\lambda_p\}}$$

Which tabulates as Table 2

Table 2 Mean acceleration flowrate and acceleration time

λ_p	0	0.1	0.2	0.3	0.4	0.5	0.6	0.7	0.8	0.9	(1.0)
$t_a \div g\,S/v_p$	1.00	1.00	1.01	1.03	1.06	1.10	1.16	1.24	1.37	1.64	(∞)
$\overline{Q}_a / \frac{1}{2}Q_p$	1.00	1.00	1.01	1.02	1.03	1.05	1.07	1.11	1.16	1.25	(2)
η_a	1.00	0.99	0.98	0.95	0.92	0.87	0.81	0.72	0.62	0.49	(0)

From Figure 6 it is obvious there is no purpose in setting λ higher than 0.8 (i.e. peak drivepipe flow equal to 80% of its maximum possible value). Maximum acceleration power occurs at $\lambda = 0.8$ but the efficiency is then low, $\eta = 63\%$. A much lower flow setting is usually preferable, for example $\lambda = 0.47$ will give 75% of maximum power but raise acceleration efficiency to $\eta = 90\%$. Although there are other factors to be discussed in the next section, Figure 6 illustrates the main trade-off between throughput and efficiency involved in tuning. It can also be used in reverse, in the sense that a designer could work back from a desired mean drive flow Q_d and desired acceleration efficiency to estimate the necessary limiting flow ($Q_\infty = A\ v_\infty$). From that the value of k in equations [4] to [8] is implied for which a suitable pipe and pump can be selected.

Refinements to this model are possible but do not greatly affect Figure 6. For example the previous recoil phase may have left the lower part of the drive pipe empty at the instant that forward motion of water recommences. This will have the effect of reducing the coefficients in equation [7] (e.g. $C_3 = 0$, $C_4 = 1$) until the water-air interface has passed back through the pump again. With normal recoils this lessening of friction at low velocities has negligible effect.

Representing, in fine detail, the flow behaviour during the last milliseconds of impulse valve closure is beyond the practical scope of algebraic models and is an area where simulation models give better insight. There is little evidence that the assumption of instantaneous valve closure will seriously falsify conclusions drawn from the acceleration model described above.

The acceleration phase model developed above does not readily yield a rule of thumb for pump tuning other than

ROT.5 "Pumps tuned to have very long cycle times (e.g. t_c over 3 seconds) will be very inefficient".

This rule is illustrated by Fig. 7: T_o is typically 0.5 to 1.5 seconds and t_a is typically 90% of measured cycle time t_c.

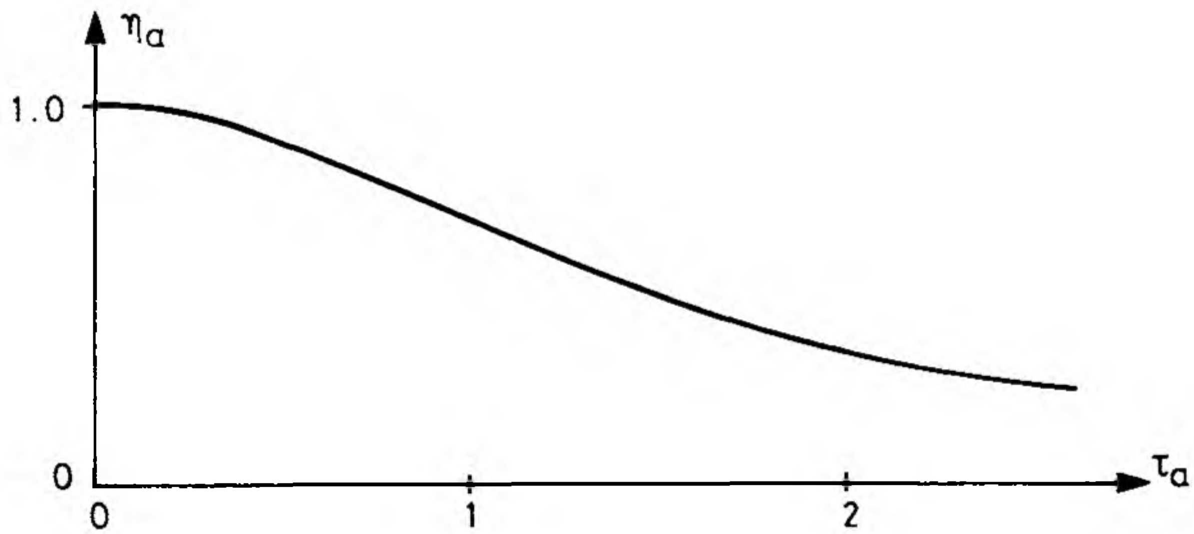

Fig. 7 Variation of acceleration efficiency with normalised acceleration time

3.4 Delivery Phase Model

During the acceleration phase the water in the drive pipe is building up its kinetic energy. It is accelerating because the impulse valve at the bottom of the pipe is open to atmosphere. During the delivery phase this impulse valve is closed and the flow is diverted through the delivery valve which it has forced open against a back head of h' (delivery head plus delivery-pipe headloss). The large net retarding force on the column of water in the drive pipe ($A \times \rho g(h'-H)$) causes it to decelerate rapidly. The detailed mechanism of this retardation is more complex than that assumed in Fig. 5 and comprises a sequence of shock waves travelling up and down the pipe. The overall effect of the delivery phase is to consume the kinetic energy formed during the preceding acceleration phase, using it to pump water. At the end of the delivery phase there is a small residue of kinetic energy that has not been used: this drives a water-recoil process namely the 'recoil phase'.

The transition between acceleration and delivery phases is very complex and must be idealised if algebraic models of tolerable complexity are to result. The sequence is as follows. Once the drive flow Q has exceeded the set threshold Q_{cc}, the impulse valve starts to close (conveniently visualised as a piston moving towards a hole smaller than itself). The flow continues increasing, beyond Q_{cc}, while the piston of the valve accelerates. As the piston gathers significant speed the fraction of the flow pressing *round* the piston decreases while the fraction *following* the piston increases (the latter is equal to piston area times piston velocity). The *velocity* of the former however increases, since the annulus through which it has to pass is rapidly getting thinner, causing the back pressure behind the piston to rise. The acceleration of the drivepipe water therefore diminishes and finally goes negative. By this time the piston is close to striking its stop and the first (annulus passing) fraction has a very high velocity manifest as a visible spurt of water above the valve. In the last millisecond of valve closure the exhaust flow falls to zero, the piston hits its stop and the pressure in the pump body rises precipitately to the Joukowski (or water-hammer) head h_J. Provided this is higher than the delivery head h', the delivery valve will be pushed open and the head will then fall back to $h' + h_L$ where h_L is the friction headloss through the delivery valve. The Joukowski head is thus maintained for a very short time whose duration depends on the velocity of sound, the distance from the impulse valve to the air-water interface above the delivery valve and the inertia of the delivery valve.

This sequence is portrayed in Figure 8 which represents approximately ten milliseconds of the change over between acceleration and delivery phases. The idealised model in Figure 8(b) is suitable for performance predictions but not for estimating the fatigue life of components. The boundary between acceleration and delivery phases has been taken as the instant the pump body pressure head has risen to the drive head H. Modern instrumentation provides ready confirmation of the 'actual' pressure transient but not of the flow transient: velocity sampling every 0.1 milliseconds is too expensive.

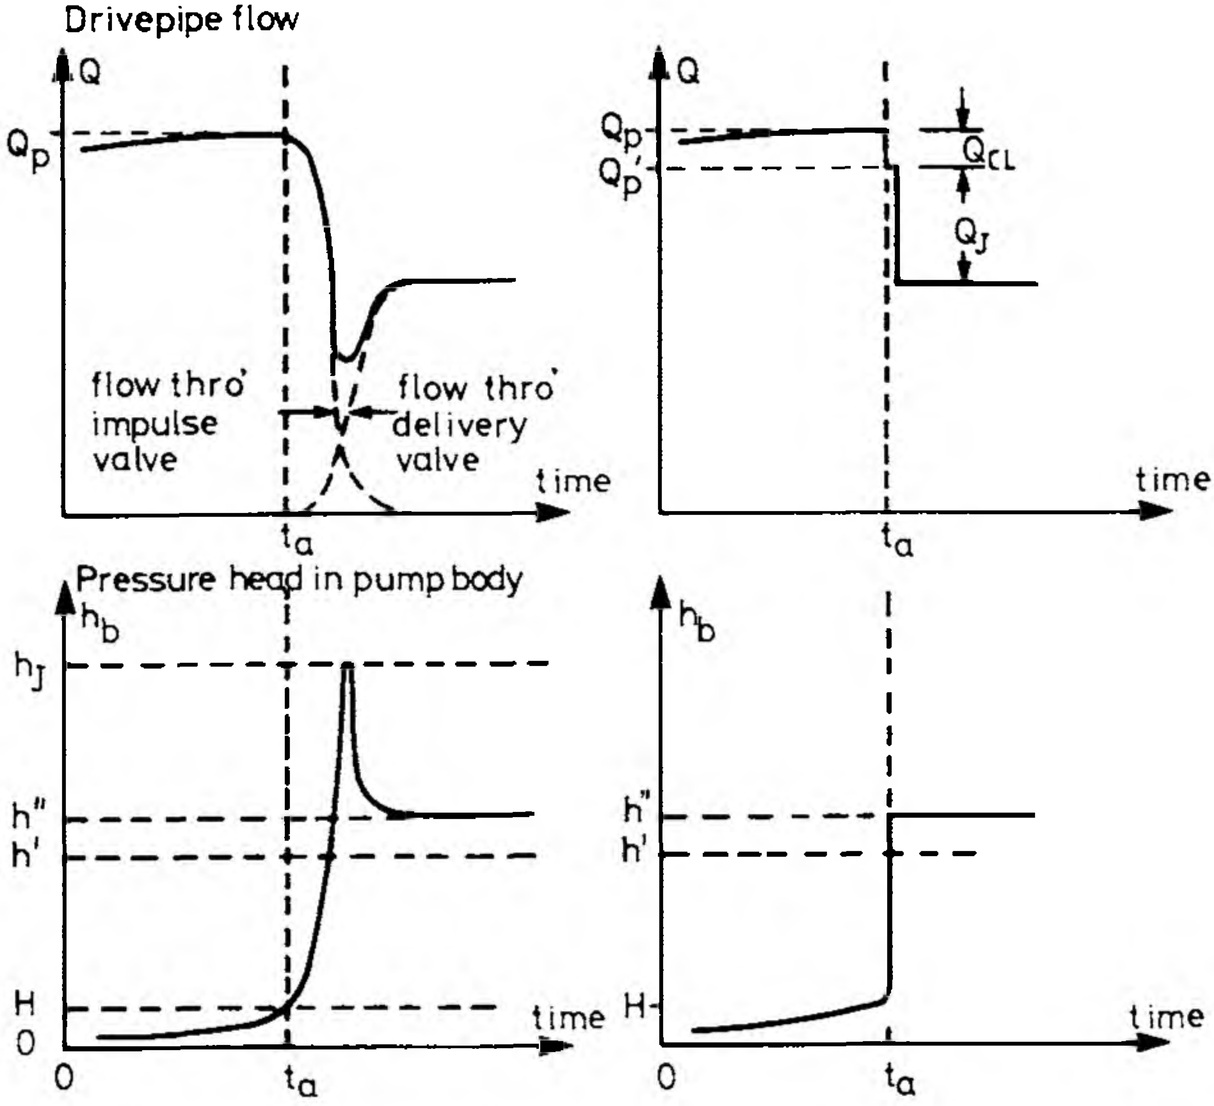
In Figure 8(b) the net effect of energy losses (e.g. lost piston KE) during the last instants of valve closure are replaced by a step reduction Q_{CL} in the drive pipe flow. The further drop Q_J corresponds to Joukowski velocity drop in a shock wave whose pressure differential is $\rho g \times (h'' - H)$

$$Q_J = A\, v_J \quad \text{and} \quad v_J = \frac{g}{c}\,(h'' - H) \qquad [11]$$

where c is the effective velocity of sound in the drive pipe and $h'' = h'$ + average delivery valve head loss. The quantities c and h'' will be discussed later. In our idealised model, which draws upon the work of O'Brien 1933 and Rennie 1980, the delivery phase starts with flow out of the drive pipe (i.e. into the pump body) dropping suddenly from Q_p' to $Q_p' - Q_J$ and the head rising suddenly from H to h''. This initiates a shock wave that travels up the drive pipe, at speed c to arrive at the drive tank after transit time

$$T = L/c \qquad [12]$$

The pressure distribution along the drive pipe is further assumed to have been the static distribution corresponding to steady conditions of no flow, i.e. head equal's zero at the drive tank surface and H at the pump entry. Effectively we are neglecting the effect of drive pipe friction during the delivery phase.



(a) **probable actual behaviour** (b) **idealised behaviour**

Fig. 8 Transition from acceleration phase to delivery phase
(over a few milliseconds around time t_a)

In the acceleration-phase model of section 3.2, behaviour depended on the peak drivepipe water velocity normalised with respect to its maximum possible value; $\lambda_p = v_p/v_\infty = Q_p/Q_\infty$. In the delivery-phase model behaviour depends on the velocity (and flow) normalised with respect to the Joukowski velocity defined in equation |11|. We therefore need to define another normalised flow

$\mu = Q/Q_J$ and its initial value $\mu_i = Q_p/Q_J$

Consider now the flow and pressure at a point in the drive pipe very close to the pump. Its form will be as in Figure 9.

In Figure 9 the shaded area is proportional to the water pumped per cycle. The dashed curve (A) is the behaviour we should expect if the delivery valve were to remain open; however to avoid reverse flow it is designed to close almost instantly. The dashed curve (B) is the projected behaviour following delivery valve closure. However the negative pressures so generated will usually take the absolute pressure below atmospheric, causing air to be drawn through the (high friction) snifter valve and shortly afterwards through the (low friction) impulse valve when it has reopened a little. Consequently trajectory (C) will be followed.

Figure 9(a) was drawn for $\mu_i = 3.3$ whose integer part is odd. Figure 9(b) shows the different behaviour when the integer part of μ_i is even.

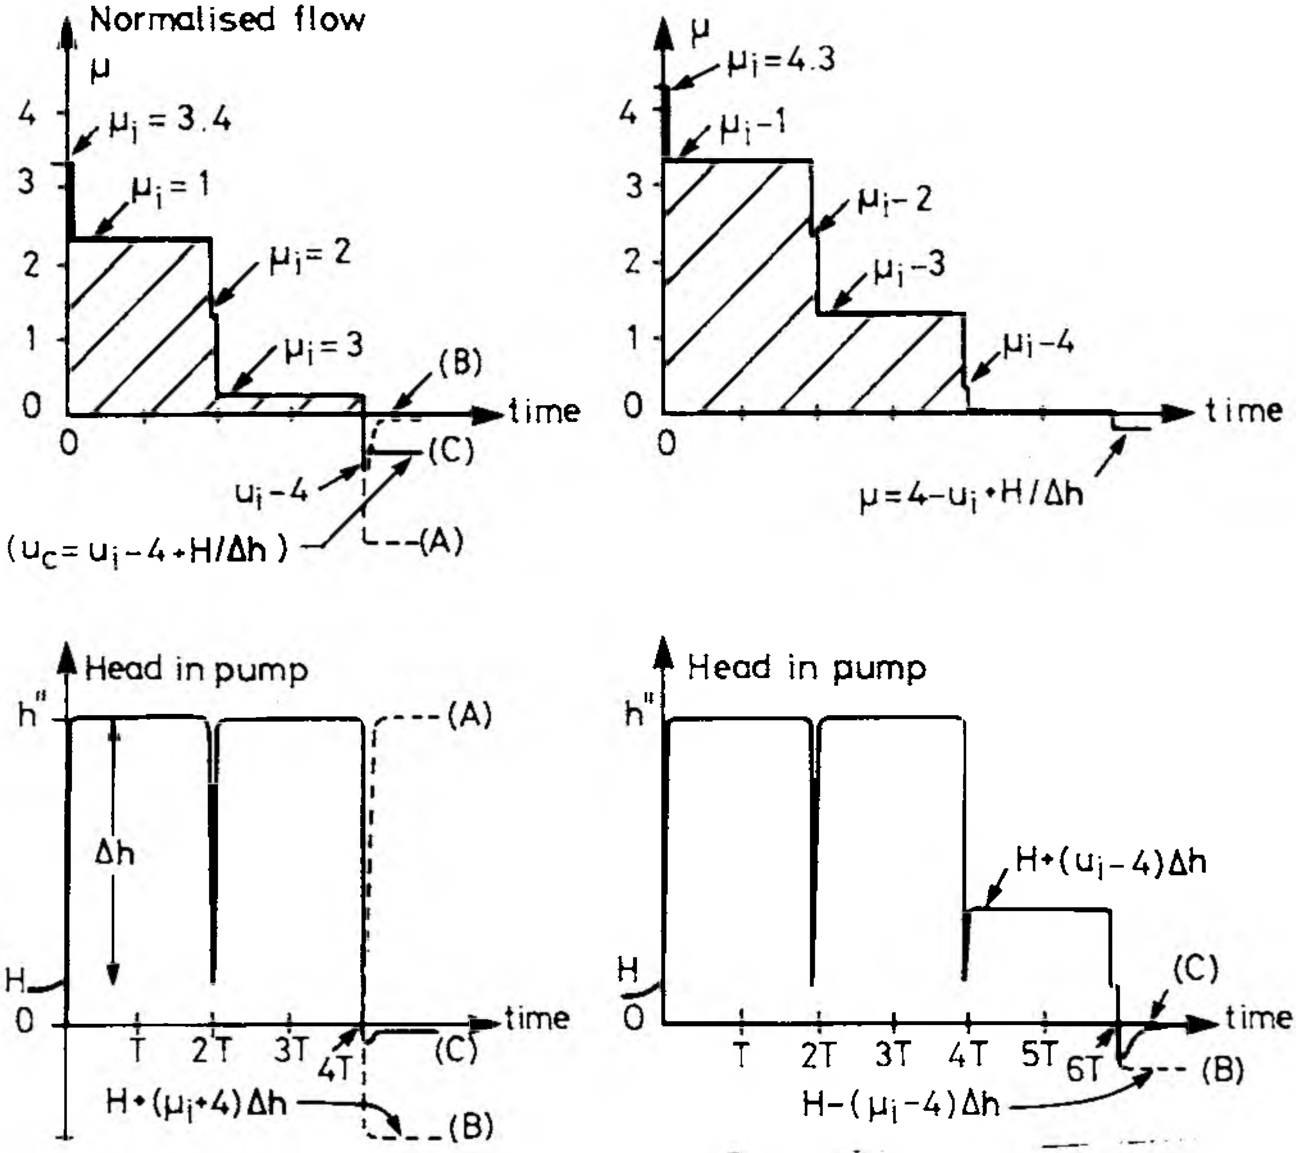


Fig. 9 Pressure and normalised flow at pump entrance

(A) delivery valve remains open

(B) delivery valve closes but impulse valve does not reopen

(C) actual: delivery closes and impulse reopens

Shaded area indicates normalised volume delivered per cycle

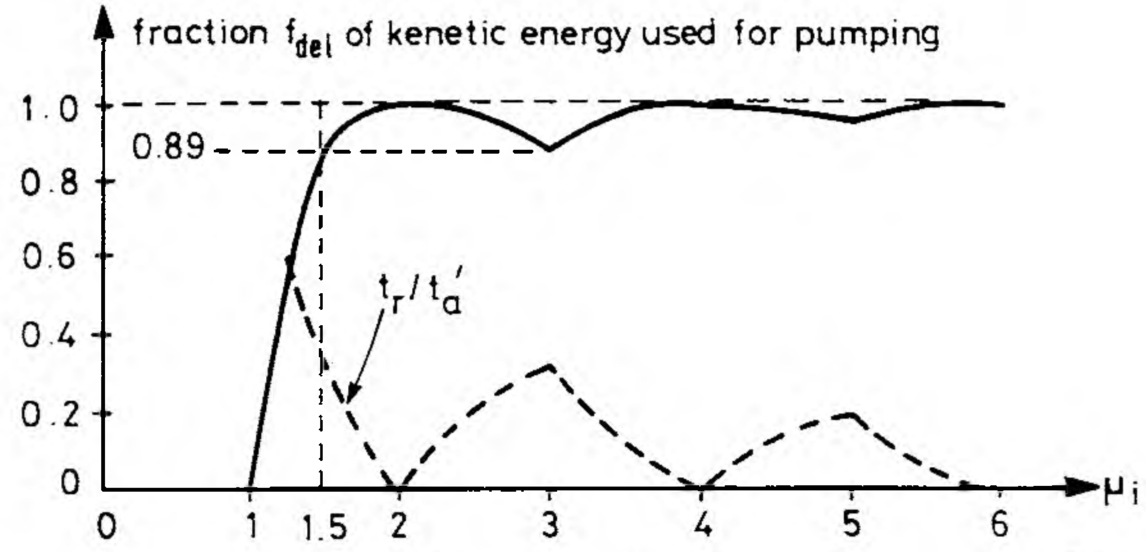
The discussions so far have emphasised the complexity of the delivery phase and the many approximations necessary to achieve a manageable algebraic model. The model developed - one of several possible - does however allow us to answer the following questions:

- how long t_d will the delivery phase last?
- what fraction of the kinetic energy developed during the acceleration phase is used in

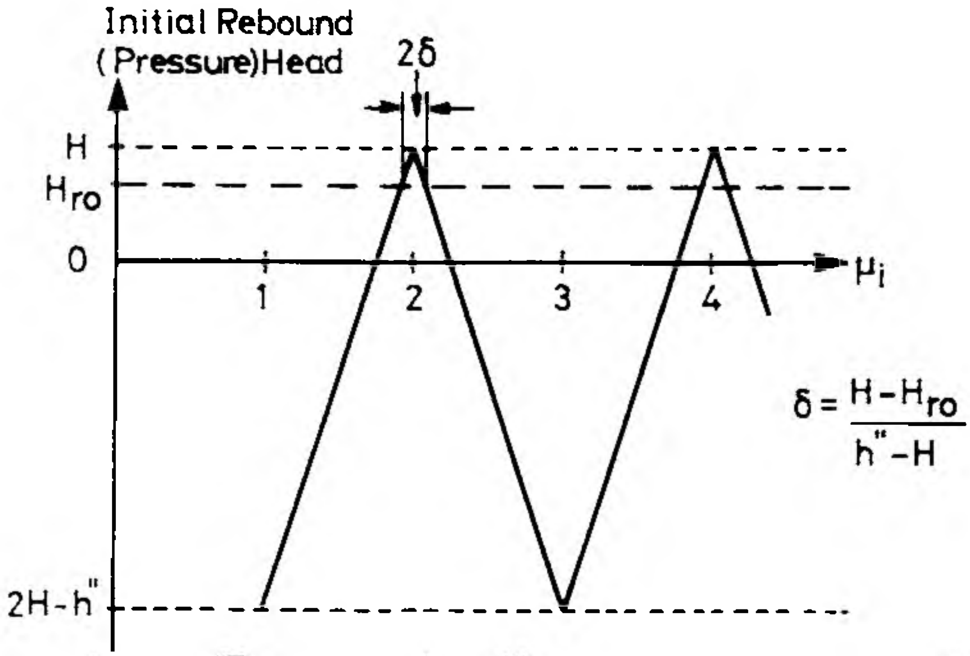
pumping (and what remaining fraction is therefore passed on to the recoil phase)?
- what therefore are the bounds within which μ_i should be tuned to lie?
- what efficiency has the delivery phase?

From the graphs we can see that the duration of the delivery phase is an integer number of 'reflections', where each reflection lasting $2T$ is the passage of a shock wave up the delivery pipe and back. By inspection

$$t_d = 2T\ (1 + \mathrm{Int}(\mu_i)) \qquad \text{where Int( ) denotes 'integer part of' and } \mu_i > 1 \qquad [14]$$



(a) **Fraction of available kinetic energy used during delivery phase and recoil time t_r** **(t_a' is acceleration time if no friction)**



(b) **Head in pump body at start of recoil phase** **(h_{ro} = head below which the impulse valve reopens)**

Fig. 10 Effect of peak flowrate on energy utilisation and rebound **(μ_i = Q_p/Q_J is normalised peak flowrate, where Q_J is the Joukowski flow rate corresponding to effective delivery head h''· H is drive head)**

It can be shown that the fraction of kinetic energy, f_{del}, applied to pumping is the shaded area (the μ - time integral) of Fig. 9 divided by $(0.5\ \mu_i\ T)$. (For various reasons it is correct with this model to exclude potential energy released by the water flowing down the drive pipe during the *delivery* phase).

The graph is of interest for several reasons. A low fraction (e.g. $f_{del} < 0.9$) indicates a reduced throughput and a reduced efficiency. The throughput is lowered not only because some of the kinetic energy is not used but also because the unused part contributes to a long rebound time (discussed later) which lengthens the cycle of operation and hence reduces the effective power. The efficiency is lowered because any losses while accelerating the water cannot be recovered even though the rebound water returns to the drive tank. The delivered fraction f_{del} is generally acceptable for $\mu_i > 1.5$ but falls sharply as μ_i drops below 1.5.

From [11] and [13] $$\mu_i = \frac{Q_p'\ c}{Ag(h''-H)} \qquad [15]$$

Low values of μ_i arise when delivering to very high heads (h'' large), setting the pump flow too low (Q_p' low), or using too large a drive pipe (A large) in combination with a low velocity of sound (c is low in plastic feed pipes). Clearly μ_i should not fall below 1 (no output) and it would be unwise to drop below $\mu_i = 1.5$ (at which use-fraction is only $f_{del} = 0.89$).

Lastly there is the matter of delivery phase inefficiency. This has been represented by an additional friction head during delivery, increasing effective delivery height h' to h''.

We can therefore define

delivery valve efficiency $$\eta_{dv} = h'/h'' \qquad [16]$$

where delivery valve headloss is

$$h''-h' = \frac{C_{dv}}{2g\,A_{dv}^2}\ \overline{q_{dv}^2} \qquad [17a]$$

The delivery valve water-flow area A_{dv} can be measured. The loss coefficient C_{dv} will lie between 0.8 and 1.2. The mean square value of q_{dv} is not easy to estimate. The instantaneous delivery flow q_{dv} has the staircase waveform shown in Figure 9, and therefore magnitude $Q_p' \times \mu / \mu_i$. The flow-weighted mean-value of $(\mu/\mu_i)^2$ rises from zero (at $\mu_i = 1$) to 0.45 (at $\mu_i = 3$) and then stays approximately constant for $\mu_i > 3$. In practice friction losses in the delivery valve are significant only at relatively low delivery heads and hence at large values of μ_i. For this condition and via a series of approximations we can come to

$$h''-h' = \frac{0.4\ Q_p^2}{2g\ A_{dv}^2} = \frac{Q_d^2}{12 A_{dv}^2} \qquad \text{which is accurate within} \pm 30\% \qquad [17b]$$

A pump designer can use equations [16], [17b] in combination with the maximum value of Q_d and minimum value of h' to decide whether the valve area A_{dv} is sufficient.

3.5 Recoil-phase Model

Water velocities during recoil are small so do not result in significant friction losses. Our interest in the recoil phase therefore centres on (i) whether the recoil suction is sufficient to reopen the impulse valve, and (ii) how long the recoil phase lasts.

From inspection of Figure 9 it can be seen that the initial rebound pressure satisfies Figure 11. However there exists a head H_{ro} above which the impulse valve will not reopen and the pumping cycle will not continue. In Figure 11 the zones of width 2δ indicate values of μ_i for which the rebound is inadequate. In an operational pump with a *weighted* impulse valve H_{ro} is never greater than the drive head H, and is usually much less. As a first approximation we can take H_{ro} as zero in which case:

$$\delta = H/(h'' - H) = 1/(R - 1) \qquad [18]$$

As $\delta = 1$ represents the valve not reopening at *any* value of μ_i (any flow setting), R should never drop below 2 and it would be risky to use values of R below say 5 (25% chance of impulse valve failing to reopen). In practice the approximation behind [18] is a drastic one; however the observed phenomena of pumps being difficult to run at low head ratios and very high drive heads is confirmed. A pump with a *sprung* rather than weighted impulse valve will have a much higher value for H_{ro}, usually higher than H in fact. Such pumps are therefore much less liable to failure of the impulse valve to reopen.

The simplest model of the rebound process is an energy one. An acceleration phase of duration t_a results in the drive pipe water having a certain kinetic energy. At the end of the delivery phase a fraction approximately $(1 - f_{del})$ of this energy remains which should cause a rebound of duration

$$t_r = t_a \times \sqrt{1 - f_{del}} \qquad [19]$$

This data is also plotted in Figure 10.

This analysis assumes constant acceleration/deceleration for a given pipe slope: it thus neglects friction effects which if included would reduce t_r/t_a by typically several percent. It also assumes instantaneous reopening of the impulse valve, whereas in practice this is so delayed by inertia that some of the rebound energy is expended in sucking air through the tiny snifter valve hole. More fundamentally, the model assumes that during rebound the water column recedes, unbroken, back up the drive pipe. In reality water and air mix and their interface is geometrically very complex. Equation [19] may be taken to give a crude estimate of the rebound time t_r. It shows that under many operating conditions t_r is not negligible and is especially large when μ_i is close to 1 (i.e. when the necessary delivery head can only just be achieved).

3.6 Combining Acceleration, Delivery and Recoil Models

In the previous sections three models have been discussed. For the acceleration phase a lumped-system model has been used, for the delivery phase a distributed-system model (with reverberating shock waves), and for the rebound phase again a lumped system model. In practice shock waves continue to roam the drive pipe water column during rebound and die away during the subsequent acceleration phase. An algebraic model to represent these would be intolerably complex and add little to accuracy. The transition from phase to phase is complex and could only be fully modelled if the dynamics (drag, mass etc.) of valves were included. The transition from acceleration to delivery and from delivery to recoil entail irreversibilities that cause loss of work energy. The first is represented by the drop Q_{CL} in delivery flowrate shown in Figure 8, which reduces both efficiency and throughput. The second energy loss, at the start of the rebound phase, arises from any backflow through the delivery valve, any air or water friction in the snifter, or cavitation. It affects efficiency unfavourable but throughput favourably (since rebound time will be reduced).

During acceleration and rebound the impulse valve is open to atmosphere, and pressures at the bottom of the drive pipe have been related to atmospheric. During delivery, however, the impulse valve is closed and the model used has related pressures (heads) to a datum at the surface of the drive tank height H higher. The change in datum has hidden certain minor energy transactions (kinetic energy to strain energy). The acceleration, delivery and rebound models can be combines as follows:

cycle time $$t_s = t_a + t_d + t_r \qquad [20]$$

where the constituent times are defined by equations [9] , [14] and [19] and Table 2.

efficiency $$\eta = \eta_{nr} = \eta_a \cdot \eta_{ad} \cdot \eta_{dr} \qquad \text{in the absence of recoil}$$

$$\eta = \frac{\eta_{nr} f_{del}}{1-\eta(1-f_{del})} \qquad \text{if recoil is significant} \qquad [21]$$

where η_a and η_{dv} are defined by equations [10] and [17], f_{del} by Fig. 10 and the acceleration-to-delivery handover efficiency η_{ad} is typically 0.97.

delivered power $$P = P_a \cdot \eta_{ad} \cdot \eta_{dv} \cdot f_{del} \cdot t_a/t_c \qquad [22]$$

where acceleration power P_a is given by equation [10].

drive flow $$Q_d = \frac{Q_p}{2} \frac{f_{del} + 1/R}{1 + 1/R + \sqrt{1-f_{del}}} \qquad [23]$$

obtained by dividing drive volume per cycle (allowing for recoil flow) by cycle time (including recoil time).

Putting the three phases together gives Figure 11.

From this graph it can be seen than mean drive flow Q_d is usually considerably less than the flow Q_{cc} at which closure commences. (Q_{cc}/Q_d is typically between 1.5 and 2.0). This yields the rule of thumb

Rot 6. *"If the source flow falls temporarily below the pump's mean drive flow Q_d the pump will stop, usually with its impulse valve open. To restart the pump without human intervention the source flow must increase to a level 1½ to 2 times Q_d".*

This rule implies that after a drive flow interruption pumps usually fail to restart without human intervention. This is a serious inconvenience in practice.

4. THE APPLICATION OF ALGEBRAIC MODELS

In the introduction to this paper reference was made to the need to explain behaviour, prepare performance graphs/tables and develop rules for system design, pump tuning and pump design. Six such 'rules' were developed in the course of model building (section 3 above). Many more might be devised. The purpose of this concluding section is to illustrate the use of algebraic models via some examples.

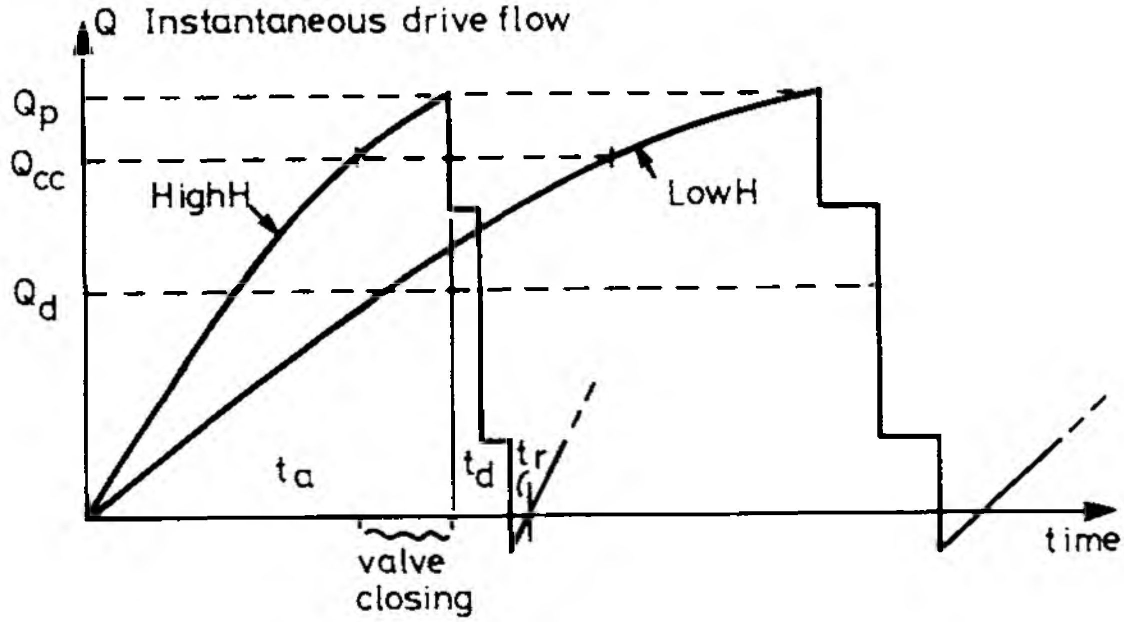


Fig. 11 Driveflow over a complete cycle for high and low driveheads
(Q_p is peak driveflow, Q_{cc} is driveflow to start valve closure, Q_d is mean driveflow)

4.1 Explaining Phenomena and Improving Pump Design

Ram-pumps, for all their mechanical simplicity, display complex and sometimes 'temperamental' behaviour. Reasons for the latter include operation too close to some limit, and blockages and leakages in pipes. Two major causes of erratic operation are the presence of excess air in the drive system (often due to excessive recoil at the end of the delivery phase) and the failure of the impulse valve to reopen (insufficient recoil). Algebraic models help us understand both phenomena.

The recoil can be expressed as an energy fraction ($1 - f_{del}$, where f_{del} is illustrated in Fig. 10(a)), a time fraction (Fig. 13) or a distance:

$$\text{rebound distance} \qquad L_r = (1 - f_{del})\,\frac{v_p^2}{2gS} \qquad [24]$$

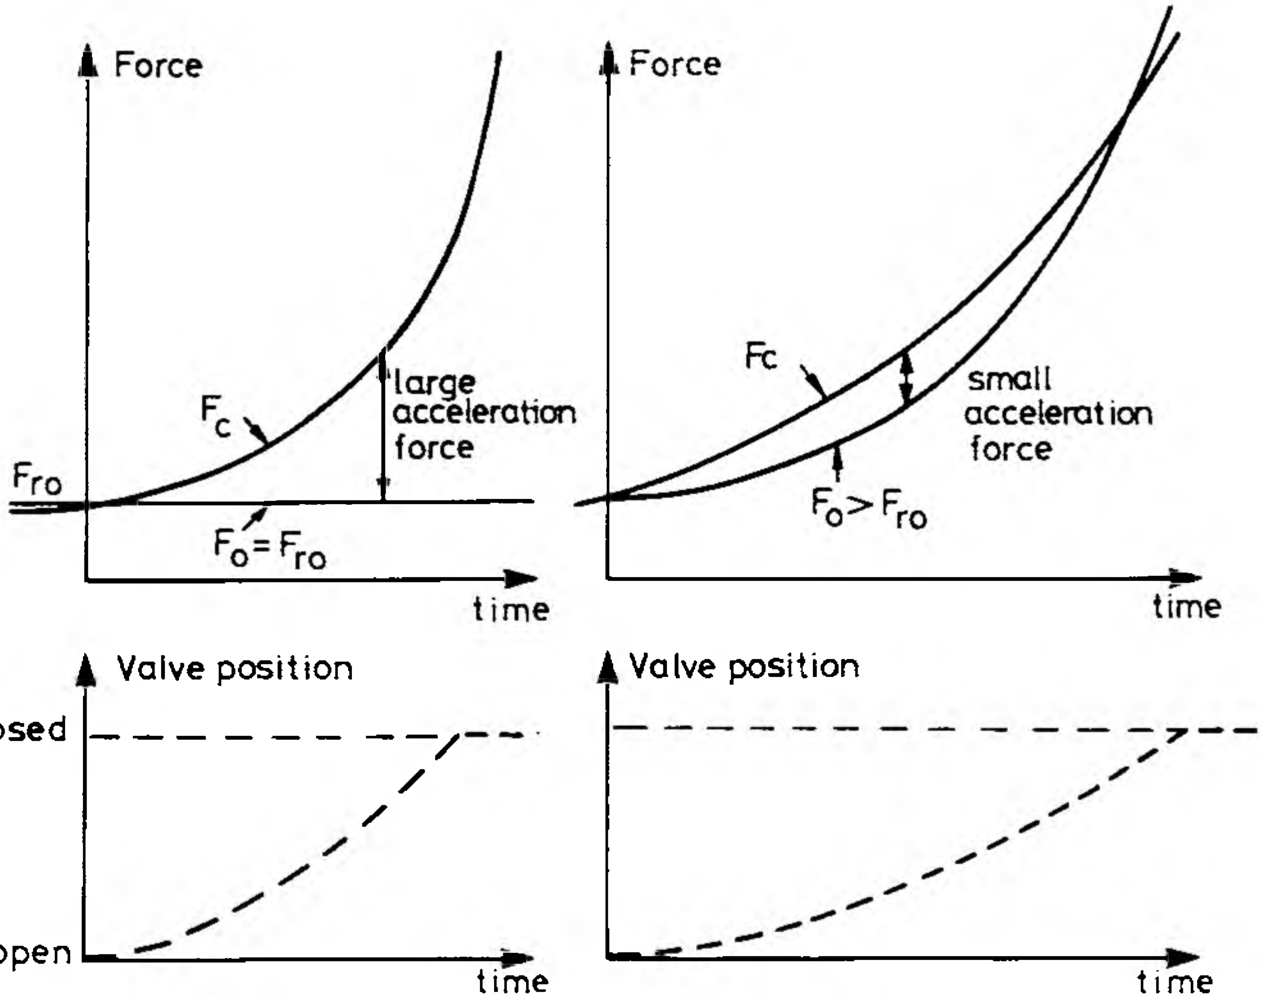
where f_{del} is determined by the ratio μ_i of Joukowski head to delivery head. The term $v_p^2 / 2gS$ is rarely greater than 100 cm, and $1 - f_{del}$ is less than 0.11 for all μ_i greater than 1.5 (see Fig. 10a). So L_r rarely exceeds 10 cm.

Excessive recoil is that which draws so much air back into the drive pipe that it is not swept out during the ensuing acceleration phase. Whether this occurs depends on L_r and the pump design. It is least likely to do so if the pump discharges under water or rises more than 10 cm from its drive pipe entry to its delivery valve. Conversely, air entrainment is most likely when the delivery head is near the maximum possible for the drive flow chosen (μ_i < 1.5), or when a high-flow pump has a low-set impulse valve.

Failure to reopen due to lack of recoil occurs when the pump is most efficient: $f_{del} = 1.0$ at $\mu_i = 2$ or 4 or 6 etc.. This is illustrated in Fig. 10(b), where a zone of width $\Delta\mu_i = 2\delta$ is shown around each even value of μ_i. Within this zone the pump may fail to reopen. Equation [18] indicates a relationship between δ and the head-ratio R, suggesting serious probability of failure to reopen at low head-ratios. However *any* such failure is inconvenient. During start-up, when a pump generally fills up a delivery pipe from the bottom, the Joukowski ratio μ_i falls with each pump stroke. Such start-up requires the continuous attention of an operator if the pump may stop whenever μ_i is close to an even number. Even worse the final full delivery head may correspond to $\mu_i = 2$ so that reliable operation is impossible until the pump is slightly retuned to change Q_p and (via the Joukowski head h_J) μ_i. Equation [18] is a special case of the more general relation:

$$\text{width of failure zone } 2\delta = 2(H - H_{ro})/(h' - H) \qquad [24]$$

So ideally we should like the head against which the impulse valve will just reopen (H_{ro}) to exceed the drive head H. The advantages and costs of raising H_{ro} may be observed from the following graph of impulse valve closure. Note that H_{ro} may be re-expressed as a force F_{ro} keeping the valve closed ($F_{ro} = H_{ro} \cdot \rho g \cdot$ valve area) which a spring force or the valve's weight must just equal and oppose.



(a) Weighted valve **(b) Sprung valve**

Fig. 12 Forces and position variation during impulse valve closure
(F_C = closure force due to water drag; F_O = opposing force; time is measured from start of valve closure)

Thus the use of a sprung impulse valve whose 'opposing force' rises as the valve closes (Fig 12(b) can give a much higher figure for F_{r0} and hence H_{r0} than a merely weighted impulse valve will (Fig. 15(a)). A pump with the former is therefore less likely to stop, provided the valve's much slower closure doesn't cause other problems.

For the pump designer many issues - and desirable proportions - have been raised in the course of the analysis. Impulse valve and delivery valve losses should be tolerable at maximum drive flow. The last stage of impulse valve closure should take less time than that for a shock wave to traverse up and down the drive pipe. An impulse valve that will reopen against full drive head should reduce the chance of maverick operation. Certain design details cannot however be decided using the algebraic models of section 3. In particular the dynamics of the opening and closing of the two main valves require more specialised models to predict velocities and accelerations, peak stresses, back leakages and so on. Time step simulations have application to these tasks.

4.2 Calculating Pump Characteristics

It was argued in Section 2 that the pump and its drive pipe should be treated as an inseparable system for performance characterisation. The many equations of section 3 can be combined to obtain performance predictions of varying degrees of accuracy. It is difficult to avoid iterative calculations since the equations are numerous and complex. However an approach of adequate accuracy for practical purposes is as follows:

A peak flow Q_p is selected.

The maximum possible flow Q_∞ is calculated from H, S, h', A, k_d and k_p.

The normalised peak flow $\lambda_p = Q_p/Q_\infty$ is obtained and used to predict acceleration efficiency η_a and mean acceleration flow $\overline{Q}_a$. The Joukowski flow is obtained (Q_J) and used to obtain the Joukowski ratio $\mu_i = Q_p/Q_J$. A modified value Q_p' may be used if the acceleration-to-delivery transition efficiency η_{ad} can be estimated. From this ratio μ_i the energy delivery fraction f_{del} can be derived and any possibility of malfunction can be identified ($\mu_i = 2, 4, 6$ etc. $\mu_i < 1.5$).

From Q_p and delivery valve geometry, the delivery valve efficiency η_{dv} is estimated. The efficiencies and energy fraction are combined using equation [21] to give an overall efficiency η. The drive flow Q_d is obtained to varying levels of accuracy using Q_a or better equation [23]. Delivery flow q can now be calculated using equation [1].

Using a sequence of values for peak flow Q_p, a table or graph of delivery flow q versus drive flow Q_d is thus obtained. Other equations can be used to obtain cycle time, although this is rarely tabulated.

4.3 System Design

System design can be undertaken using performance charts or graphs for a range of pump/drive pipe combinations: the lowest-cost option capable of meeting a specification should be chosen. This approach requires many such graphs and the ability to interpolate reliably between them. Alternatively, likely candidate systems can be evaluated using a computer programme to generate delivery flow versus driveflow loci. Unfortunately neither of these approaches fits the situation frequently met with in the field, where computers are remote and water technicians not very numerate. Rules of thumb also have their place.

Consider the difficult task of choosing drivepipe diameter and slope. The drivepipe pressure rating needs, incidentally, to be about twice the *delivery* pressure to limit fatigue failure and the drive pipe should be able to withstand negative heads down to $-H$.

Slope S is usually site-constrained: it is difficult to lay a pipe steeper than the valley side. Low slopes are expensive (the drive pipe is long) and inefficient. Very high slopes give a high operating cadence (and thus high noise and a short pump life), low efficiency through increased frequency with which valve closure losses occur, and possibility of impulse valve malfunction due to too short a drive pipe.

Too large a drivepipe diameter D result in excessive drivepipe cost and peak velocities too low to generate the required delivery pressure. Too small a diameter results, for a given drive flow, in excessive acceleration phase losses and low overall efficiency.

It has already been argued that for reliable operation the Joukowski ratio should not fall below 1.5. This can be expressed as a *upper* limit on pipe size. Noting that at $\mu_i = 1.5$, $Q_p = 3Q_d$ and $A = 0.67\ c\ Q_p/g\ (h-H)$, we need to know the effective wave speed c to derive any specific rules. For steel pipes we should use c = 1400 m/s and for PVC pipes (of wall thickness one-tenth of their diameter) c = 400 m/s. These lead to the rough rule of thumb.

ROT.7 "For steel pipes, drive pipe diameter in mm should not *exceed*
$600\sqrt{\textit{drive flow in litres / sec} \div \textit{delivery head in meters}}$;
for PVC pipes replace 600 by 300"

A *lower* limit for pipe diameter in combination with pipe slope can be obtained by ensuring Q_p/Q_∞ does not exceed 0.8, yielding $Q_\infty/Q_d > 2.5$. However Q_∞ is the maximum flow obtained when drive pipe and pump together are left to run with an open impulse valve. The flow through an open-ended drive pipe alone, laid down the slope, would be higher. By a series of assumptions one can arrive at a rule:

ROT.8 "The drive pipe diameter and slope must be sufficient that its flow open-ended, the pump having been removed, is at least 3.5 times the intended drive flow".

4.4 Tuning

The contribution of algebraic models to achieving good pump tuning is not very great. Tuning of ram-pumps on site is not essential, as a pump set for a mid-range drive flow will operate on most sites. Indeed with some operators the provision of a means of tuning may be unwise: the pump is then vulnerable to gross maladjustment. Where the pump is tuneable, by variation of the flow Q_{cc} at which impulse valve closure begins, heuristic methods are often adequate: the operator finds by experiment the setting that maximises delivery flow within the limits of available source flow, Only when several pumps are operated in parallel is this trial-and-error approach likely to prove difficult.

An operator usually has little data with which to work. On many sites the pump cycle time is the only easily measured variable; drive flow and waste flow may be inconvenient to gauge, delivery flow is measurable but only at the delivery tank sited many minutes climb away from the pump house. Unfortunately cycle-time is not simply related to the flow variables of interest. Figure 13 shows cycle time, drive flow and delivery flow as functions of Joukowski ratio μ; itself a measure of peak flow and hence of tuning. The plot is for a representative system and displays considerable complexity.

No simple tuning rule for finding a high efficiency point (such as $\mu = 2$) by observing cycle time suggests itself.

With knowledge of site parameters and in particular of drivepipe diameter, an installer or manufacturer can pre-set a pump's tuning Q_{cc} to a suitable value, or can constrain it to lie within a particular range of flows. A suitable range might be that which makes μ_i lie in the narrow band $1.25 < \mu_i < 2$, or the wider band $1.5 < \mu_i < 4$. The lower limit prevents the pump being tuned to give negligible delivery or to entrain air. The upper limit prevents use of unnecessarily high drive flow and also protects the pump for excessive over-pressures should its delivery become blocked. The optimum range will depend on the ratio of open-pump flow Q_∞ to Joukowski flow Q_J.

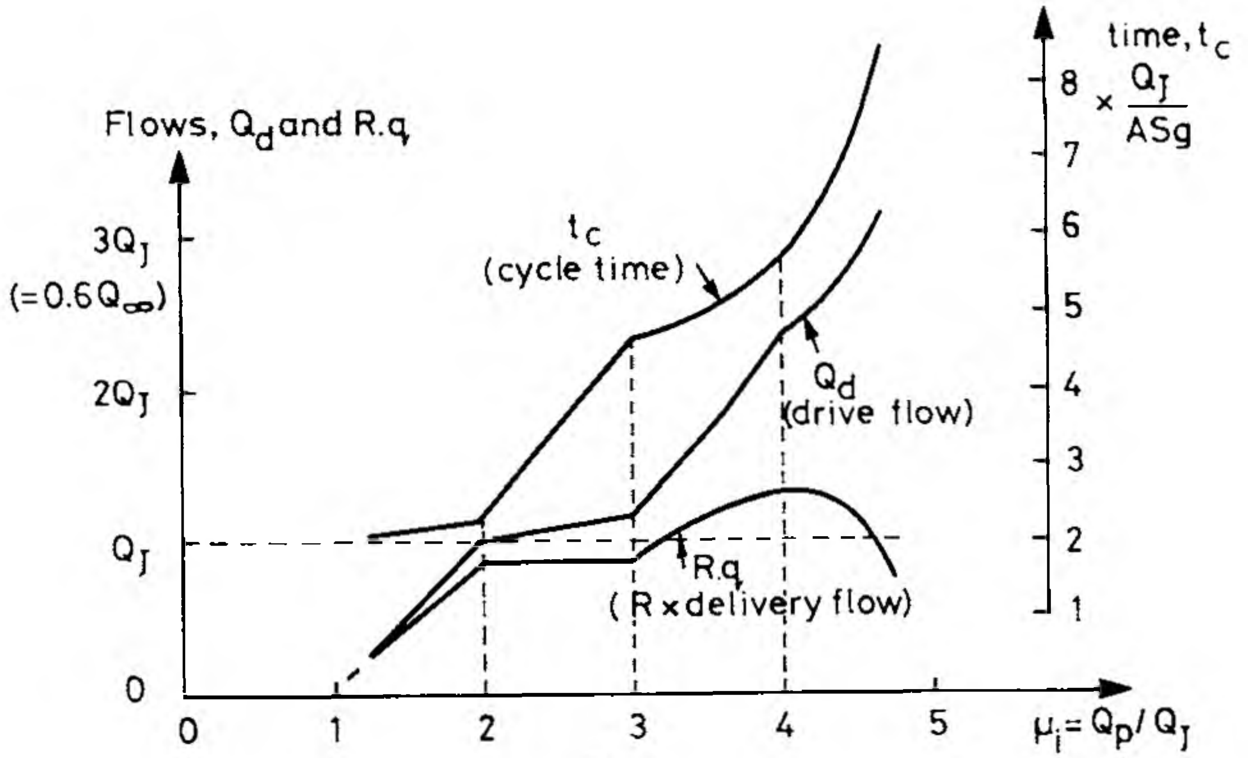


Fig. 13 Driveflow, delivery flow and cycle time variation with tuning

(Q_J is flow just sufficient to attain delivery head, t_c is cycle time, Q_d is driveflow, q is delivery flow, assuming $Q_\infty = 5Q_J$ $R = 20$ $\eta_{dv} = 0.9$)

5. CONCLUSIONS

The three main phases - acceleration, delivery and recoil - of a ram-pump cycle have been modelled using equations of manageable simplicity. Several rules of thumb have been derived. The paper has throughout stressed the application of algebraic modelling to solve common problems in system design and tuning.

Equation [1] in section 3.2 represents the level of modelling usually employed by manufacturers in the preparation of data sheets. This paper has shown that its assumption of constant efficiency is unreasonable and its objective of describing the performance of a pump in isolation (from its drive pipe) is unrealistic. Such simple models are incapable of explaining many phenomena important to pump users. Through the use of two ratios ($\lambda = Q_p/Q_\infty$ and $\mu_i = Q_p/Q_J$) much more can be explained, even though the peak flow Q_p itself can not be readily measured. The several approximations and omissions in the model developed make it inadequate for some aspects of pump design optimisation, for which complex simulation models are preferable.

LOW COST RURAL TRANSPORT FOR SIERRA LEONE

TH Thomas and CE Oram

0. Abstract

This short paper reviews the demand for rural transport services and discusses the present inadequacy of such provision in Sierra Leone. It examines the main transport modes that might meet its transport needs and concludes that both animal power and assisted human-powered transport have the potential for a significant contribution. The focus of the paper is on the provision of vehicles rather than on the provision of roads and paths, and various interventions are suggested relating to the use and manufacture of such vehicles. In this context manufacturer training, marketing and vehicle design, are discussed. It is concluded that small town manufacturers and artisans are the most appropriate sources of vehicles for rural transport and that their needs for profit and return on labour must be met if there is to be any hope of sustainable development.

1. Introduction and general comments

Transport is essential to rural development and future prosperity. But in most countries in sub-Saharan Africa, from the Sahel to the Zambesi, the cost and inconvenience of transport for farmers is very high. Each person in a rural community in Africa is likely to spend an average of over two hours per day on transport tasks, despite walking less than 10km with a payload of only 20kg or so. This represents a poor level of effectiveness when compared with some of the more sophisticated transport methods shown below. Such ineffectiveness adds to the burden already carried by the farming community and severely inhibits improvements in productivity and hence development.

Improved transport is needed to allow ready movement of materials and tools around the farm to improve the timeliness and efficiency of farming operations and reduce wastage of crops. Farmers often generate surpluses which cannot command proper prices because the goods cannot be sold in a favourable market. Such produce must rather be disposed of at much less advantageous rates by the nearest roadside, itself often at such a distance that spoilage occurs. (Highly perishable goods may even be unmarketable.) In Sierra Leone the paucity of roads and the general absence of suitable vehicles makes these problems more acute than the African average. Clearly the rural community will operate at a depressed financial status, when compared to urban areas, and in such situations it is difficult to accumulate capital which might be invested in improved infrastructure and farming inputs.

One of the major factors contributing to the shortage of transport is the cost, and in particular, the initial outlay on vehicles. Farmers are understandably reluctant to increase their risk as this may increase their exposure to money lenders and credit schemes. Cheaper transport modes, of greater effectiveness, are likely to make smaller demands on scarce capital and allow faster and more thorough development. With limited resources and skill levels, most countries find however, that provision of suitable vehicles is difficult. Little effort has been invested anywhere, either in the developed or the developing world, into designing low-cost and, more particularly cost-effective vehicles, for use in the rural areas of developing countries.

What is required are vehicles which can be made locally and repaired locally. Many studies have suggested that mutual proximity benefits the user and the producer of goods in rural areas, by facilitating dialogue between the two (Starkey, 1988, Kanu, 1988). Users become aware of the limitations of the technology, and producers become familiar with the needs of the users and adapt designs to suit local conditions. Regarding the types of vehicle most beneficial to rural dwellers; analysis of the data in the table below suggests that animal carts represent a considerable increase in transport power or effectiveness over head-loading. They are relatively cheap and cost effective. They cannot compete however, with motorised transport, if sufficient capital is available to purchase it.

Whilst this position paper attempts to give a general view of low-cost transport in sub-Saharan Africa and of transport in Sierra Leone in particular, it concentrates upon the animal cart because this is the most powerful and accessible innovation which could be introduced into the country. It is recognised however that a major constraint to the growth of this transport mode is the very low numbers of draught animals in the country and the cultural resistance to their use. Only about1% of the national herd in Sierra Leone is used for draught purposes and by about only 5% of the farming population (Kanu and Sankoh, 1990).

A danger during any period of change is that the interests of women will be overlooked and that they will be left worse off as a result. To combat this danger, one trend over the last few years in other countries, has been to emphasise donkey-cart rather than ox-cart development because there is generally less resistance to women handling equines than bovines. Women are then able to retain a stake in an income generating activity. Sierra Leone has very few working equines and so it is likely that other measures will have to be taken to protect womens' income in the areas affected by animalisation schemes.

2. Present Transport Use

There have been a number of studies of rural transport in developing countries, (eg Barwell 1985). About two thirds of the total transport demand in rural Africa is met by women headloading payloads of up to 30kg. Headloading occupies the average adult for up to three hours per day and represents a daily transport output of about 100kg.km. Three-quarters of trips are less than 6km in length, but they absorb major proportions of rural dwellers' time - perhaps 20% of the average women's active day. Table 1 below (Dennis, 1993) shows typical labour time demand and usage of rural transport and Table 2 (Adeoti et al 1989) gives an idea of trip lengths in a Guinea Savannah environment similar to that in some areas of Sierra Leone. Of the remaining one quarter of trips, most are less than 15km and are over unsealed (ie dirt) roads.

TABLE 1: Household transport statistics for rural Africa.

purpose	time input [hrs/year]	transport output [kg×km/yr]
domestic: firewood+water	600-1500	20 000-60 000
agricultural	200-450	6 000-10 000
social	200-600	zero payload

TABLE 2: Trip lengths undertaken by rural dwellers.

purpose	avg distance [km]	relative frequency [%]	proportion total travel distance [%]
to farm	3	70	23
to market	25	10	25
for domestic needs *	6	6	4
social and religious	45	10	40
medical, educational	30	4	8
total	11	100	100

* The figures for domestic purposes are low and may perhaps reflect the difficulty of obtaining data from women in an Islamic society.

Demand for transport in connection with farming activities is very seasonal and transport owners use various means of spreading out total transport demand over the year. Thus building and maintenance work, often requiring the transport of significant amounts of material, is undertaken away from periods of high agricultural demand and there is normally also a great deal of informal transport hire or borrowing and barter. Cart operators appear very conscious of their animals' condition and nutritional status and usually regulate the load they carry to reflect this. It is fairly rare to encounter a badly overloaded cart.

3. Characteristics of Present Transport Modes

The main transport vehicles or transport modes used in rural areas in Africa are shown in the Table 3 below. The values shown in the table are estimates, but are believed to be representative of West Africa. They demonstrate the power of the more sophisticated modes. (The column 'power' is deliberately included to highlight the somewhat irrational attractiveness of the more powerful modes). Not shown in the table is the ox-drawn sledge, which is generally regarded as being too destructive of road surfaces and is banned in some countries.

TABLE 3: Characteristics of rural transport modes.

transport mode	average payload [kg]	speed [km/hr]	'power' (payload xspeed) [kg.km/hr]	daily range [km]	capital cost [$_US]	total cost/ day* [$_US]	'power'x hrs/day /dailycost [kg.km/$]
human-powered							
head loading	15	5	75	15	1†	2.0	112
wheelbarrow	25	5	125	10	30	2.0	123
handcart	100	5	500	10	30	2.0	494
bicycle	17	12	210	50	100	2.1	420
animal-powered							
four pack donkey train	100	5	500	20	100	3.1	648
donkey cart	150	5	750	20	125	3.1	966
ox cart	200	4	800	20	150	3.1	1 280
engine-powered							
2-wheel tractor+trailer	200	20	4 000	50	2 000	6.7	1 490
mini-bus/ pick up truck	750	80	60 000	200	10 000	20.5	7 320
lorry	7 500	70	525 000	200	50 000	64.5	23 300

* The daily cost includes the daily wages of an operator ($_US 2) or driver plus the cost of fuel/ feed and depreciation of vehicles.
† The price of a pair of shoes.

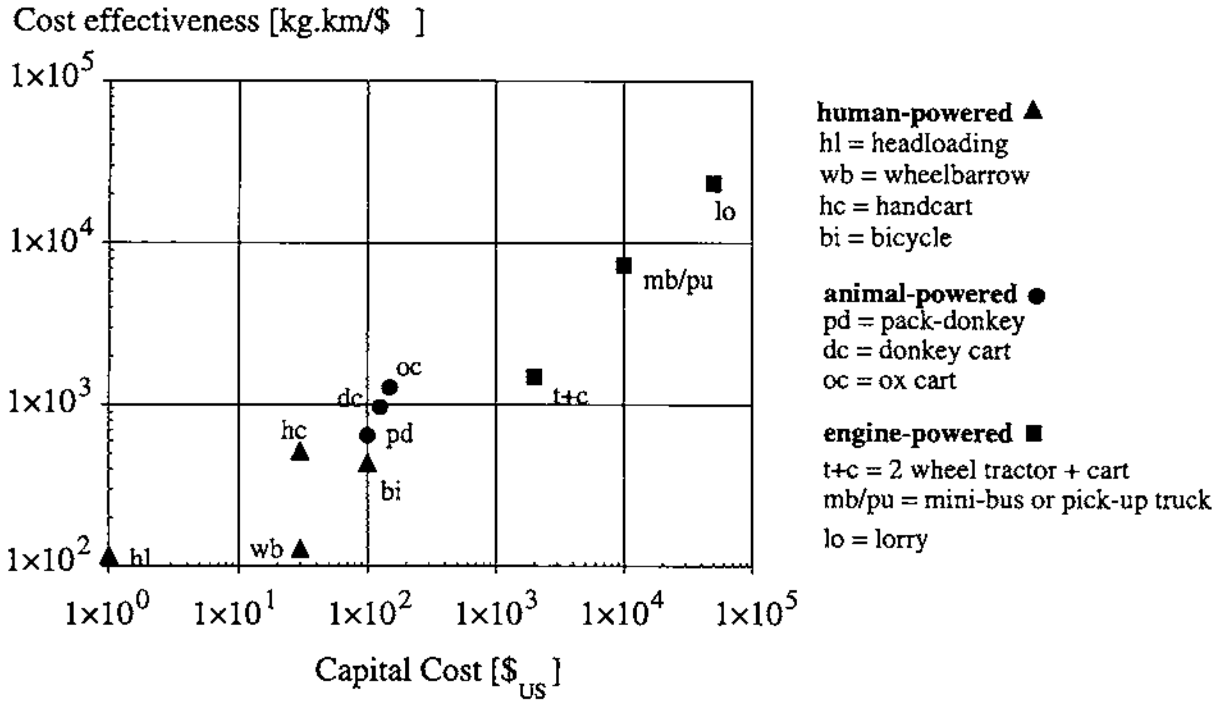

Figure 1: Cost effectiveness versus capital cost for a range of transport modes.

The graph below demonstrates that the cost-effectiveness of transport (the typical daily output divided by the cost per day) rises with capital cost. In other words more capital-expensive transport modes are more cost effective. This confirms the commonsense view that it is probably the high capital cost of more powerful transport devices that mainly prevents their more widespread use.

The graph clearly shows a progression in productivity and cost effectiveness from human to engine-powered vehicles. It does not however take into account the nature of the transport demand or the environment in which transport operates. For the great majority of trips, as illustrated by Table 2, the apparent economics of using motor vehicles are not obtainable for a number of reasons. Loads are usually small and users must wait before vehicles become available, suitable roads and tracks may not be available, and the costs in the table do not include maintaining vehicles in areas where spares are not available at any reasonable price.

The following three sections examine human, animal and engine-powered vehicles in turn, to identify opportunities for improvement in their performance, supply or operating economics.

4. Human Powered Transport

Head loading has been mentioned elsewhere as being a large user of time; it is also suspected of causing significant injury to neck and spine. Damage to neck joints may manifest itself later in life with arthritis and deformity. Support of a large load, whilst not requiring energy in a physicist's theoretical sense, involves considerable muscle tension and therefore much energy use and fatigue.

A fairly recent innovation, in many urban areas, is the introduction of wheelbarrows, usually operated by children. Wheelbarrows are able to carry higher loads over reasonable surfaces with slightly less chance of physiological damage to the user than headloading methods. It should be understood that wheelbarrows are deliberately designed to load the operator through his/her hands in order to provide better control and grip on poor ground surfaces. Patented and novel devices, such as the Chinese wheelbarrow, claimed by some agents to reduce operator fatigue by reducing handle forces, may not therefore secure an overall benefit.

Two-wheel handcarts are also used in large numbers in African towns where road surfaces allow low traction forces to be effective. In rural areas the narrowness of paths as well as their roughness discourages their use. Two types are widely in evidence; the water bowser and the heavy wooden-body cart. The former appears, like the wheelbarrow, to be a relatively recent innovation. Two light motorcycle wheels support a body made from angle iron and steel reinforcing bar and carry up to 500 litres of water, propelled by several children. Design of the the latter carts is very similar to that of oxcarts, but payloads are inevitably less. The economic status of these carts is, if anything, lower than that of animal carts and most are made from scrap vehicle components - very few are made new.

Bicycles are popular where road surfaces are adequate and where they are affordable - prices are usually high by European standards. Punctures in very worn and old tyres are frequent. It is not in general realised how variable is the susceptibility of rubber to puncture - old brittle rubber may be one thousand times more likely to puncture than new rubber. The major benefit from bicycle use is increased speed - bicycle adaptations to carry high loads do not appear very successful. By contrast with the Asian situation there is very little if any use of cycle rickshaws and cycle trailers and this probably arises from the poorer road conditions and the greater distances. Indeed the spread of rickshaws into the rural areas of India followed the progress of rural road building.

5. Animal Powered Transport

5.1 General Characteristics

The introduction of animal power into most of sub-Saharan Africa, with the exception perhaps of Ethiopia, is a phenomenon of the twentieth century. Rural dwellers in many areas are still unfamiliar with the care and feeding of animals and this, and the problems of harnessing and disease, have acted to restrict their introduction. Where these problems can be overcome, animal-powered transport is usually a cost-effective and appropriate technology by which to improve rural productivity. This has been shown by its success in certain other countries in west Africa - Senegal and Niger, for example.

Whilst animal traction has not, in the past, been popular with the farmers of Sierra Leone because of cultural attitudes and government policies (Bangura 1988), the realisation that there is little alternative to their use is beginning to gain currency. Technical and engineering literacy among many farmers is at only a modest level and there is considerable attraction in a device that 'makes and repairs itself', and which is able to use almost any plant material as fuel. Draught animals too are unusual in another respect: few industrial products appreciate in value, but that is the case with a draught animal. Up to about ten years of age, animals gain weight and add value - the European taste for young tender meat is not common in Africa.

Many different animals are used for draught purposes including goats, camels, horses and buffalo, but the main ones are donkeys and oxen. These two are sufficiently disease resistant and adapted to tolerate heat stress, to be widely popular. Draught animal physiology and performance has been investigated by a number of expert teams worldwide and quite a good understanding of their behaviour, characteristics and needs is beginning to be assembled. Draught animals cannot usually eat whilst working and may require high quality supplementary feeding if they are not to lose weight during periods of sustained labour, such as at harvest time. The nature of this supplementary feeding and its quantity have been investigated in a number of different countries and animal breeds. A fairly recent innovation to be investigated by modern scientific methods is the use of cows as draught animals even when pregnant. Such comprehensive use of an animal requires a considerable skill and understanding of its physiology, but does appear to give an improvement in the economic return from many animal breeds.

Until the turn of the century in the now industrialised countries, animals were not only used for transport purposes, they were used to provide shaft power for both portable and stationary machinery as well. Animal power units (APUs) or animal 'gins' were extensively used to drive hay elevators, grain kibblers and flour mills for example. These traditional machines are unsuitable for production in Sierra Leone and most other countries in Africa, but the Sierra Leone Work Oxen Programme has been investigating some of the recent German assisted attempts to design locally manufacturable animal power units. The importance of APUs to Sierra Leone's transport programme lies in their potential to increase year-round utilisation of animal power and thereby improve the economics of operation. Keeping animals in work throughout the year preserves training and fitness, which are otherwise lost quickly. However the present and future supply of animal carts is probably the key determinant of whether animal-powered transport can be expanded in Sierra Leone.

5.2 Present Supply of Animal Carts

Farmers' carts come essentially from three sources:

i) manufacturers outside the country, operating in the international market, who produce new carts, either assembled or more often, in knocked-down form;

ii) urban manufacturers in-country, with perhaps 50 employees, also producing new carts;

iii) local artisans who produce carts using scrap automotive wheels, tyres and axles for the moving parts, and new timber and steel for the body.

International manufacturers produce high quality products, sometimes at attractive prices (one UK/Italian supplier is quoting about $\$_{US}80$ for a 2½ tonne axle suitable for fitting to animal carts and equipped with commercial roller bearings). International suppliers are able to benefit from a ready supply of materials at the best prices; they are able to submit credible tenders to international development organisations and thus obtain large orders; and they are able to smooth their production over many different markets, probably not all experiencing poor economic performance at once. But they do have to support a large international sales team and cover high distribution costs both internationally and in-country. Furthermore they cannot afford to produce anything less than the highest quality, which may well not be affordable or attractive to farmers. (Honouring warrantee/guarantee failures with poor communications is very expensive.) There is another important point too: because of the high capital costs an essential component of any improved transport scheme involving major imported products such as carts, is credit. Credit managers are not farmers and engineers, but often end up deciding which products to support, thus distorting any local preference or opinion. The result is often inappropriate products, lack of sustainability, local debt and high foreign exchange costs.

Local supplier companies (type ii above), are usually able to benefit from the lower labour costs in-country, but are often faced with material prices above those paid in industrialised countries because of local import duties. They do not have the expensive international sales team however, nor the international transport costs, but they are still faced with in-country communications difficulties and distribution costs, which may render the concept of dealerships and spares networks completely unworkable. They are able to make lower quality and cheaper products and those more appropriate for local conditions and tastes, but the quality is often reduced more than the price.

The availability of scrap automotive parts in developing countries for cart production is usually poor and scrap may even be imported from industrialised countries. There are additional problems with the quality and methods of use of such components. Although the loads and speeds to which these scrap components may be exposed in animal carts is usually within the original design envelope, such components are often badly worn or partly broken, and such damage may be compounded when the parts are adapted for cart use. A very common procedure for example, with scrap vehicle axles for animal carts, is to remove the 'banjo' unit - the central final drive unit and differential - to lighten the axle and reduce friction. Often the hole is not covered, leaving the remaining bearings unlubricated and exposed to abrasive dust. More significantly, these bearings are not designed to carry wheel loads without the support of the banjo unit bearings and consequently they fail fairly quickly. The poor supply, and the consequent high price of scrap, has acted as a lid on the activity of indigenous carpenters and blacksmiths engaged in the cart construction business.

Cart bodies built by local artisans are usually of fairly complicated design - perhaps attempting to copy the sophisticated products which their customers would like to obtain from overseas - but construction is often poorly executed, with the result that overall utility and longevity is low, whilst construction costs and times are high. Considerable improvement could be made here, but only if there is good communication between customer and user. The education and training of users is necessary both to help them make best use of what is available and for them to understand the costs and difficulties of making what they want, as opposed perhaps to what they need.

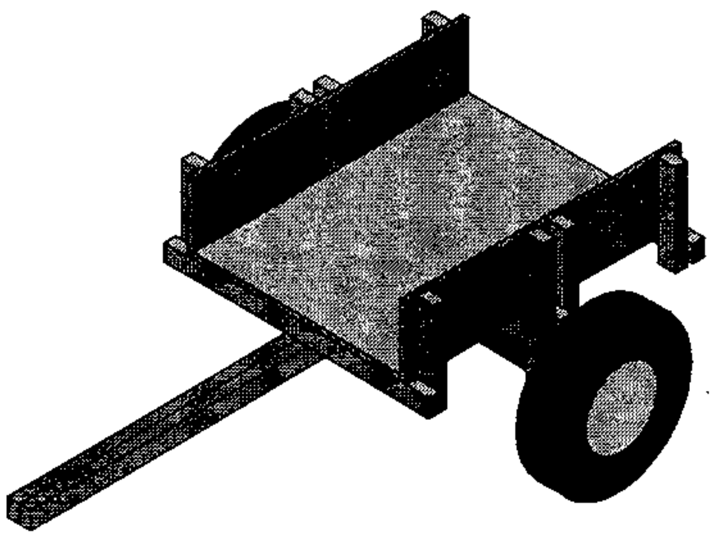

Figure 2: DTU low-cost wooden oxcart with clenched re-bar fixings.

5.3 Animal Cart Design

Current standards of design of animal carts are fairly low, which may arise from a variety of causes. In general, there is at best, only a very weak market; purchaser choice is almost invariably very restricted, and price is a very poor indicator of quality. Most purchasers appear technologically unsophisticated and unlikely to be able to judge desirable qualities in their tools. There is a massive lack of what, in the industrialised countries, would be called salesmanship, so that communication between customer and manufacturer is poor or non-existent. The producer does not know what is wanted or needed, and reluctantly or otherwise, must guess. The user is unaware of what is expensive and difficult to produce and, if asked, requests adjustability and complicated features. The result is expensive, inappropriate and inefficient products.

Compounding these difficulties is the need of the manufacturer to avoid failure and a bad name. There is thus a reluctance to try lightening, cheapening or unconventional features and no natural mature product can develop as a result. Where there is intervention, in the shape of animalisation programmes or the like, the outside scheme administrator cannot afford failure either and buys his way out of it with expensive products, often with imported components which need credit arrangements and foreign exchange.

Only a very few organisations have devoted any significant effort, whether to quantifying existing standards, to measuring needs, or to developing guidelines for carts. Recently however there has been activity in Zambia (Dogger, 1990) and Malawi (Malawi Bureau of Standards, 1986), which has measured cart usage in terms of distance travelled and has developed standard tests for durability and strength.

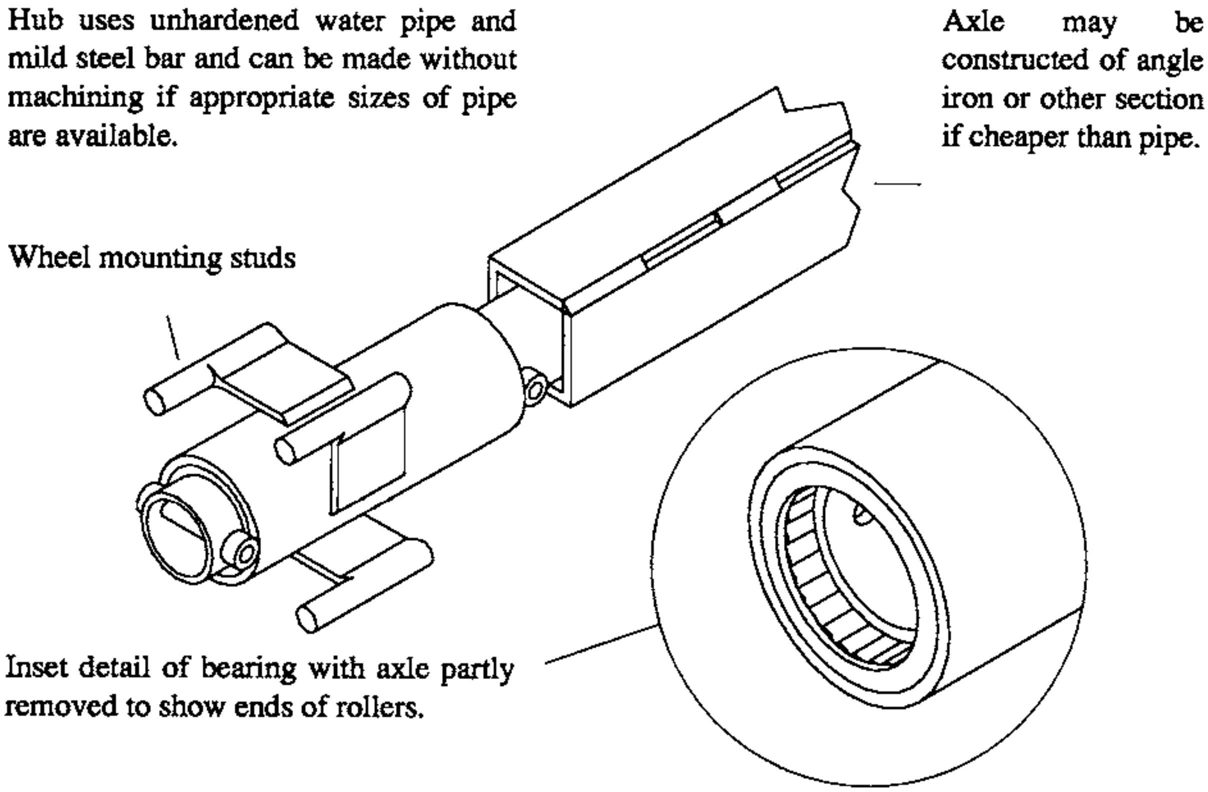

Figure 3: low-cost axle, rolling element bearing and hub for animal carts.

There exists no clear understanding or rationale for even the most basic requirements of cart design including:

- lifetime of running gear (wheels, axles and bearings),

- longevity of bodies,

- height of load trays (oxcarts are usually made with low trays, whilst donkey carts usually have high ones),

- optimum load tray lengths and widths,

- the need for head, tail and sideboards.

High load tray height, and the consequent high load centre of gravity, might be expected to have an effect on animal fatigue in areas with poor road surfaces. Not only are animals then subject to changes in draught as the wheels traverse bumps, but they also experience rapid changes in vertical load. This is because of the offset between centre of mass and any retarding/ acceleration force acting on the wheel, this causing a fore and aft pitching effect on the cart. On the other hand low tray height may allow load wetting whilst fording rivers, and does not necessarily ease loading if the people engaged in loading must bend their backs twice; once to pick up the cargo from the ground and then again to set it down on a low tray.

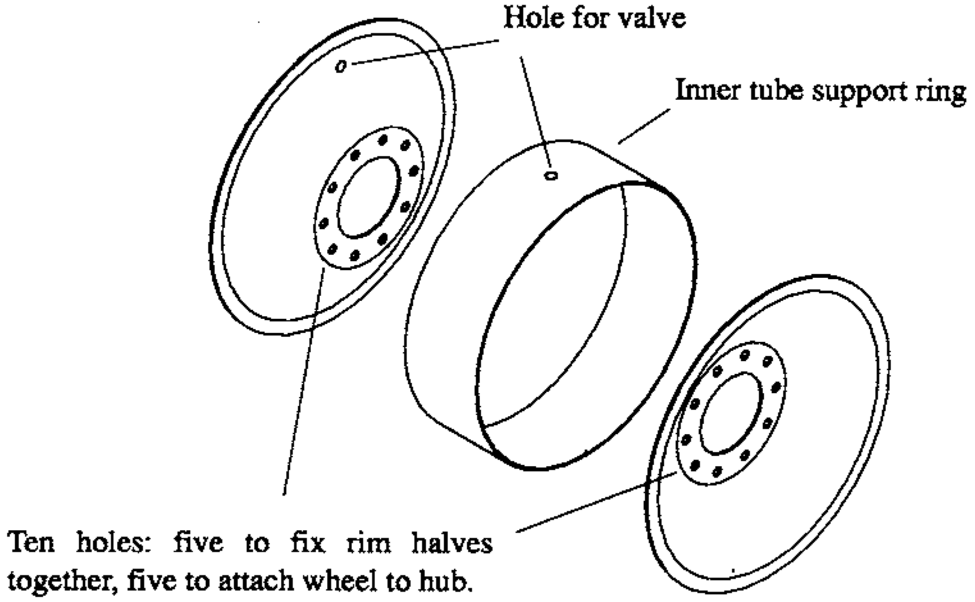

Figure 4: pressed steel wheels for local manufacture.

Notwithstanding the comments above regarding the rationale for existing designs, there appear to be several extant cart styles in west and southern Africa. Body height has already been commented upon, body lengths are around 1.9m, and widths around 1m. Most bodies are equipped with sides, sometimes removable. Wheels are generally pneumatically tyred and large sizes such as those from Land Rovers are preferred because of their reduced rolling resistance. Where there is no established axle supplier like the SISCOMA plant in Senegal, most carts use a scrap vehicle axle with a locally built body. In west Africa this is usually in timber but in eastern and southern Africa steel is preferred.

6. Motorised Transport

The most basic level of motorised transport in most countries in sub-Saharan Africa is the light motorcycle. Such machines, up to 200cc, are used both privately and for hire as taxis. Relatively little goods transport is undertaken by them, though it is possible to see things as large as beds and mattresses transported on them. Just as there are no rickshaws in Africa, so too are there very few of the light three-wheeled trucks and people-carriers seen widely in Asia. Another popular innovation in China and elsewhere, the single-axle tractor and trailer combination, is also almost unknown. Most mechanised transport in Africa is by mini-bus, pick-up truck and rigid lorry. Overloading in all vehicles is almost universal - thirty-five people plus baggage on a pick-up is commonplace, and vehicle breakdown as a result of this practice, poor maintenance and a shortage of spare parts, is frequent.

The most obvious potential improvement to motorised transport in Sierra Leone is to fill the gap identified above; that occupied by the three-wheeled light truck in India and the single-axle tractor and trailer combination in China. Such machines might be copied from Asian sources or developed specifically for Sierra Leone conditions and might be popular especially if the cost can be reduced significantly. A number of organisations are involved in improving or developing new small motorised vehicles for rural use and it is not inconceivable that a light single-axle tractor and trailer combination of adequate strength to withstand the abuse discussed above, could be marketed for $\$_{US}$1500 or even less.

7. Interventions

To improve the status of rural and low-cost transport in Sierra Leone a number of different interventions might be considered. A choice has consciously been made below to discuss only those interventions which require modest investment and which can be made in an incremental manner. For completeness some other interventions, which are considered to be less appropriate, are also listed. But the preferred interventions are as follows.

i) Introduce new designs and production processes appropriate to the needs of Sierra Leone, which will make local manufacturing of animal carts easier to carry out. A number of innovations in the design and production of animal and human-powered carts have been made in the last few years and promise to change the cost effectiveness of such transport significantly. Such improved products and methods include pressed steel and cast aluminium wheels, low-cost ball and roller bearings, some of which require no machine tools (Oram 1992), and low-cost body designs in both steel and wood using cheap fixing techniques. These modified cart designs can be produced with only two or three days labour per cart, and with a total cost including body, axle and bearings, and scrap wheels and tyres, of as little as $\$_{US}$ 50.

ii) Provide technical training of metal and woodworkers to complement these improved cart manufacturing techniques, This is very important if they are to advance and adapt the designs to cater better for their customers needs. The designs suggested above are specifically tailored to require little improvement in skill level to make adequate working products. Nevertheless training of artisans and manufacturers, including rudimentary book keeping, would be very beneficial to improve financial viability and longterm sustainability.

iii) Improve the communication between producer and user by providing training to extension agents and farmers. The market for low-technology equipment for the farming sector has already been described as poor, and the maintenance of a sales and spares network too expensive for companies supplying low-cost vehicles. As a consequence the customer often has unrealistic expectations and has no good idea of the cost of the provision of particular features.

iv) Undertake a programme of standards testing of vehicles and equipment by a government body and make the results widely available. The various parties would then become aware of inadequacies and should be able to make informed purchasing decisions. Such an approach is being followed in Zambia and has already been mentioned above.

These measures to improve animal traction equipment no doubt hinge on good working relations and cooperation with the Sierra Leone Work Oxen Programme and with its drive to increase the numbers of available draught animals in the country. The farmers' preference for engine-powered machinery is probably more difficult to support in the country's present circumstances and their technical proficiency may be too low to allow effective and sustained economical use of such machinery.

Other interventions considered less realistic or easy to introduce are listed below.

- Introduce extra credit facilities to allow farmers to buy already existing vehicles, either in-country or more probably, internationally.

- Introduce hire facilities through government or other agencies, so that suitable vehicles and resources are shared effectively over the rural population. This indeed was the method by which tractors were provided by the Sierra Leone government up until 1986 for field operations.

- Guarantee raw material availability to encourage the engineering and manufacturing sectors. But subsidies and special imports of materials are likely to be expensive and difficult to achieve, and to require intervention at high level. An easy-does-it approach using existing materials suppliers may be more productive.

It is the DTU's opinion that any sustainable improvement in rural transport must rest on local manufacture of appropriate vehicles. Interventions solely with users have not succeeded, nor those that assume the availability of imported equipment. Interventions must be concerned to improve the lot of farmer and that of the rural artisan and small town manufacturer. Because the linkage between the manufacturer and the user is often unsatisfactory, one feature of all interventions should be to strengthen them - to support what would normally be the work of the sales team.

8. Conclusions

The rural transport needs of Sierra Leone appear to be poorly met and to be a severe check on rural development. This document has set out to provide some analysis of the situation and suggest some interventions. Firstly the present transport needs in rural areas have been examined and an overview of present transport modes, including those based upon human muscle power has been given. Then animal-based transport modes, in particular animal carts, have been examined in more detail and small motorised options discussed briefly. The document closes with an examination of the interventions which might readily be made by an agent, either governmental or non-governmental, to improve rural transport provision. The report specifically avoids issues surrounding the provision of track (paths and roads) and notes the difficulties which have been (and might be) experienced with the provision of motorised facilities to the rural sector. It notes also the difficulties facing animal traction - the general lack of familiarity with draught animal husbandry and the poor status of animal power in the rural community.

Some points stand out from this analysis and from other considerations.

i) Improvements in rural transport demand increased availability of vehicles and lower prices. Any sustainable development in vehicle production must secure a profit for the artisanal and small town manufacturing sectors involved. Too often there has been a concentration on the requirements of the user and on how these may be satisfied, whilst relatively little effort has been expended on expanding local provision of equipment. Resisting urban drift, a problem in almost all the developing nations, requires that wealth be generated locally and spent locally. Income generated in the farming sector is better spent on local infrastructure, including transport, and on rurally produced vehicles if possible.

ii) An important cause of low profitability in the small manufacturing sector is the preponderance of fairly poor designs of vehicle, both from the manufacturing and from the use points of view. Significant improvements could be made here to reduce the cost of vehicles and their demand on foreign exchange.

iii) Inspection of the existing transport infrastructure of Sierra Leone suggests that, in common with much of sub-Saharan Africa, a significant gap in the capacity (payload×speed) spectrum exists. On the one hand, the major portion of the transport demand is met by headloading, whilst on the other, mini-buses, pick-up trucks and lorries, handle a much smaller proportion. Apart from handcarts, small and intermediate capacity vehicles (such as bicycles, rickshaws and three-wheeled motorised vehicles) are scarce or absent.

iv) A survey of the availability of small engines in Sierra Leone would be appropriate to determine the potential to supply small-scale motorised vehicle manufacture. There is little doubt that small motorised vehicles could be developed to provide a useful alternative to cheap but slow headloading and expensive but fast pick-up trucks.

v) Training of artisans and small entrepreneurs, particularly in elementary book keeping and marketing, is of great importance to their longer term survival, let alone prosperity. Their failure to understand the consequences of poor pricing and sometimes even of the difference between sale price and profit, means that artisans often struggle to cover their costs and renew their tools.

By these means, the DTU feels that the level of rural transport in Sierra Leone may brought up to a level from which more sophisticated development can take place. There is little doubt that the present difficulty experienced by farmers attempting to market their spare produce, acts as a severe constraint to their drive to improve their standard of living. Incremental and evolutionary changes such as those suggested in this document are probably the best way to help them.

PART A: ANIMAL CARTS IN AFRICA & THE BORNO CART.

SECTION 1: GENERAL COMMENTS.

1.0 Introduction.

This paper covers work carried out by HS Pearson and colleagues in northern Nigeria in 1993 and 1994. The paper is divided into two parts: part A (sections 1 to 4) discusses animal carts in general, the design options available for their various components, the particular circumstances affecting the development of the DTU Borno oxcart, and its main design features; part B is a set of full manufacturing instructions for the basic cart and some minor variations of it. We have written the paper because there is a dearth of detailed information about cart design and manufacture - especially information that identifies the context of use and manufacture and the assumptions underlying the approach used.

The DTU Borno cart incorporates a mix of novel and traditional features, and it draws heavily of course, upon designs used elsewhere. We believe it to be substantially cheaper than most alternatives of comparable performance. It has been moderately tested in the laboratory and in the field where production in significant volume started only in late 1993. However certain components were already well proven and others have been fairly easy to test for performance. Every reader of this paper intending to use the design elsewhere should compare their own context and objectives with those described below and feel free to adapt the design to their own circumstances. We believe nevertheless, that the specifications and constraints worked to in NE Nigeria are representative of those in many other parts of Africa.

1.1 Animal-Drawn Carts in Africa.

The use of animal-drawn vehicles for agricultural purposes in rural areas of Africa is relatively new when compared with the millennia-long history of using animals to pull carts, coaches and wagons etc in Europe and Asia. In Europe by the late 19th century, at the height of its development, the animal-drawn wagon required very skilled artisans for its construction. Though examples of these 'high tech' wagons can be found in some African countries (in particular the Republic of South Africa) the technology for construction never took hold amongst African artisans. Perhaps, because the technology took hundreds of years to develop in Europe, insufficient time was available to pass on the relevant skills into Africa before the motor vehicle swept away animal traction in Europe itself.

Some areas of sub-Sahara Africa will not support the use of animal-drawn vehicles because the topography is unsuitable, e.g. very hilly terrain, or because the area is not suitable for draft animals, because of disease. The most common impediment has been sleeping sickness transmitted by the tsetse fly, which is found in rain-fed forest areas.

Animal-drawn vehicles were first used in Africa at ports for the transportation of goods to and from ships. Even today, on balance probably more animal-drawn carts are used in urban areas than rural ones. There is little doubt that if they were more readily available and were cheaper and of better quality, animal-drawn carts would be used in much greater numbers by rural people.

In the absence of carts, rural people carry goods on their backs or heads - work often left to women. For moving goods and agricultural produce from the farm or homestead to the nearest town or motorable road, pack animals such as donkeys are sometimes used. Even where carts are available, women do not traditionally operate them, and still find themselves carrying loads.

After African independence, development organisations, in cooperation with African governments, have had many programmes aimed at improving designs of animal-drawn carts and increasing their availability to the poorer members of farming communities.

It has always been difficult to justify the expense of a purely agricultural cart, an investment perhaps larger than that of any other equipment the farmer uses (for example a cart can cost about three times as much as a medium sized plough). The ox-cart on the farm does not directly contribute to increased crop production as does theplough, where the relationship to an increased crop is more readily obvious. Moreover the farmer would require extra animals if he wished to use them for transport at the same time as preparing land.

But any farmer operating above subsistence level will need transport to get his/ her produce to the nearest town or line of road or rail. Outside the harvest season farmers living in villages or near towns often hire out their carts and animals, to be operated by a relative, for use in hauling goods other than traditional farm produce. Optimum use of the cart and trained animals is important in terms of income generation, but it does not eliminate the need to reduce substantially the costs of carts in Africa from their present high levels.

Since the moving of heavy loads, crops, water, building materials etc, forms a major part of the working life of African people, the importance of transport is self evident. Programmes aimed at cart development have generally been more successful than efforts in many other technologoes. The construction of animal-drawn carts is one of the few industries that can be found readily in most African countries and is undertaken by a broad spectrum of agents - from the blacksmith operating under a shady tree, to large urban companies.

Some African countries have a long history of cart making. For over sixty years in Madagascar, professional cartwrights have been making wooden spoked wheels with metal rims, of a type very similar to those which were formally made in Europe. In other countries, such as the Central African Republic, less skilled artisans with more limited tools, make solid wooden wheels by building up layers of timber and cutting them to shape. In recent years in most African countries however, parts from old motor vehicles have formed the basic materials for cart construction.

Many areas of Africa are heavily dependant on animals for transport and for agricultural purposes. Rural people in Ethiopia rely heavily on the use of animals for crop production - donkeys are extensively used as pack animals, as they are in semi-arid areas in West Africa. Because of the mountainous terrain and the lack of reasonable rural roads in Ethiopia, animal-drawn vehicles are usually used in urban areas. Donkey carts, horse-drawn two-wheeled taxis and flat-bed four-wheeled commercial carts, drawn by three horses are widely used here. The Sahel and Botswana are also rich in mule and donkey carts - in fact over much of Africa there is a realisation that animal traction is a sustainable technology that can deliver useful results without the costs associated with motorised transport. It is often forgotten that animal traction is new technology in many areas in Africa, ie it is *novel* and the detail of the technology must be developed from a low base. This present work is part of that technology development.

1.2 Main Types of Animal Cart in Africa.

Most carts now available in Africa originate from one of three sources:

- importation from overseas;
- importation of axle assemblies, complete with wheels and tyres, and sometimes including metalic body parts - wooden floor and sides added locally;
- local construction of entire carts using scrap parts from motor vehicles or simple locally-made bearing systems combined with wooden bodies.

The ideal would be full local manufacture using designs at various technological levels to suit different manufacturing facilities and financial situations.

Animal carts are only one of many types of non-motorised vehicle for carrying freight. Such vehicles may be grouped into three classes:

- Human-propelled devices such as wheel-barrows, water-carts, bicycle-carts and hand push or pull carts.
- Horse-drawn wagons and carts. Horses are not widely used in African countries because of disease and high feeding costs, also horses are not as robust working animals as donkeys and oxen.
- Other animal-powered vehicles such as donkey carts, ox carts and wagons for one or two animals.

This report focuses on the third class: donkey and ox-carts and wagons for use with one or two animals.

SECTION 2: THE DTU BORNO OX-CART.

2.0 Background to Development.

Borno State (the site of the activity for the present project) was until recently a very large part of Nigeria but has recently been divided into two smaller states, Borno and Yobe. The Northern part of Borno is dry Sahel Savanna containing three towns, many agricultural villages and Fulani (nomad) camps. The landscape is flat, the soil is sandy and the population density is quite low. There are a few sealed roads, but most villages are at least 10 km from the nearest one. Motor vehicles and motor fuel are quite plentiful in Nigeria (although there are serious fuel shortages from time to time), but there is a substantial demand for animal carts for local movement of crops, fuel, water and building materials.

In 1990 the Nigerian Government and the European Community established a large interlinked rural development programme in North Borno entitled the North East Arid Zone Development Project (NEAZDP). Improving rural conditions, services and incomes were major aims written into the programme. The DTU Borno Cart was developed out of cooperation between the DTU (Warwick University), a new Centre of Appropriate Technology (RAMCAT) at Ramat Polytechnic in Maiduguri (the Borno State capital), and NEAZDP field staff. NEAZDP has also been involved in increasing the number of draught oxen in the arid zone, training urban and rural artisans, and establishing a market distribution system for 'rural equipment'.

Carts are already made in several villages in the arid zone. They use wheels and axles from old pick-ups which are combined with a timber body. The supply is inadequate to meet demand and prices are quite high, yet the assemblers (carpenters) get a poor living from making them. Poor availability of components is a major constraint on output.

Nigeria has a substantial formal industrial sector and, even in relatively isolated Borno State, there are several machine shops in Maiduguri and a couple in smaller towns, such as Gashua. There is also some informal industry, including aluminium casting. Trends in the Nigerian economy discourage ongoing dependence on imported components and articles.

2.1 Specification of Borno Ox-Cart.

The DTU Borno Cart was therefore developed against the following specification:

- to be assembled by village carpenters who will also continue to produce cart bodies (an urban fabricated alternative body was also required);
- to carry loads of up to 1 tonne (1 metric ton = 1 000kg - very nearly the same as an Imperial ton) when pulled by two well fed oxen over flat sandy tracks:
- to use pneumatic tyres, as these are readily available, repairable and non-damaging to sealed roads:
- to make full use of Borno State's existing industrial capacity and not be heavily dependent on imported items:

- to cost less than $\$_{US}150$ to produce (in 1993):
- to reach volume production within 3 years (of 1991) and therefore to use techniques and components that are rapidly provable or already proven elsewhere in Africa.

This working paper has been written in the belief that these conditions in NE Nigeria are not markedly different from those in many other parts of Africa and therefore that both the design and our experiences from other countries will be of interest to organisers of animal drawn transport programmes elsewhere in Africa.

2.2 Interaction Philosophy during Project.

The technology-transfer philosophy adapted in this programme was:

- to aim at durable products of moderate price rather than short-lived ones of extremely low price;
- to employ the highest levels of technology sustainable in the area- for example to use jigs and fixtures to aid production, which themselves require a certain amount of skill to reproduce or modify;
- to upgrade the general skills of the casters, fabricators and assemblers involved in cart production so that they might also improve their range and output of other products;
- to encourage interchangability of parts by adopting local standards wherever possible - to multi-source components and avoid reliance on any single producer;
- to minimise dependence on imported materials particularly those whose market availability is erratic.

2.3 Output from Present Project.

The Nigerian economy and the institutions involved were subjected to many changes in the period 1991/94 and the objectives adopted in 1991 were not fully achieved. However the cart, whose manufacture as described in detail in Part B of this paper, had been produced in some numbers (over 20) by July 1994 and some hundreds of operating hours had not revealed any major problems in use. One manufacturer of axle sets, one caster of aluminium hubs and two cart body builders were trained and supplied with the necessary jigs and moulds to attain good quality production. However extension of the production of running gear (axles, hubs, bearings, wheels) to several competing urban manufacturers has still to be arranged, as has the training of significant numbers of village carpenters to incorporate the new cart components into their production.

SECTION 3: CART DESIGN OPTIONS.

3.1 Wheels.

In general, fabricators of animal drawn vehicles in sub-Saharan Africa, use second-hand wheels from motor vehicles. Such wheels often come attached to an old rear or front axle, which is also used in the cart's construction. Wheels entirely manufactured in African countries specifically for use on animal drawn vehicles are not so widespread. Several designs however, have been adopted and used with various degrees of success and popularity. These are identified as follows.

3.1.1 Solid wood wheels.

Solid wooden wheels with solid rubber tyre made from old motor vehicle tyre outer cover. This wheel is constructed using layers of flat planks that are cut and bolted together to give the required thickness of about 100mm - with the grain of successive layers set at right angles for strength. The diameter of these wheels is about 1 meter, or a little more. Bearings are likely to be of a simple bush type incorporated in the hub of the wheel.

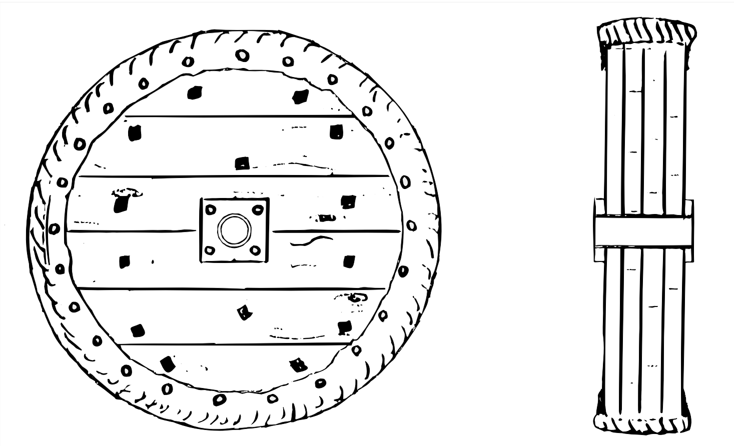

Figure 1: solid wood wheel.

Advantages: easy to make with readily available materials, simple to repair. Good for use over rough terrain or in remote areas where punctures to pneumatic tyres may be a problem to repair.

Disadvantages: there are limitations to the types of bearings that could be used successfully as a more complex hub structure would be required. On hard road surfaces the cart would ride very roughly, transmitting large shock loads to the bearings. The wheels are very heavy (100kg).

3.1.2 Fabricated wooden wheels.

Fabricated wooden wheels of traditional European design (Fig 2) with a heavy wood hub supporting wooden spokes fitted into a wooden sectioned rim with a narrow steel band as a tyre. The European spoke wheel is normally dished, whereas the Asian and African versions are not.

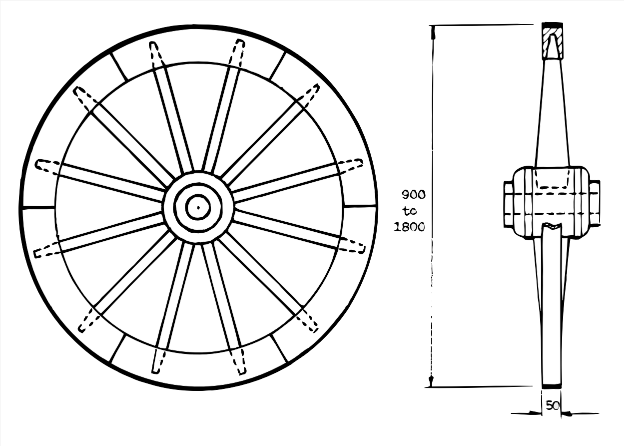

Figure 2: wooden spoked wheel.

This design of wheel has not been produced in large numbers in Africa. They were most prolific in South Africa where they were used by settlers from Europe, in particular the Boers, on their large ox wagons. Cruder versions of the spoked wooden wheel are however still made in some African countries. These wheels are usually fitted with thin solid rubber tyres cut from old commercial vehicle tyres.

Advantages: good for use in remote areas or over rough ground. Much lighter than solid wheels and more flexible under shock loads.

Disadvantages: requires considerable woodworking skill in manufacture and repair. 19th century European cart makers underwent a five year apprenticeship. Uses well-seasoned high-quality wood, that is becoming scarce in many countries.

3.1.3 Fabricated steel wheels.

Fabricated steel wheels with flat steel rims, 800mm to 1000mm diameter with a 100mm wide rim. Welded or blacksmith riveted construction, Figure 3. The fabricated steel wheel is still occasionally manufactured by large companies in developed countries for use on tractor-drawn agricultural equipment. Designs suitable for use on animal drawn carts have been produced in many African countries. Given reasonable construction they will last for many years without giving trouble, but the joints between spoke and rim can give trouble.

Advantages: fairly easy to construct and obvious.

Disadvantages: shock loads from bumps fed to bearings, fatigue of welds between spokes and rim, damage to road surfaces, noisy, bumpy ride.

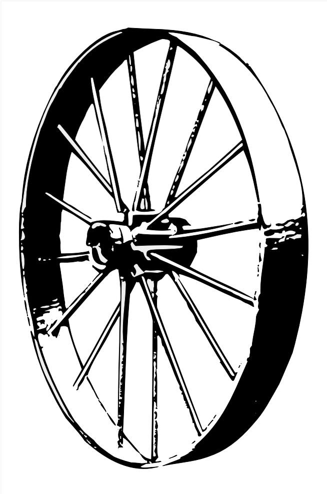

Figure 3: spoked steel wheel.

3.1.4 Fabricated all-steel split rim.

This rim is designed to be fitted with a commercial inflatable tyre, and is shown in Figure 4. Joseph Wirth, a development engineer working in Tanzania, designed a split rim fabricated wheel in 1965. Many hundreds have been manufactured in Tanzania and other countries since then and used on animal drawn vehicles. Very similar is the design by Intermediate (Technology) Transport. Both models use flat strips and round bars in their construction. Most popular sizes are for 16" (Land Rover) and 14" (Peugeot) tyres.

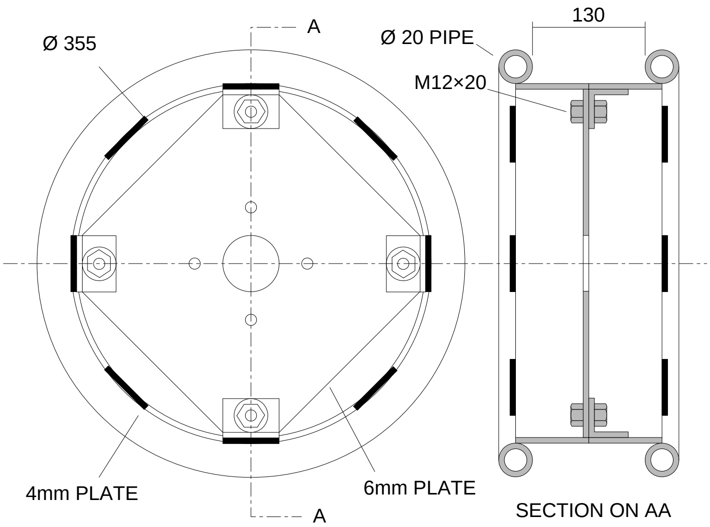

Figure 4: ITDG steel split rim for use with pneumatic tyre.

Advantages: split-rim design simplifies tyre repair. May be used with a selection of bearing and hub configurations. Use of pneumatic tyres gives an improved ride and a better rolling action.

Disadvantages: requires a workshop equipped with electricity for welding and drilling. The metal sections of the wheel have to be bent in a special, and quite expensive bending tool (e.g. that designed by IT Transport for the purpose) or a conventional rolling machine. The wheel is material intensive, using up to 5 different metal sections, and is heavy weighing about 25kg.

3.1.5 Pressed steel wheels for local manufacture.

This design (Figure 5) was developed at CAMARTEC in Northern Tanzania in 1988 and several hundred are in use. The construction of the wheel is very simple and is of a split rim design. Rims for two popular tyre sizes are available, 16" (Land Rover) and 14" (Peugeot).

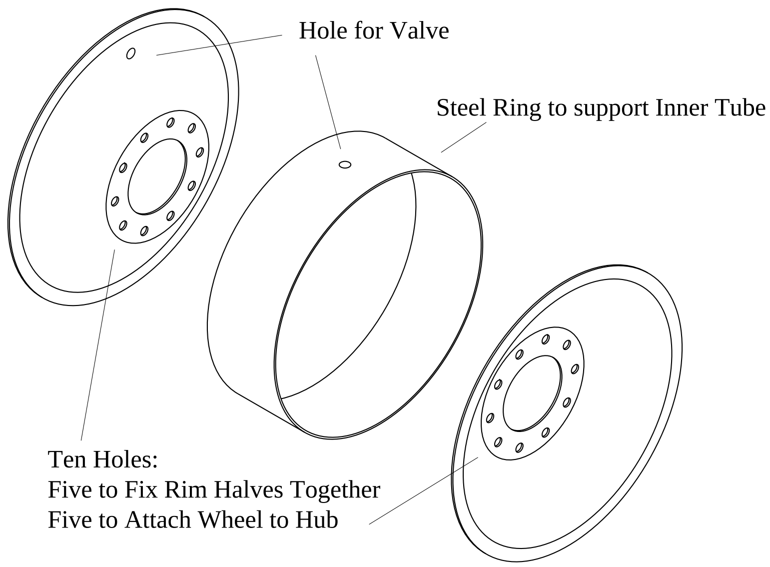

Figure 5: DTU pressed steel wheels for pneumatic tyres.

Advantages: split rim design simplifies tyre repair. May be used with a selection of bearing and hub configurations. Use of pneumatic tyres gives an improved ride, a better rolling action and lower shock loads on bearings. One size or material, 3mm steel plate, is used throughout the wheel's construction. Simplicity of design will allow many different sizes to be made using the same material and methodology. Adapts easily to small or large batch production. Light weight 12 kg.

Disadvantages: Requires a workshop with electrical power and access to an hydraulic garage-type press of not less than 40 tonf capacity (1 tonf is a unit of force = weight of 2240 lb). Not suitable for manufacture in most rural environments.

3.1.6 Wheel Chosen for Borno Cart.

The pressed steel wheel design was selected as the most suitable design for use on the DTU Borno oxcart. This decision was based upon previous experience in Tanzania and the availability of facilities and materials availability in the project area, and was taken to reduce wheel costs whilst retaining the advantages of pneumatic tyres already experienced in NE Nigeria.

3.1.7 Other Wheel Developments.

An extension of aluminium casting technology is presently being researched is the all-in-one cast aluminium wheel and hub shown in Figure 6. In this design the bore of the hub is unmachined and rollers bear directly on it and on the pipe axle. Test wheels have survived over 4 000 km of continuous running to date.

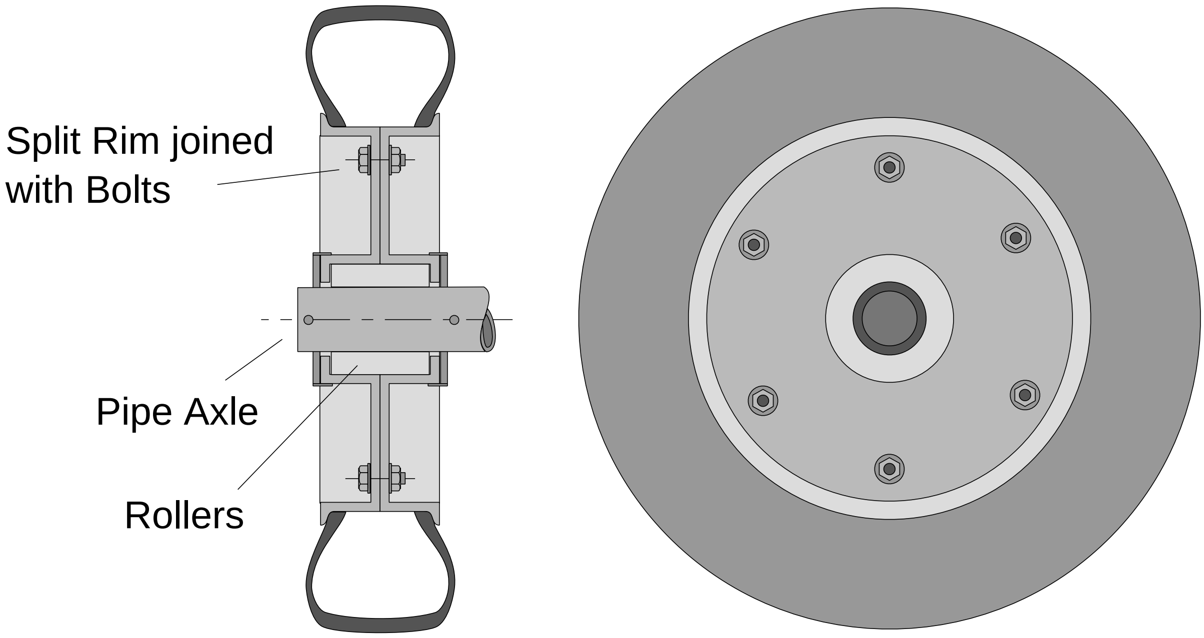

Figure 6: cast aluminium split rim for use with pneumatic tyre.

3.2 Hubs.

The design of a hub for local manufacture will depend upon the manufacturing climate, materials availability, bearing system, and wheel fitment. Some of the more well known designs are discussed below.

3.2.1 Traditional wooden hub.

Traditional wooden hub used in conjunction with wooden spokes and rim. Used on carts, wagons and coaches. Popular at the turn of the century in the northern industrialised nations and fitted to carts used by European settlers in Africa.

Advantages: strong and easy to maintain, will support heavy loads at slow speeds.

***Disadvantages*:** requires skilled craftsmen and good quality wood for its construction. Limitations to bearing designs that can be used.

3.2.2 Simple pipe hub.

Simple pipe hub with a flange welded to it for mounting the wheel. This design is often used in conjunction with a wood bearing pressed into the hub pipe and used in conjunction with rigid wheels of wood or steel.

Advantages: can be manufactured locally. Very simple in design and construction and cheap to build. Easy to service.

Disadvantages: depends on availability of reasonable workshop facilities and materials supplies. Limitations to the types of bearing that can be fitted.

3.2.3 Fabricated machined steel hub.

Fabricated machined steel hub but with more sophisticated mounting facilities to incorporate bronze bush, roller or ball bearings.

Advantages: can be manufactured locally. This design is adaptable for various bearing designs. Used with roller or ball bearings can run at higher speeds.

Disadvantages: advanced workshop facilities required with more complex fabrication and increased manufacturing costs. Regular supplies of raw materials may be a problem.

3.2.4 Cast or forged hub.

Cast or forged hub fitted with bush, roller or ball bearings. Cast hubs are used on all commercial high speed vehicles, with the bush-bearing hub used on slow speed agricultural equipment.

Advantages: provided that foundry facilities are available, this is very cheap to produce in a wide variation of designs for different bearing configurations and wheel fittings.

Disadvantages: requires foundry and machining facilities. Unsuitable for rural manufacture.

3.2.5 Hub Chosen for the Borno Cart.

A cast hub design using aluminium was selected for the Borno oxcart because of the availability of facilities, the raw materials cost, and the product quality required.

3.2.6 Other Hub Developments in the Programme.

A development of the fabricated hubs discussed above is being pursued by the DTU and is shown in Figure 7. Here low steel requirements have been achieved by mounting the wheel fixing studs on struts welded tangentially to the hub tube. This method has been shown to be cheap and reliable. A further important development has been the use of non commercial roller bearings, discussed briefly in a later section. The hub and bearing are in advanced stages of development and testing, but are not yet ready for widespread use.

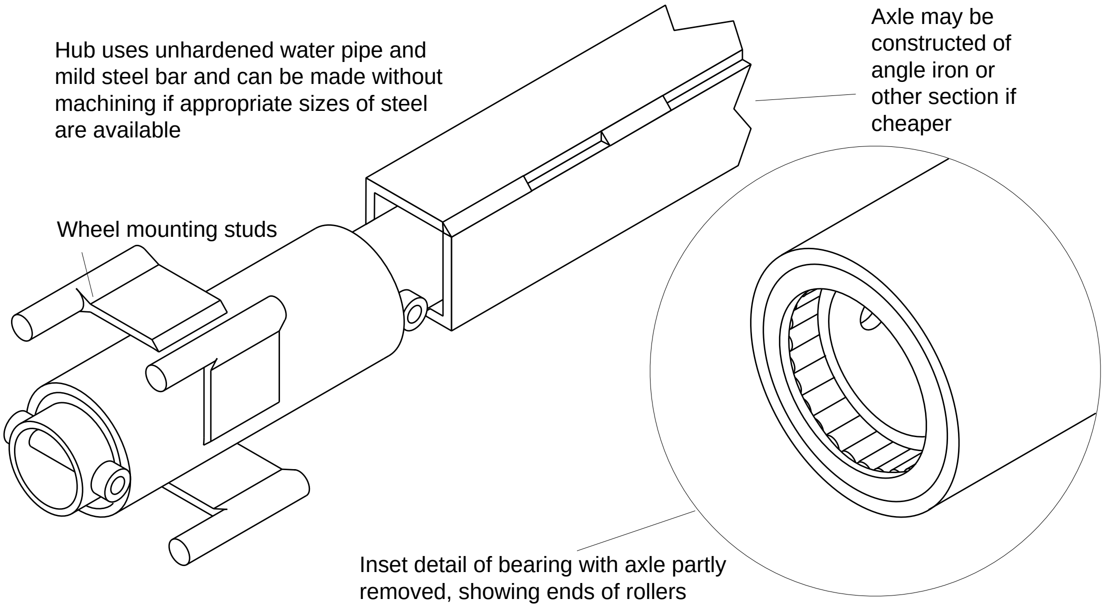

Figure 7: fabricated pipe and roller axle.

3.3 Bearings.

There are many bearing systems available that have been tested for use on animal-drawn carts, the following is a list of the more successful.

3.3.1 Steel pipe or solid axle running in oil soaked wood bearings.

These hubs can be arranged with the bearing (Figure 8) fixed in the hub of the wheel and rotating on a fixed axle, or with four sets of split block bearings arranged on two short axles, these rotating with their respective wheels.

Advantages: simple to make and will last reasonably well, providing hardwood is used and lubrication is adequate. Easy to service in rural areas where skills and tools may be limited.

Disadvantages: suitable hard wood may not always be readily available (eg many tropical hardwoods have silicate inclusions which cause rapid wear to mating shafts). The hub-fitted bearing requires some skill in manufacture, particularly if the spokes of the wheel are incorporated into the hub. The bearings show quite high friction, especially under load, which makes the cart hard to pull and reduces popularity with users. With four block bearing and overhung wheel designs, the outer bearings carry loads greater than the wheel load, which gives rise to high wear. This wear problem is often aggravated because most wood bearings are open to the ingress of dust and dirt.

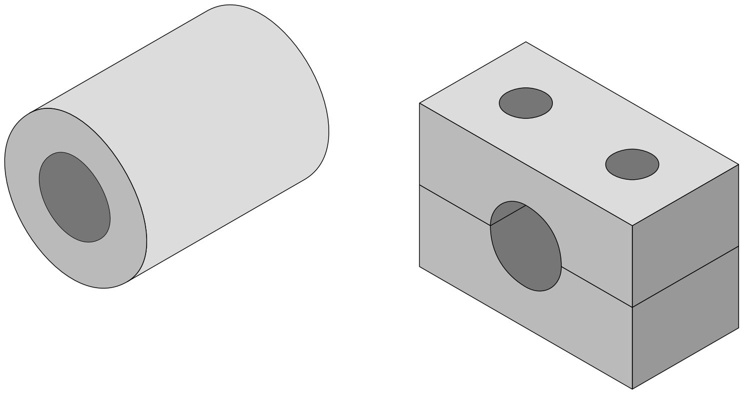

Figure 8: wooden bearings.

3.3.2 Solid steel axle running in a heavy-duty cast iron hub or bearing.

Figure 9 shows the next generation of bearing design after the wooden bearing. Because of its free graphite, cast iron is to some extent self lubricating, and runs well against other bearing materials such as steel, bronze or even itself. This type of bearing has been extensively used on agricultural equipment such as planters, harvesters and harrows.

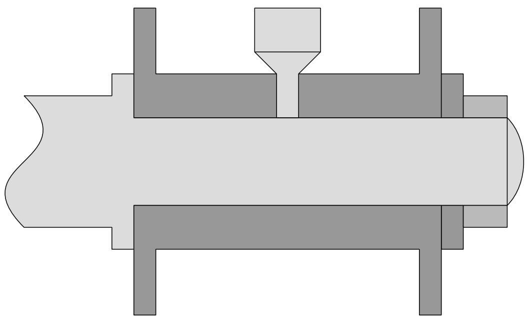

Figure 9: steel axle in cast iron hub.

***Advantages**:* using cast iron allows for intricate hub shapes with the bearing integral. It wears well provided that lubrication is adequate.

***Disadvantages**:* requires iron foundry facilities and skills such as pattern making and moulding and a source of raw materials. The bearing system should be well lubricated and sealed against dust and dirt. There are some frictional losses and excessive wear in the integral bearing could necessesitate replacement of the entire hub.

3.3.3 Steel axle in cast iron/ steel hub with bronze bush bearings.

This system (Figure 10) is a natural development from option 3.3.2 above. For interchangeability separate bearings are made and fitted into a cast iron or steel hub. Until the advent of rolling element bearings this system was used extensively in carts, wagons, agricultural equipment, and stationary steam engines worldwide.

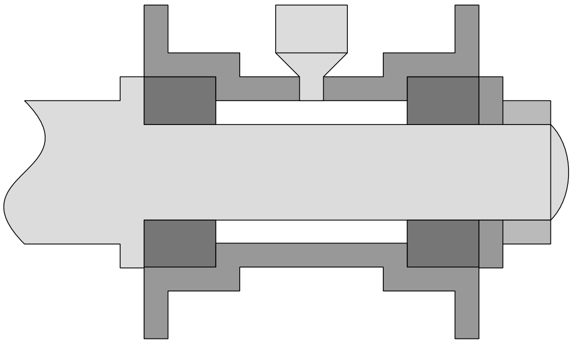

Figure 10: steel axle in cast iron hub.

Advantages: bearings are cheap to manufacture, fairly easy to replace and will tolerate heavy loads at low speeds. Different combinations of bearing materials can be used.

Disadvantages: regular lubrication and the exclusion of grit and dirt are very important. A breakdown in lubrication can lead to damage to the hub, and rapid wear. These bearings show significant frictional losses and require extensive workshop facilities and skills in manufacture.

3.3.4 Steel axle with ball or roller bearings.

Such an arrangement is shown in Figure 11. Rolling element bearings operate by interposing rollers or balls between the fixed component (usually the axle and the rotating component, (usually the hub). This reduces the frictional losses and results in a very free running bearing with a long life.

Advantages*:* Tapered-roller and cup-and-cone (or angular-contact) designs are adjustable and will accommodate axial as well as radial loads. With minimum maintenance or lubrication they can last a very long time if correctly sized and are particularly good when used in slow vehicles such as oxcarts.

Disadvantages: such bearings require complex machinery and accuracy and good quality control in their manufacture. Bearing components must be heat treated and fitted correctly. Heavy shock loading during installation or use can cause rapid destruction of these bearings.

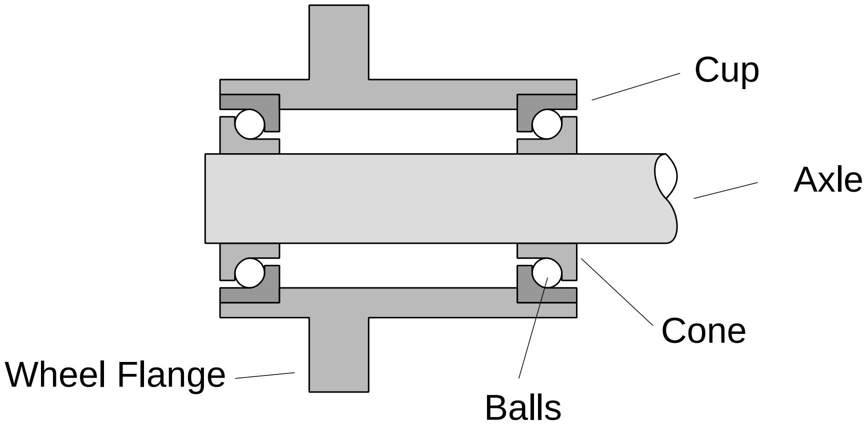

Figure 11: cup and cone bearings.

3.3.5 Bearing Option Chosen for Borno Oxcart.

Locally manufactured cup-and-cone ball bearings were selected as most suitable for use on the DTU Borno oxcart. This decision was based on availability of manufacturing skills and materials, performance and potential lifespan of the finished product.

3.3.6 Other developments in programme.

As mentioned above and shown in Figure 7, the DTU is currently developing a system of low-cost rolling-element bearing which can be made without machine tools. Limited trials of these axles have been made in Africa with encouraging results, but further work is needed before designs can be fully released.

3.4 Bodies.

Once a suitable axle has been obtained or built a body will be required. Some of the more popular options are listed below. The dimensions of cart bodies vary from country to country but are approximately as follows: width 1.3 to 1.5 m, length 1.8 to 2 m. Underbody clearance should be as much as possible but should not put the loading platform of the cart unrealistically high, ie above 700 mm. Variation in vertical load on the animal, as bumps are traversed, also increases with load tray height. The main types of cart body used in Africa are discussed below.

3.4.1 Scrap motor vehicles.

Scrap motor vehicles are a common source of oxcart bodies utilised in African countries. A scrap body, salvaged from an old small truck or pick-up, is often used in conjunction with the rear axle assembly from the same or similar vehicle.

Advantages: generally found in towns or near main roads where there is a good supply of scrap vehicles. Strong and able to outlast most axle systems, the owner will transfer the body as the axles wear out. Suitable for urban construction.

Disadvantages: use of scrap bodies can only be considered in the construction of limited numbers of non-standard carts, because of lack of local availability in large quantities. Often very heavy and best used in conjunction with a ball or roller bearing axle.

3.4.2 Wooden flat bed.

Wooden flat bed without sides made up of 50 mm ×100 mm wooden beams and 25 mm thick planks bolted and nailed together. Often mounted on a scrap rear or front axle from a motor vehicle.

Advantages: easily made and repaired under rural conditions. Can be built to suit different axle sizes, can handle bulky but light loads and may be inexpensive.

Disadvantages: without sides the underbody requires rigid bracing. Not suitable for carrying loose loads such as sand or grain.

3.4.3 Wooden box body.

Wooden box body similar to that above, but with sides, head and tail-board.

***Advantages*:** all the advantages of that above but capable of carrying a wider range of loads.

Disadvantages: can become material intensive and heavy if the construction and design is not carefully thought out.

3.4.4 Bodies of composite construction.

Bodies of composite construction using steel sections of angle iron, flats or box tubing welded and/or bolted with wooden planks for floor and wooden sides bolted on.

Advantages: providing the design is well thought out the body will be strong and light.

Disadvantages: requires the constructor to be skilled in metal fabrication as well as having some woodworking skills. Less suitable for rural construction, where steel sections and welding facilities may not be readily available.

3.4.5 Choice of Body for the Borno Oxcart.

The Borno ox-cart can be fitted with either of two DTU designed bodies shown below, one of welded steel box tubing and wood planking (Figure 12); the other of all-wood construction (Figure 13). Both designs have short construction times by virtue of their small component counts and simple manufacturing processes. For example only square cuts are required at the ends of all components and none are required to be cut more accurately than about 5mm.

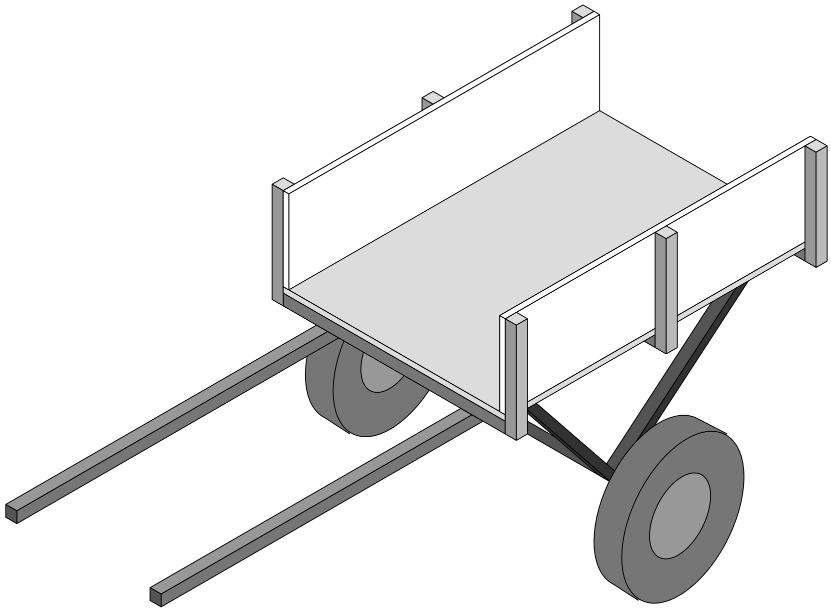

Figure 12: steel box tube framed cart with wooden planking.

In both carts, clenched fixings are used to hold the wooden components together or to the steel frame. This method is quick and sraightforward. Lengths of 6mm diameter steel wire or rod (such as that widely used in concrete reinforcement) are inserted into holes drilled in the wood (the drill can be made from the same rod) and the ends of these bent over using a hammer. The wire can then be tightened using a second hammer as if tightening a rivet.

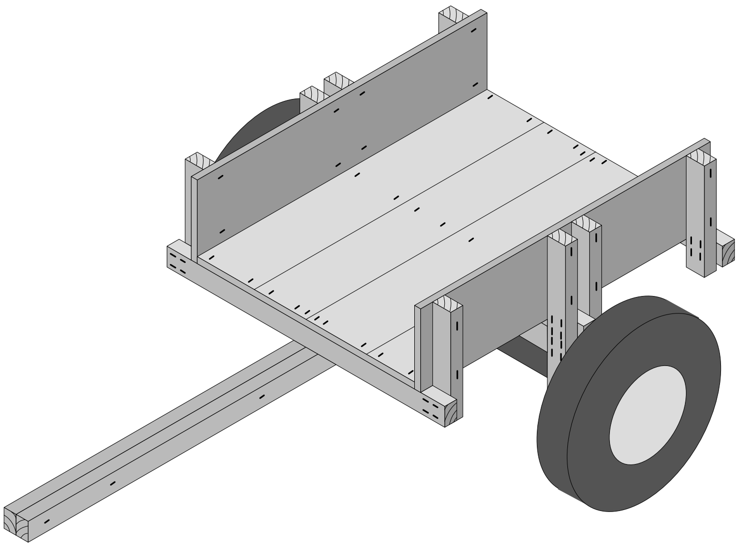

Figure 13: all wooden cart using clenched wire fixings.

3.4.6 Overall Cart Performance.

Testing both in the UK and in Nigeria of all-wood and of combination designs of cart have shown few problems so far. The all wooden design has been loaded with 400 kg of sandbags and towed over a repeated-kurb track at speeds of up to 15 km/h without damage, and the combination design has been supplied to about twenty farmers who have used the carts for up to one year at the time of writing.

SECTION 4: DESIGN DEVELOPMENT AND TESTING.

4.1 Pressed Wheels: Previous Experience.

Development of locally manufactured pressed steel wheels began when the first author was working at CAMARTEC, Arusha, Tanzania in 1988/90 with the United Nations. Development demands in Tanzania called for an improved wheel design to supersede the dated steel fabricated one similar to that shown in Figure 4 that had been manufactured locally since the mid 1960's. Between 1988 and 1990 tests were carried out on pressed steel wheels by running them, complete with an inflated tyre, on a static test rig. The wheel under test was run, day and night, at a speed 9 km/h (double that of an animal drawn cart) with a load of 300 kg. A bump was introduced to simulate partially rough road conditions. Tested wheels covered over 3 000 km trouble free. Figure 14 shows the Tanzanian test rig.

Pressed wheels were also tested in Tanzania by use with two wheeled trailers towed behind Station's tractors. These trailers were often loaded in excess of one ton and taken over very rough ground. Since 1990 several hundred wheels have been produced and used on animal-drawn carts.

The DTU programme in Nigeria has further developed and tested pressed steel wheels over the period 1992/4. Two sizes of wheel (16" and 14") are now available, both manufactured from 3 mm steel plate.

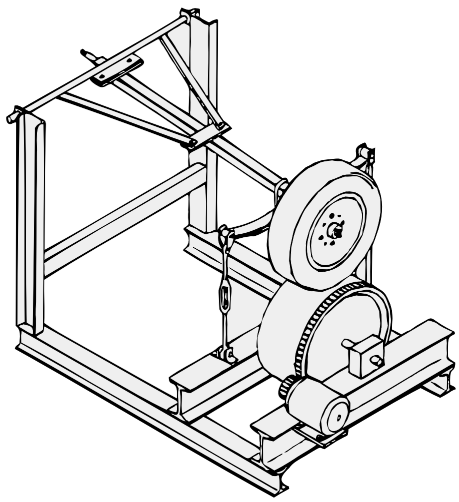

Figure 14: rolling road test of wheels and bearings.

4.2 Safety Tests on Wheels.

The DTU pressed steel wheel is a split rim design with the two halves of the wheel bolted together. With a tyre fitted and inflated to 2 bar (30 psi) a force of several tons is exerted on the rims, trying to push them apart. Concerns have been expressed that a potential danger exists to anyone attempting to split the rim halves with the tyre inflated. Clearly this is unlikely because the wheel is not usually taken off the cart unless the tyre is punctured. Nevertheless initial tests were conducted in Nigeria to determine the results of an attempt to split the rim with an inflated tyre in place.

These tests and findings are discussed below.

4.2.1 Test of complete wheel with fully inflated tyre at 2 bar.

Purpose of test: to determine the restraining capabilities of the four 10 mm Ø (diameter) bolts.

With the wheel securely held in a safe manner, an attempt was made to undo the four 10 mm Ø bolts. The force on the bolts was high and progressive and could be felt in the force required to undo them. It was obvious to those observing that all was not well. Three of the bolts were removed completely and the fourth undone half-way. At this point the two halves of the wheel sprang open on the unsupported side, allowing the inner-tube to escape into the inside of the rim and there rupture. The single 10 mm Ø bolt maintained the wheel's integrity.

Conclusions: the four retaining bolts are strong enough to hold the wheel together whilst inflated. A single bolt is strong enough to keep the wheel assembly together, albeit with some distortion to wheel and bolt.

4.2.2 Complete wheel with fully inflated tyre at 2 bar.

Purpose of test: to determine at what point the inflated inner tube would rupture upon separation of the wheel halves.

The wheel was placed in a hydraulic press with the two halves of the wheel held together by the force of the press. The tyre was then inflated to 2 bar (30 psi) and the restraining force on the wheel gradually released, allowing the two halves of the wheel to come apart. At a point when the wheel half discs had separated by 25 mm the inflated inner-tube began to migrate into the inside of the rim, rupturing on an unprotected sharp edge.

Conclusion: It was found that once the wheel discs had separated by 25 mm or so the inner-tube would expand into the inside of the wheel and possibly rupture against a sharp edge.

4.2.3 Complete wheel with fully inflated tyre at 3 bar.

Purpose of test: to measure wheel rim movement as tyre is inflated.

A complete wheel, supported at its centre, was slowly inflated to 3 bar (45 $lbf.in^{-2}$) and deflection measurements taken at the extreme edge of the of the wheel rim. A dial indicator showed that, under inflation, the rim halves moved apart 1.5 mm in total. The movement was progressive during inflation, but stopped as soon as the compressed air flow ceased.

Conclusion: the very small amount of movement was expected. Any movement during service occurs under the tyre bead and is therefore unable to induce puncture in the inner tube. If movement must be eliminated the width of the inner-tube support ring shown in Figure 5 can be increased slightly and the wheel discs given a small pre-load during assembly of the wheel.

4.2.4 Recommendations.

1) The four bolts holding the two halves of the wheel together should be long enough that if undone with the tyre inflated, the rim halves will come apart more than 25 mm before the nuts can be removed from the bolts.

2) A sharp component (a small spike) should be welded inside the inner rim to rupture the inflated inner tube before the bolts being fully undone.

3) A notice should be printed clearly on the wheel in the appropriate language, warning of the dangers involved in splitting a wheel with the tyre inflated.

4) Develop the design to make it impossible to split the wheel with an inflated tyre fitted (these design changes have been made but not practically implemented as yet).

4.3 Mk 4 Cast Aluminium Hubs: Testing.

The use of cast aluminium as a material for a low speed vehicle hub as been questioned on the point of strength. In order to address the issue some basic tests have been carried out in Nigeria and at Warwick and these are described below.

4.3.1 Shear test on lugs.

A Mk 4 hub was mounted (axis vertical) in a 60 tonf hydraulic press so that the ram applied load to one wheel mounting lug. In two tests the average force required to fracture the lug from the body of the casting was 17.5 tonf.

4.3.2 Casting strength around wheel studs.

A Mk 4 hub was mounted (axis horizontal) with one 12 mm Ø (diameter) wheel stud under the ram of a 60 tonf hydraulic press. In tests with two different presses the average force required to push the 12 mm Ø steel stud sideways out of the casting was 2.5 tonf. The stud suffered some bending before the casting gave way.

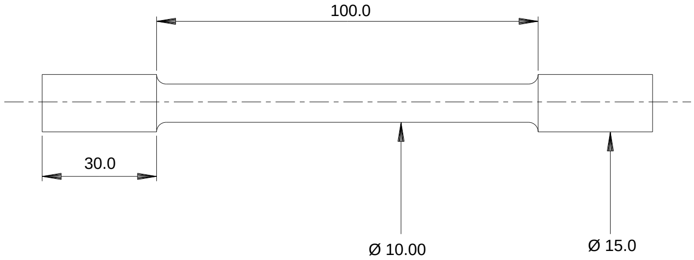

Figure 15: test piece: strength of aluminium castings produced in Nigeria.

4.3.3 Tensile test on samples taken from a Mk 4 hub.

In these tests carried out at Warwick, two samples taken from the hub were machined as shown in Figure 15 and tested in tension. Failure occurred at about 165 MPa at approximately 3% strain - well within the range expected for good quality alloy castings.

4.3.4 External analysis of five samples taken from a Mk 4 hub.

Results of these tests on five samples are presented in Appendix 1, and show the alloy to have about 8.5% silicon, 2% copper, 0.8% iron and 0.6% zinc, plus traces of many other elements. This is typical of the sand-casting alloys used in automotive components from which the scrap metal is obtained.

4.3.5 Conclusions.

The strength of cast aluminium hubs is well up to the loads, even at extremes, likely to be encountered in animal drawn carts, or even tractor drawn trailers. A regular good casting quality can be expected from the small aluminum foundries in the Nigeria project area. Monitoring of casting quality would be required if this technology were used in other countries for the production of hubs.

4.4 Bearings.

4.4.1 Recent Developments.

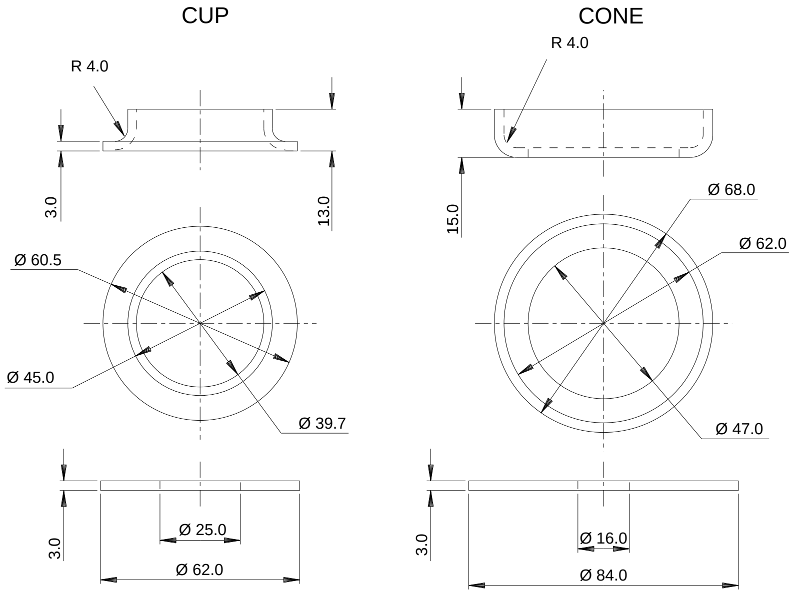
Prototype cup and cone bearings made at CAMARTEC, Tanzania in 1989 were put on a test rig (Figure 14) and run at 9 km/h with a load of 300 kgf. The drive roller of the test rig had a bump on it to simulate something of rural road conditions. An inspection was made after 3,000 km continuous running. The bearings were in very good condition with very little sign of wear. These bearings had cups and cones machined from solid mild steel bar, case hardened in charcoal as described below, and fitted with 17 × 8 mm diameter balls.

An identical set of bearings were fitted to a tractor drawn trailer for use by CAMARTEC in Sepember 1989. In just under one year the cart covered 500 km, often with loads in excess of 750 kg. Whilst the distance covered was not great, the speed, load and road conditions were very severe. The bearings fitted to this cart were inspected a year later in September 1990 and found to be in good order. Communications with CAMARTEC in 1993 confirmed that the cart is still in daily use, fitted with the original bearings. By 1990 an initial order for 25 ball bearing axle systems was in production and to date about 200 axles have been produced.

4.4.2 DTU Cup & Cone Bearings.

Development and testing of cup and cone bearings continued under the RAMAT/ Warwick linkage programme.

Early in 1993 two complete sets (for one axle) of cup and cone bearings were made in the Warwick Department of Engineering workshops to the dimensions shown in Figure 16 and heat treated with 'KASNET' (a proprietary carbon bearing formulation specifically developed for case-hardening).



NB Blanks (shown below components pressed from them) must be annealed before pressing. Case harden after pressing in charcoal plus 1% sodium carbonate for three hours at 850/900°C. Allow to cool in the carburizing box, then remove, re-heat to 800°C and quench in oil.

Figure 16: cup-and-cone bearing components.

Loaded with 17 × 8 mm diameter balls the bearings were mounted in DTU design cast aluminium hubs imported from Nigeria. The hubs were fitted with Land Rover wheels and run on the DTU bearing test rig (Figure 18) with a load of 200 kgf per hub at 120 rpm for 32 000 km. Inspection showed that wear was advanced, in particular on the cones, which had worn severely (approximately 1.5 mm) on the loaded side. The 8 mm diameter balls did not show any signs of wear. Grease had been packed into the bearings before the start of the test - the rig being stopped only to check for bearing free play and for adjustment of the bearings about mid way.

Pressed cups and cones, made from 3mm thick steel sheet and carburized with charcoal as described below, were tested next. Being very thin, these pressed components allowed an increase in the number of 8 mm balls used from 17 to 20, whilst also allowing thick walled pipe to be used for the stub axle. (More expensive 30 mm diameter solid bar was required with the cones machined from solid material.)

The bearings were fitted into Nigerian cast aluminium hubs and run at 80 rpm at Warwick over a period of seven months loaded to 200 kgf. A complete inspection showed very little wear with lubricant still in place, when the rig was stopped at 30 000 km.

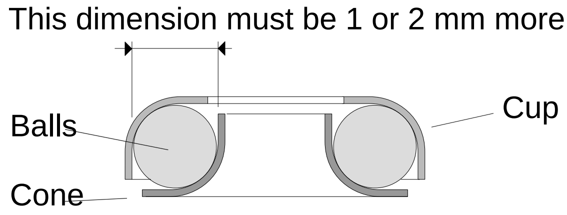


Figure 17: essential cup-and-cone bearing dimensions.

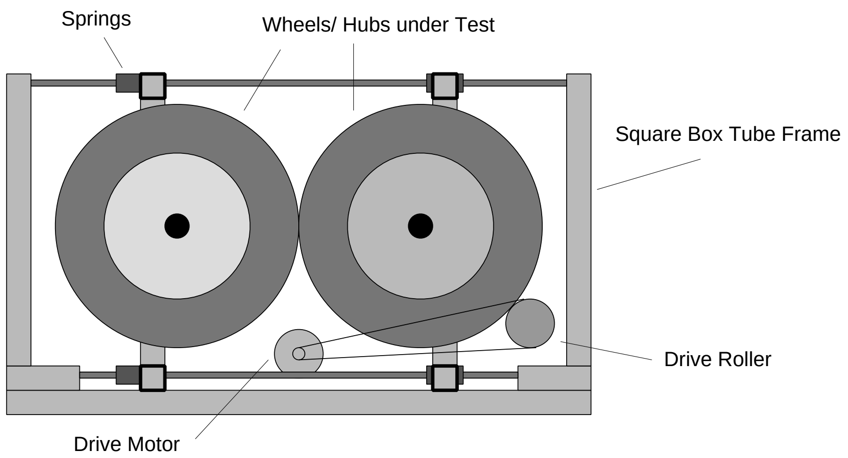

Figure 18: DTU wheel, hub and bearing test rig.

4.4.3 Tests on Locally Available (Nigeria) Bicycle Balls.

Commercially available bearing balls normally have a hardness of about 55 Rockwell C. The most readily available balls in Nigeria were those sold widely and cheaply for use in bicycles. These balls are 1/4" diameter and come in small tins of about 150 units from China and sometimes from India. Experience in Tanzania in 1988/90 with a product of the same origin, had been disappointing, with balls failing after a few hours of running under test conditions.

However low cost and ready availability in Nigeria tempted the author and his Nigerian colleagues, to conduct further tests on Chinese and Indian 1/4" balls. Samples brought back to Warwick were sent to GKN Materials Ltd testing laboratory for analysis and the results are shown in the test certificate (Appendix 2). The important constituents to note are C (carbon), Cr (chrome) and Mn (manganese). Carbon content in the samples is much too low at 0.29% and should be in the range 0.9% to 1.0%, Chrome content is similarly extremely low at 0.02% - commercial bearing steels would normally be from 1.0% to 1.5%.

Cup-and-cone races case-hardened in charcoal, were run at 80 rpm and 200 kgf load at Warwick with 26 × 1/4" Chinese balls. Only the equivalent of 14 km was covered before the test rig began to omit nasty grinding noises. On inspection it was found that several of the balls had disintegrated totally, although the cups and cones were intact.

Back to the drawing board!

Thus the Chinese/Indian balls were not hard or strong enough for the purpose. An attempt was made therefore to treat some balls to bring them up to satisfactory hardness. Balls were heated to 900°C and quenched, some in cold water and others in oil. Some Chinese balls that had been carburised by Nigerian staff, but not hardened, were sent to Warwick and were treated in the same way as the 'off the shelf' samples above. Hardness test results for these balls are shown in Table 1. As can be seen there is much variation, even within the groups of five balls, suggesting that quality control during production is poor.

This variation and poor hardness rendered unviable the use of Chinese and Indian balls in the present cup-and-cone bearing systems for animal-drawn carts. The suggestion that better quality 1/4" balls be used was rejected because of the strong temptation for unknowledgable or unscrupulous constructors to revert to the use of inferior balls. Guarding against such a possibility would not be possible and the decision was therefore taken to standardise on 8 mm diameter balls, this size being available new or second hand in Nigeria only from quality manufacturers.

4.4.4 Conclusions.

The development of locally pressed cup-and-cone bearings can be seen as a breakthrough for indigenous manufacture of animal drawn vehicles and other equipment in Sub-Saharan Africa. Technicians in Nigeria were most pleased to realise that local manufacture of quality rolling-element bearings was within their capability. Important or "key" technologies have also been introduced including simple press tooling and heat treatment processes. The fundamental understanding of such key processes is a very important step forward for small manufacturing industries in Africa.

4.5 Concluding Remarks on Design Development and Testing.

Key components of the Borno cart are the results of previous developments and testing. Wheels, bearings and to some extent hubs, have a development history dating back to 1988 in Tanzania. The basic technology applied in the making of pressed steel wheels is not new and was used in the early days of wheel development in Europe to carry pneumatic tyres. Cup-and-cone ball bearings represent some of the earliest developments of rolling-element bearings - though fairly simple in construction they are capable of withstanding heavy loads and giving good bearing life because of their tolerance of dirt and poor manufacturing standards. Such qualities have been proven by their universal use in bicycles for example. Improved bearing technologies needed better and more versatile hubs to accommodate them. Cast-iron hubs are cheap to produce if the technology is available, but aluminium castings make a very acceptable alternative.

Table 1: Hardness Tests: Nigeria purchased Chinese 1/4" balls - July 1993.

Ball #	Treatment	Rockwell C #	Vickers #
1	As purchased	46	460
2		35	350
3		40	400
4		48	490
5		47	480
6	Heated to 800/900°C	43	430
7	Quenched in oil.	33	330
8		26	275
9		33	330
10		45	450
11	Heated to 800/900°C	55	600
12	Quenched in water.	45	450
13		60	700
14		55	600
15		52	550
16	Carburized in Nigeria	41	410
17	for 8 hours in charcoal.	57	650
18	Re-heated (at Warwick) to	55	600
19	800/900°C and Quenched in	52	550
20	oil.	54	580
21	Carburized in Nigeria	58	660
22	for 8 hours in charcoal.	54	580
23	Re-heated (at Warwick) to	52	550
24	800/900°C and Quenched in	63	780
25	water.	60	700

1 to 5 Average = 436,	Standard Deviation = 60
6 to 10 Average = 363,	Standard Deviation = 74
11 to 15 Average = 580,	Standard Deviation = 90
16 to 20 Average = 558,	Standard Deviation = 90
21 to 25 Average = 654,	Standard Deviation = 93

PART B: MANUFACTURING THE BORNO ANIMAL CART.

SECTION 5: MANUFACTURE OF PRESSED WHEELS.

5.1 Introduction.

Second-hand wheels from motor vehicles are the usual choice of the animal cart builder in Africa. Considering the number of motor vehicles imported or assembled in Africa since the second world war - particularly since independence in the 60's - it is not surprising that many discarded wheels are available. Although the use of such wheels is a reasonable solution for the needs of cart builders constructing small numbers of carts, they should not be thought of as the only alternatives to wooden or heavy steel rimmed wheels. In fact they have several disadvantages for cart builders including a lack of controlled quality from one wheel to the next, a lack of consistency and standardisation in size of mounting and centre holes, and a shortage of supply leading to rapid rises in price as soon as any number are purchased in one area.

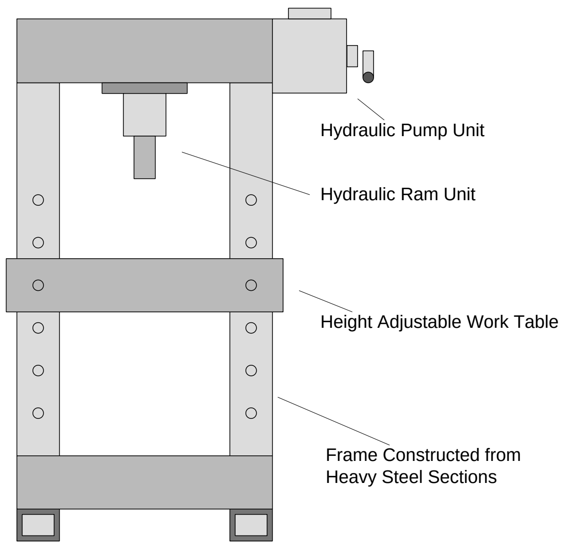

Figure 19: hydraulic press used in pressed wheel manufacture.

Manufacture of the pressed steel wheels described in this document utilizes a hydraulic press of minimum 40 tonf capacity. In fact such presses are not so rare in developing countries, as may be thought. Rail systems have never really developed in Africa and bulk goods and people are transported along roads. It is inevitable, therefore that a network of auto-repair workshops and garages has sprung up along roads carrying motorised traffic of any density. Buses and lorries in Africa break down regularly, ensuring plenty of work for the workshops. Breakdowns often involve damage to heavy suspension and transmission parts, and the repair of these cannot be carried out solely by hand as the forces required are considerable and must be carefully controlled. Thus it has become essential for many garage workshops to have an hydraulic press. These presses are not to be confused with the power presses used in manufacturing industry - the garage press (Figure 19) is a simple affair which uses a hydraulic unit similar to a hydraulic jack, set in a very robust frame, to exert large forces slowly in a controlled manner.

Before proceeding with pressed wheel development in Nigeria, a brief survey was made of Maiduguri town to determine the availability of a suitable press. It took only a couple of hours to locate six hydraulic presses of 60 tonf capacity. Three of these presses were located in Government controlled workshops, the other three were in the private sector. All were available for use by one means or another - the government presses free, the private sector presses by paying a small fee. All but one of the presses was manually pumped - probably an advantage because manual operation is likely to be safer than electric operation in unskilled hands.

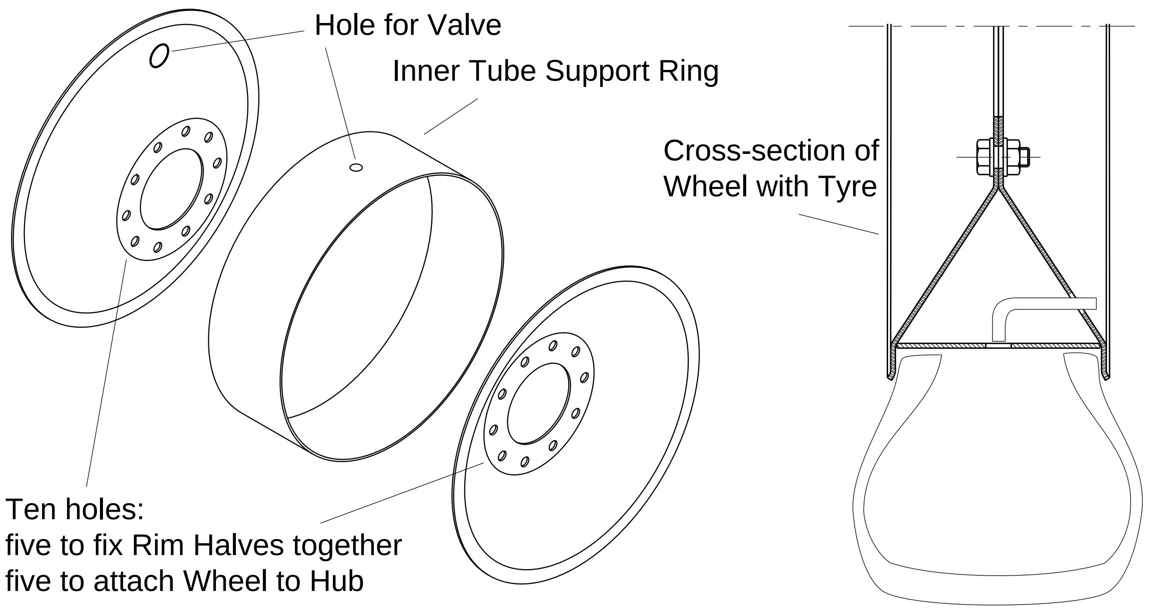

Figure 20: pressed steel wheels.

5.2 Overview of Wheel Manufacture.

The development of pressed steel wheels was centred around the use of 3mm (or 1/8") thick black mild steel sheet. The aim was to produce a wheel (Figure 20) that would be simple to make using a minimum of differing material sizes and manufacturing processes.

The manufacturing process involves pressing two round steel blanks into dish shapes, which are then bolted back to back. A circular inner rim, also made from 3mm steel sheet, is added to support the inner tube. The entire fabrication process consists of about thirty steps and when complete results in a wheel weighing about 12 kg. This may be compared with the earlier Worth and IT Transport designs which weigh about 25 kg, require five different material sections and take up to fifty construction steps to complete.

The hydraulic press is the central piece of equipment, extensively used in the manufacture of this particular design of wheel. The press is used for all the following processes :

- First and secondary wheel-rim pressings.
- Punching a 16mm diameter pilot centre hole in each wheel blank.
- Punching a 113mm diameter wheel centre hole.
- Punching the 16mm diameter valve hole in the wheel rim
- Punching a 30mm diameter valve access hole in one wheel blank.
- Punching the 14mm diameter wheel hub bolt holes and the 11mm diameter wheel rim holes, a total of sixteen per wheel.
- Pressing the bearings into the hubs.

Note, the 113 mm diameter blanks produced when punching the centre of the wheel discs can be reduced using a press tool and then utilized as bearing cover plates at each end of the hubs.

5.3 14" Pressed Wheels: Detailed Manufacturing Procedures.

Two sizes of pressed steel wheel have been developed for use with 14" and 16"tyres, two very popular sizes in Africa. The description below concentrates on the 14" variant and refers to the drawings in Appendix 3. The methodology for making 16" wheels is identical.

Wheel disc blanks are cut from standard 3 mm or 1/8" thick steel sheet and a 4 ft × 8 ft sheet provides enough circular blanks and flat strips for five complete wheels with their inner rims. The remainder of the plate may be used for making cup and cone bearing housings and hub end bearing cover plates, resulting in very economical use of the material.

The manufacturing procedures for the 14" wheels are as follows:

1. Blanks for 14" wheels are marked out on the sheet and cut to the diameter shown in the drawings. Cutting can use oxy-acetylene equipment or a band saw. After cutting, a 16 mm pilot hole is punched in the centre of each blank disc and one disc also requires a 30 mm diameter inner tube valve access hole in the position shown. The blanks must then be annealed, or softened to make them suitable for pressing. This is most readily done by standing the blanks evenly spaced and building a fire around them of scrap wood. The plates need to be heated for about 30 minutes, but they need not reach red heat. The plates should be moved about within the fire for even treatment and left to cool when the fire goes out.

2. Annealing may distort some of the blanks, but this is not a problem provided that each blank will fit into the press tool and the top clamp ring can be bolted in place. Any badly distorted blanks may be straightened by placing them on a flat floor and jumping on them, as in its annealed state the plate is soft and is easily bent back into shape. Eight 16 mm diameter bolts hold the top clamp ring down - it in turn holds the blank in place and forms the outer flat section of the wheel, preventing distortion around the rim during pressing. The blank is centralised in the press tools using the

16mm diameter centring post in the bottom tool.

3. The top tool is now put in place, again using the 16 mm centre post for positioning and the press operated which will force the top tool down into the bottom tool and form the blank into the desired shape. Depth of pressing will be controlled by the plywood spacer in the bottom of the bottom tool: when this is reached ram pressure will rise rapidly. From experience 35 tonf is enough with 40 tonf as a maximum. On inspection the pressed blank should be evenly formed with the central hub mounting area, 200 mm diameter, well defined and flat. After pressing, the rims of two wheel discs placed back to back should be separated by 94 mm internally. In order to maintain this dimension it is important that the pressing force used should not vary from one pressing operation to another.

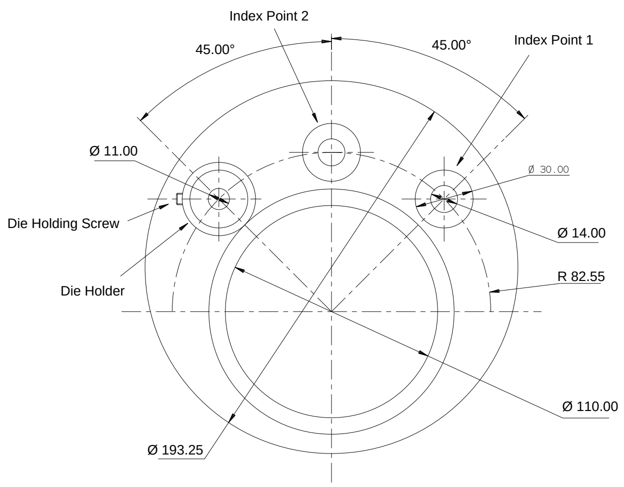

Figure 21: layout of jig used for punching holes in pressed steel wheels.

4. Once all the blanks have been pressed, secondary pressing of the outer rim (which takes the sharp disc edge away from the wall of the tyre) can take place. For this the clamping ring is left in place, but the top tool is turned over. Each disc is then placed, dish side down, on top of the clamping ring, the inverted top tool placed in position, and the press operated to around 30 tonf. The outer rim should be turned up about 30 degrees as a result.

5. A small clearance over the aluminium hub is provided by the 113 mm diameter central hole and this allows for slight deviations in casting size. It is important that the size of the hole is exactly the same in all the wheel discs, as the placement of the four rim bolting holes and four wheel-to-hub fixing holes is determined from the centre hole. This central hole can be produced most quickly and accurately by punching with a simple press tool in the hydraulic press: the force required will be about 38 tonf. In Nigeria a suitable set of tools were made from scrap gears from a lorry gearbox. Blanking forces can be calculated by multiplying metal thickness by length of perimeter of blank, to get the area to be cut, and then multiplying this area by the shear strength of the material.

6. Eight bolt holes are punched in the wheel disc, all on a 165 mm PCD (pitch circle diameter; ie the centres of the holes all lie on a circle of 165 mm diameter). Four of these holes are 14 mm diameter (for fixing the wheel to the hub) and four are 11mm diameter (for bolting the two wheel halves together). A complete wheel has 16 bolt holes (eight in each half) which must not only align when the wheel halves are put together, but the holes must also align with the four studs of the hub. One method of achieving sufficient accuracy is by using a drilling jig, a circular plate which has the holes to be drilled accurately set in it. To avoid rapid wear through repeated use, it is best to fit hardened steel bushes in the jig which can be replaced when worn. A second method is to punch the holes using a press tool that, ideally, produces all eight holes in the correct location, at one time. An alternative punching method, and the one used by the project in Nigeria, produces one hole at a time in conjunction with an indexing system (Figure 21).

7) The inner rim of a complete wheel is a flat strip of 3 mm steel sheet 1094 mm long and 94 mm wide. Before bending the strip into a cylinder the 16 mm diameter valve hole has to be punched in the position shown, and the ends of the strip pre-bent in a vice. It is not necessary to anneal the material as the bend is a gentle one. If a sheet roller is not available the strip can be bent around a wooden former which should be 350 mm diameter. After bending, the ends of the strip can be welded together on the inside of the ring only.

5.4 Wheel Assembly.

On assembly, with the bolts slack, rotate the cylindrical inner rim to be sure that the valve hole in the wheel disc half and the valve hole in the inner rim are aligned. The inner rim should sit comfortably in the pressed area. With the second disc in place and bolts finger tight, the two halves should come nearly together with a gap of about 2 mm. If the gap is greater than this the inner rim will have to be reduced in width and all other inner rims made to the new dimension. With the two halves bolted tightly together the inner rim can be tack welded in two places to the rim disc that DOES NOT have the valve hole in it. After tack welding disassemble the wheel and make four heavy tack welds between the inner rim and disc on the inside of the inner rim. The inner rim is welded to the disc only to prevent movement when the wheel is being taken to pieces or assembled, the strength of the wheel when in use is not dependent upon the welding.

SECTION 6: CAST ALUMINIUM HUB MANUFACTURE.

6.1 Introduction.

In several towns in the north of Nigeria, including Maiduguri, Jos, Kano and Zaria, there is a small but thriving cottage industry of aluminium foundries making cauldron type cooking pots and other small aluminium goods. The Linkage Programme worked with one of these small foundries in Maiduguri. Scrap aluminium is readily available in quantity (by the ton if required) from specialist merchants operating from Kano, Jos, Onitsha, and Lagos, among others. The caster also operates an exchange scheme with his customers, ie new pots for old, as part of his source of scrap. Aluminium, as of May 1994, cost Naira 40/kg (= 0.60 p/kg).

The company (Aluminium Pot Makers and Casting Workshop, Gwange Sabon Line, Post Box 4181, Maiduguri) employs from four to six workers and produces up to 60 cooking pots of 350 mm diameter maximum per day. The owner, Malam Umar Usman is about 35 years old and had been in business for nine years at the time of our involvement. His workshop comprises a floor of about 10 m × 15 m, partially covered with a corrugated iron roof mounted on wooden poles. The floor of the covered area is a thick layer of local sand which is used for the moulds. Aluminium is melted in steel pots (cut from old LPG cylinders) in a ground level furnace, using an blown-air charcoal fire. Air is supplied from two or three metres away, by an underground pipe fed from a centrifugal blower, cast locally in aluminium. It is driven by a rubber belt (made from old inner-tube) from a bicycle wheel turned by a small boy.

Observation of Mal Umar in operation shows that he and his workers are highly skilled from long experience, and have an in-depth knowledge of the process and of solutions to the technical problems involved in aluminium casting (for example old dry cell batteries are added to the melt to assist in de-gassing), and this skill allows the consistent manufacture of high quality products.

6.2 Casting the Mk 4 Aluminium Hub.

The MK 4 cast aluminium hub (Figure 22) represents the final hub development in the present programme. The hub has four studs on a 165 mm PCD and weighs 2.8 kg. Only limited machining of the preformed bearing housings and the drilling and tapping of the four stud holes is required to complete the hub after casting, because a steel mould giving accurate outside dimensions, is used. About four castings per hour can be produced by this method and machining time for the two bearing housings and the four wheel stud holes is twenty to thirty minutes.

Inserts in the steel mould preform bearing housings in both ends of the casting, and a finished-to-length steel core pipe is located in the mould before pouring to provide the central axle space. The mould, totally enclosed, is filled through a simple filler and riser system consisting of two short lengths of 40 mm diameter pipe which stand over holes in the top of the mould (nb they are not fixed to it). The mould and these filler and riser pipes are completely filled during pouring, and as freezing progresses the aluminium in the pipes feeds down into the casting and prevents shrinkage cavities forming. It was observed that the aluminium had to be very hot before pouring into the steel mould in order to flow freely and not freeze too quickly. After about two minutes the filler and riser can be broken off the mould before the aluminium has had time to solidify completely. Extracting the casting from the mould can begin after five to seven minutes (and certainly no later than ten minutes) after pouring, or the aluminium will contract onto the mould bearing inserts, even though they have generous release tapers. Should this occur, allow the mould and casting to cool completely and then suspend the whole issue over a hot charcoal fire for about 15 minutes. The aluminium will expand more rapidly than the steel components and release will be possible.

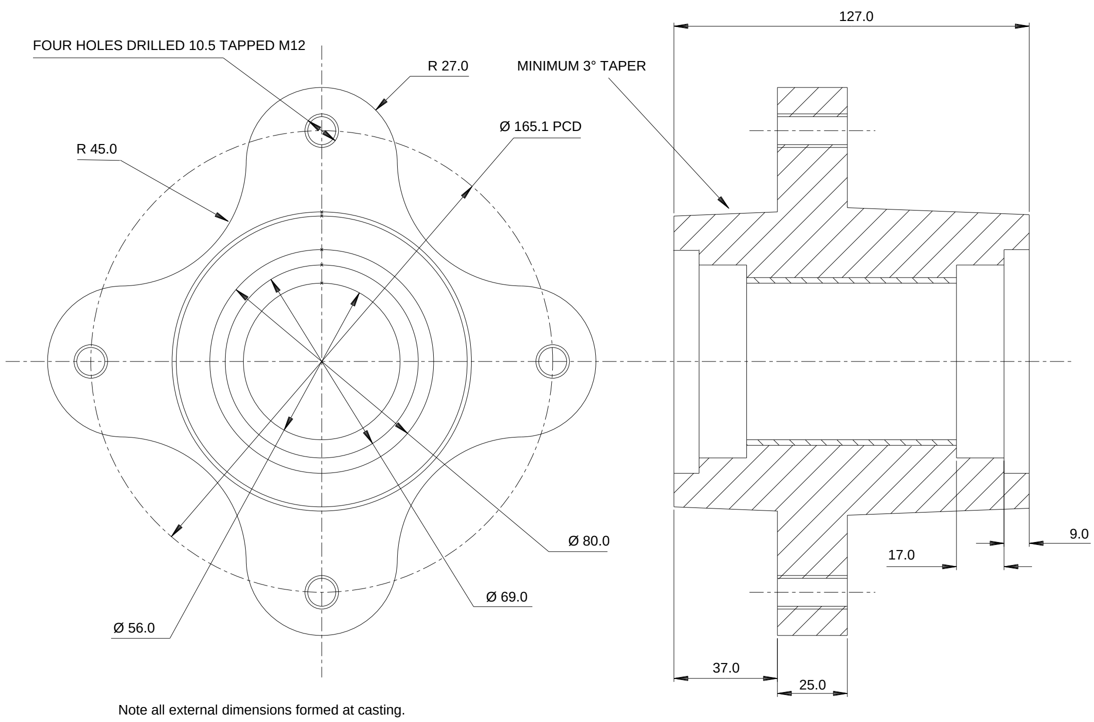

Figure 22: Mk 4 aluminium hub - gravity die cast in steel mould.

It may be argued that foundry facilities or raw materials do not exist in all African countries. This may or may not be the case, but where the materials are available the technology itself is not difficult and could be introduced.

6.3 Further developments.

Figure 23 shows an alternative sand-cast hub, which may be used with commercial tapered-roller bearings which are available at reasonable price in Nigeria. It exploits the bearings' high load capacity and allows machining of both bearing housings in one cut. A snap-ring, made from mild steel wire or similar and let into a groove in the bore, locates the bearing pair in the hub. The wheel studs are fitted into slots in the struts, saving a drilling and tapping operation.

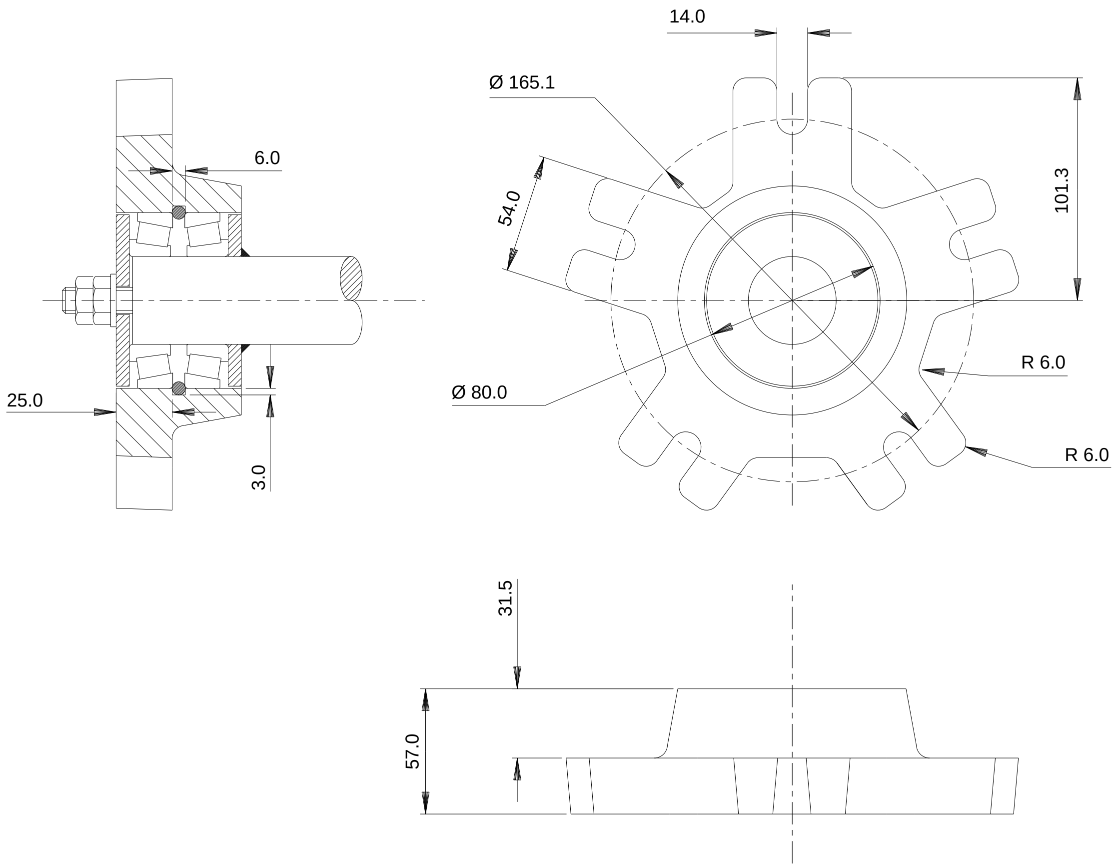

Figure 23: sand-cast aluminium hub - for 6208 tapered roller bearings.

SECTION 7: BEARING MANUFACTURE.

7.1 Introduction.

The current Warwick axle and hub design being constructed at RAMAT Polytechnic utilizes three bearing alternatives, commercial taper roller, fabricated roller (Figure 7) and locally manufactured cup-and-cone ball bearings (Figure 24), the type specifically dealt with here. Cup-and-cone ball bearings, as used in bicycles, are one of the earliest examples of a rolling element bearing. It is a simple system that is adjustable and will carry both radial and axial loads.

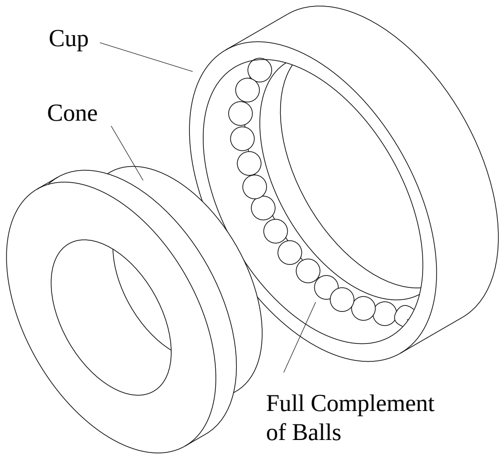

Figure 24: cup and cone ball bearings.

Cup-and-cone bearings are made up of three parts: an outer race (the cup), an inner race (the cone), and the rolling elements (the balls). Commercial bearing balls have a very high finish and are heat treated to be hard enough (55 Rockwell C) to withstand the loads imparted to them when in use, this in turn requires the cup and cone races to be hardened.

Design criteria for the use of these bearings in the axle systems of animal drawn carts were as follows:

1) able to withstand maximum loads of approximately 250 kgf per bearing,

2) easy to fit, adjust and replace,

3) simple and cheap to manufacture.

Earlier versions of cup and cone bearings developed in Tanzania in 1988 were machined from solid bar and did not comply with the third, and perhaps, most important criteria above. Solid bar sections larger than 20 mm dia are hard to come by, and expensive, in most countries in Africa. Also machining these components requires the constant availability of expensive machine tools, a lathe, and the appropriate skilled labour to operate the machine. In order to alleviate this problem development proceeded with a programme for pressing the cups and cones from 3mm thick mild steel plate.

7.2 Production.

Bearing components must be consistent dimensionally in order to operate reasonably well and be interchangeable when worn. Such regularity should not be dependent on constant machine tool availability and a skilled labour input over a long production run of components. Even if facilities and personnel were available, costs would be high, as production rates would be low. A better approach to the problem is to develop a set of specialised tools, the function of which is to replicate bearing components speedily and faithfully, using unskilled labour.

Simple press tools for producing cups and cones can be made from mild steel to save costs and may be case hardened using the same process (described below) as for for the cups and cones. Figure 16 gives the dimensions of the cups and cones to be produced with the press tools. The top tool is made to the internal dimension of the component whilst the bottom tool is made to the outside dimensions. Blanks for the cups and cones are made from the same material as the pressed steel wheels ie 3 mm steel sheet. These are annealed as described for the wheels. Each component blank is located centrally on the bottom tool whilst the top tool is forced down and into the bottom tool - pressing the blank into the tools and taking up their shape. The process takes very little time and requires minimum skill - although skilled input is required in the initial making of the press tools and to some extent in setting them up for use. Tools maintenance is minimal provided that checks are made on the components being produced from time to time, and wear on the tools is monitored.

Bearings easiest assembled with heavy grease to hold the 20 × 8 mm diameter bearing balls in place. Adjust the bearing to run freely once the wheel is fitted.

Bearing components produced from pressing are of mild steel and will require heat treatment using a process called case hardening. The simpler aspects of heat treatment and the case hardening process are explained below.

7.3 Heat Treatment of Steel - General.

Before proceeding it should made clear that steel with less than 0.5% carbon cannot be hardened by the normal process of heating to 850/900°C and quenching in cold water or oil. Such low carbon steels are generally known as "mild steels". If in doubt take a very small sample, heat it to bright red and quench it in cold water. If the treated sample can be cut easily with a file then it is a mild steel, if however the sample is very hard and cannot be filed or cut, then it is almost certainly a high carbon steel.

To render steel soft or malleable, a reverse process of the above is applied - the steel is heated to 700/800°C, a dull red heat, and left to cool slowly - a process known as annealing. The blanks for the pressed cups and cones for the bearings and for pressed steel wheels are treated in this way.

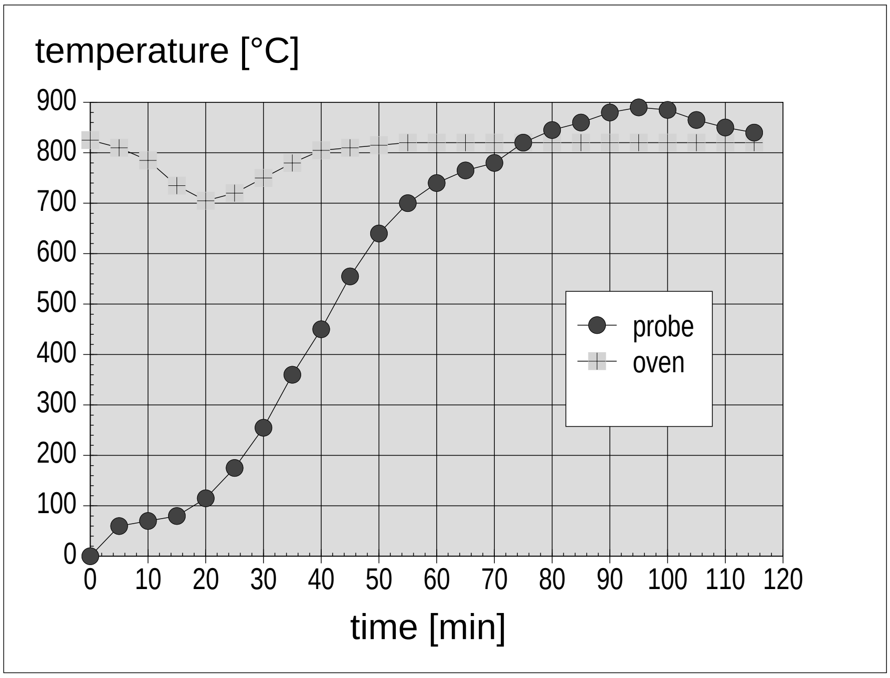

Figure 25: temperatures during carburisation of bearing components.

7.4 Case Hardening - The Process.

This process is applied to articles of mild steel where a hard skin or surface is required (gears in an automotive gearbox for example) as opposed to hardening the components right through. The best results are obtained with steels containing from 0.1% to 0.2% carbon. Articles to be case-hardened are embedded in some form of carbon-rich material - in developing countries the most readily available material is probably wood charcoal, and this should be ground into a fine powder. The process is considerably improved if 1% by weight of sodium carbonate (**nb not 'bicarbonate of soda'**) is mixed with the charcoal as an activator.

Items to be hardened are packed, with the carbon rich mixture, in a steel or cast iron container not less than 4 mm thick. It is important that the container is as airtight as possible because air getting in will oxidise and waste the carbon (clay can be used to seal the lid). Also the container must be big enough to allow a space of about 25 mm between each component and the sides and top and bottom of the box. Carbon diffuses into the components and converts the outer layers into a steel that will harden, having a surface carbon content of about 0.9%. The depth of case depends upon the size of the article being hardened, the carbon rich material used, the length of time the process is continued and the temperature held during the process.

The box containing the articles to be carbonized must be heated to 850/950°C and the temperature maintained for a period of three hours. This can be achieved with the use of an electric furnace or a blacksmith's forge. Using a forge, the steel container must be kept bright red, covered with hot charcoal at all times and it should be rotated in the fire from time to time to ensure an even distribution of heat. Treatment is normally considered to start when the box reaches working temperature (visually a bright red) and at this temperature the depth of case can be expected to increase at about 0.2 mm/hr.

After the allotted time the box should be removed from the furnace or fire and allowed to cool naturally. To harden the components they must be removed from the box and re-heated to 700/800°C (visually a dull red) and quenched in oil or water. Bearing components must be cleaned with a wire brush or emery paper before assembly into hubs. The charcoal mixture is re-usable but must have the volume made up with the addition of new charcoal powder/ sodium carbonate mix. Figure 25 shows the temperature changes in a carburization box (measuring 230 × 100 × 100 mm and constructed from 6 mm mild steel plate) during the heat treatment of cup and cone bearing components.

Bearing cups and cones, heat treated for three hours, will be carburized to a depth of a little over 0.5 mm. Such a depth of case is required to withstand the pressure from the hardened steel balls when the bearing is under load. Charcoal case-hardening prolongs the life of the bearing components considerably and in itself is a *'key process'*, potentially of great value to rural and urban artisans and to small industries in developing countries.

SECTION 8: CART BODY MANUFACTURE.

As discussed above, two cart bodies have been developed for construction in the current project. The body developed by the DTU for use with the DTU Borno Ox-Cart is made from sawn timber with simple fixings which are very easy and cheap to construct. Construction details of the oxcart body are detailed in Technical Release 24 attached as Appendix 9.

Also available is a design for a lightweight donkey cart. Construction of this cart utilises 50 mm × 50 mm light steel box section for the frame, with floor and sides made from wood. Construction details for this body are available in DTU Technical Release 23 included as Appendix 10. This design can easily be modified for use as an ox cart with small increases in material sizes and overall dimensions.

SECTION 9: TOOLS FOR DTU BORNO CART PARTS.

9.1 Introduction.

Earlier in this paper, details of the manufacture of the various components for the Borno ox-cart were described. Production of many of these parts depends upon the use of tools, dies, jigs and fixtures - generally known as special tools. These are used in order to ensure dimensional regularity, interchangeability, speed of production and general high quality of finish. This section of this document will describe how to construct these various special tools and as some of the tools are similar in their function, a general description of the tool will be given before a description of the variants needed for producing different parts. For example, making a hole-punching tool is explained in a way that can be applied to different punches of various sizes. The special tools dealt with are as follows:

- forming or bending tools for wheel-discs and cup-and-cone bearing components,
- punching or blanking tools for holes in the wheel discs, cup-and-cone bearing components and hub end-thrust washers,
- drilling jigs for holes in cast aluminum hubs,
- steel casting moulds for aluminium hubs.

It is recommended that the making of these tools should only be considered if it is expected that a significant number (say 100) carts are to be manufactured each year. For more limited production, traditional methods, such as drilling, cutting and filing can be employed. Of course press tools would still have to be made for the wheels and the cup-and-cone bearing components.

Regarding limited scale manufacture, the DTU is committed to developing other designs which can be made without special tooling and has made significant progress (as exemplified by the axle shown in Figure 7). Further development of this axle is necessary before it can be released for general use, but it is able to give up to 15 000 km in good conditions, and work is in hand to reduce still further the level of tooling required. New designs may even be able to avoid the need for drilling.

9.2 Forming or Bending Tools - General.

It may be helpful to the reader to understand the pressing process and the importance of controlling pressing forces during the manufacture of the sorts of component discussed in the sections above. The following is an attempt to throw a little light on the subject for those not already well informed.

A hefty blow from a large hammer delivered onto a thin piece of steel will bend it or change its shape, usually not for the better, unless the person wielding the hammer happens to be very skilled. It will be even more difficult to bend a second piece of the metal to the same shape as the first. The problem is that the force of the blow from the hammer (and its position and angle) is not well controlled, because it is delivered by hand. Most of the problems of force control are overcome by using a press which delivers the force in a straight line, usually vertically. The problem still remains however, that the material being pressed will have a tendency to form or flow along the least line of resistance, which may or may not be that intended. A simple form like a straight bend across a flat strip is easily controllable, whereas multiple bends close together may cause a problem because the stresses in the material pull in different directions. Such forces in the material can be controlled using press tools, which are designed to hold the material firmly in place and, under the force of the press, make all the bends at once. Figure 26 shows a simple bending tool which might be used to produce a V-bracket.

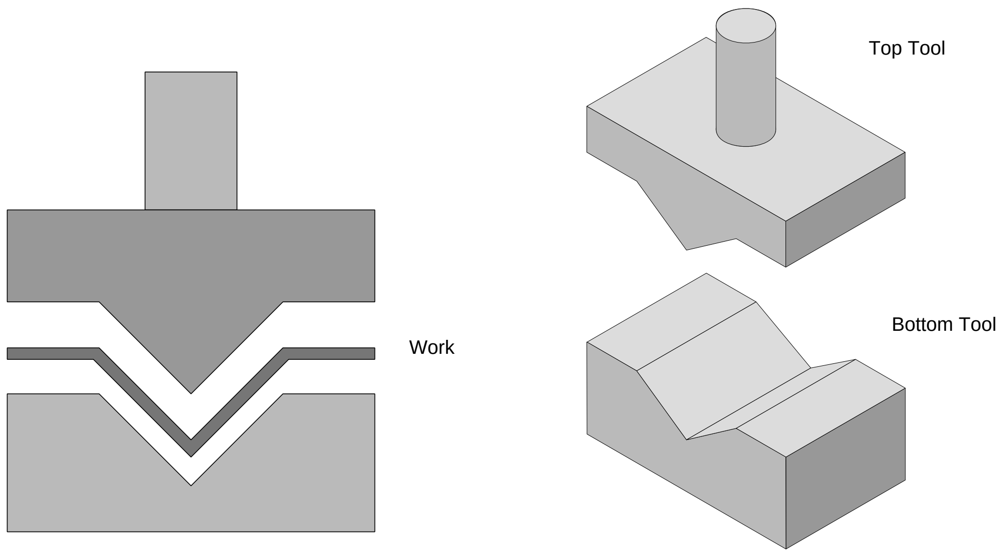

Figure 26: simple press tooling example - here for a V bracket.

Before pressing a blank must be made, but material stretch during pressing will cause dimensional changes which must be allowed for in the size of the original blank. It is possible to calculate the amount of stretch that will take place, but such calculations are not easy and will depend on the original state of the material - for instance if it has been annealed or not. The simplest method for determining the correct blank size is to run a series of pressing tests. By comparing the pressed components with the required design for a series of blanks, a reasonable estimate can be made of the necessary blank size.

The operation of the bending tools for wheels is to change the shape of the material being formed into that required. For this purpose the tools have to be sufficiently robust to withstand the pressing forces whilst the operation is taking place. Details of the simple tools for pressed wheels are shown in Appendix 3. The materials used are the lightest that may be expected to tolerate the pressing forces imposed when pressing wheels, and still give reasonable tool life. If available, heavier materials can be used with an obvious increase in cost and life. The important function is to form the rim and press the centre 200mm diameter portion to the correct depth in relation to the rim. The exact shape of the coned or dished portion of each wheel half is not important, and so its exact shape is not controlled by the press tools. In practice it may take up a slightly rippled shape, but this will not detract from its strength or function.

When making the wheel discs, simply to press the centre portion down without controlling the rim would result in an irregular dish shape with a corrugated and ill defined rim. The very important function of the pressure ring is to hold the wheel disc in place and control the flow of the material. The wheel rim is held flat and in a horizontal plane by the pressure ring whilst the centre portion is pressed down to form the dish. The pressing of cups and cones for bearings is a very similar process to that of the wheels, and basic pressing methodology applies. Details of the press tools required are shown in Appendix 3.

9.3 Punching or Blanking Tools - General.

Correctly set blanking or punching tools produce an accurate hole or blank, (the 'blank' is the piece that falls out of the hole). Other advantages compared with drilling are that the finish is good and that the production time is short. Tools, once made are long lasting, and easy to service. The most important parts of the tool are the punch and die, both of which must be made of a high carbon steel and hardened (heated to 850/900°C and quenched in oil). Figure 27 shows the general arrangement of a simple punching tool. Hole or blank size is determined by the size of the die and not the size of the punch. A small clearance is required between the die and punch, as the material being punched is only cut for about one third of its thickness, the other two thirds being sheared or broken. This clearance is determined by the thickness of the material being punched - a good guide is to subtract 0.10 mm from the dimension of the punch, for every 1mm thickness of material being punched. It is of essential that the relative position of the punch and die be accurately controlled as otherwise damage will occur to both tools.

9.3.1 Pressing Force for Blanking.

The force required to punch holes, or cut out blanks of any size or shape, depends upon the total cross sectional area of metal to be cut, and the shearing strength per mm^2 of the material. It is usually expressed in tonnes force (tonnef) and is calculated by multiplying the total length cut by the thickness to obtain the sectional area in mm^2 (square millimetres), and multiplying the result by the shear strength of the material in N/mm^2. A typical example with mild steel, which has a shear strength of 430 N/mm^2, might be a blank 50 mm × 100 mm in 3 mm plate. This would need a force F of:

length of cut × plate thickness × steel shear strength.

$= 300 \text{ mm} \times 3 \text{ mm} \times 430 \text{ N/mm}^2$

= 387 000 N = 39.5 tonnef, (as 1 tonne force = 10 000 N)

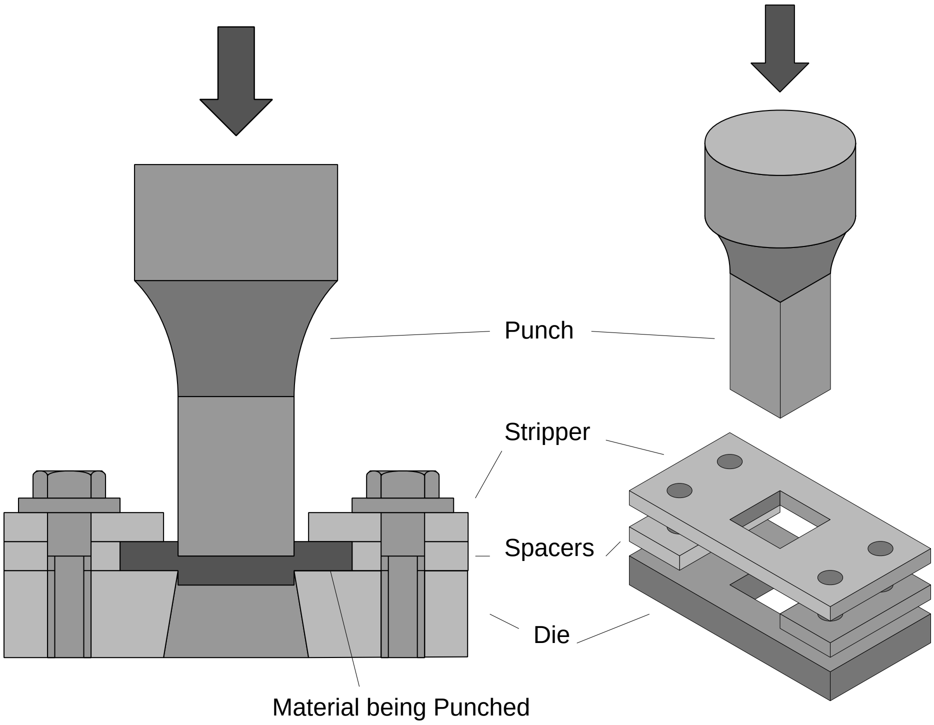

Figure 27: design of a blanking tool to produce a square hole.

A similar example using imperial measurement would be:

rectangular blank 2"× 4" = 12 sq ins (length of cut) × 1/8" (thickness) = 1½" sq ins (area of cut) × 30 tonf/sq in (shear strength of mild steel) = 37.5 tonf.

The capacity of many presses is expressed in tons force (tonf), and materials are often sized in imperial measurement and so it is useful to have the Imperial formula handy. (In any case the reader will notice that there is only a small difference between tonnef and tonf and that 4" is nearly the same as 100 mm.)

9.4 Punching or Blanking Tools for Ox-Cart Manufacture.

In the manufacture of components for the Borno oxcart, punching tools are used for producing the following, (Ø means diameter):

wheel discs:

1. eight (four Ø 14 mm & four Ø 11 mm) wheel hub and bolt holes,
2. one Ø 32 mm valve hole,
3. one Ø 113 mm centre hub hole,

hubs:

4. bearing endplate protectors (these can be made from the discarded Ø 113 mm blanks from the centre hub hole),

bearings:

5. blanks for cups and cones.

Tools for punching the above items are constructed as illustrated in Figure 27. Details of the punching tools for the items 1 and 5 are shown under Appendices 4 and 5 of this report.

9.5 Drilling Jigs - General.

A drilling jig is used for accurate placement of a hole or a series of holes. This is particularly important in production and for the interchangeability of parts. Accurate drilling of holes is a difficult exercise at the best of times. Though drilling appears simple and straightforward, it is full of pitfalls for the unsuspecting - for example accurate marking out, accurate centre punching, adequate holding of work and correct sharpening of the drill are all difficult, and any one, or a combination of the above, will cause inaccurate placement and size of the hole being drilled if badly done.

A drilling jig is made to locate over the component being drilled, and hold the component firmly in place whilst the drill is guided through a well fitting bush. Of course the jig itself has to be made accurately if it is to do the job correctly. The time taken in making a good drilling jig will be more than compensated for in the time saved with accurately drilled components.

When designing a drilling jig some thought has to be given to the method of inserting, holding, and removing the component. The jig has to have an open plan of construction to allow the swarf (cuttings that result from the operation) to clear from the jig and not block it up. An example of a simple drilling jig is shown in Figure 28.

If press tools are employed, only one drilling jig is required in the manufacture of the Borno ox cart. This jig is employed to locate accurately the four stud holes in the lugs of the cast aluminium hubs. Details are shown in Appendix 4 of this report. Ideally drilling bushes are made from high carbon steel and hardened, or they can be made from mild steel and case hardened as described earlier.

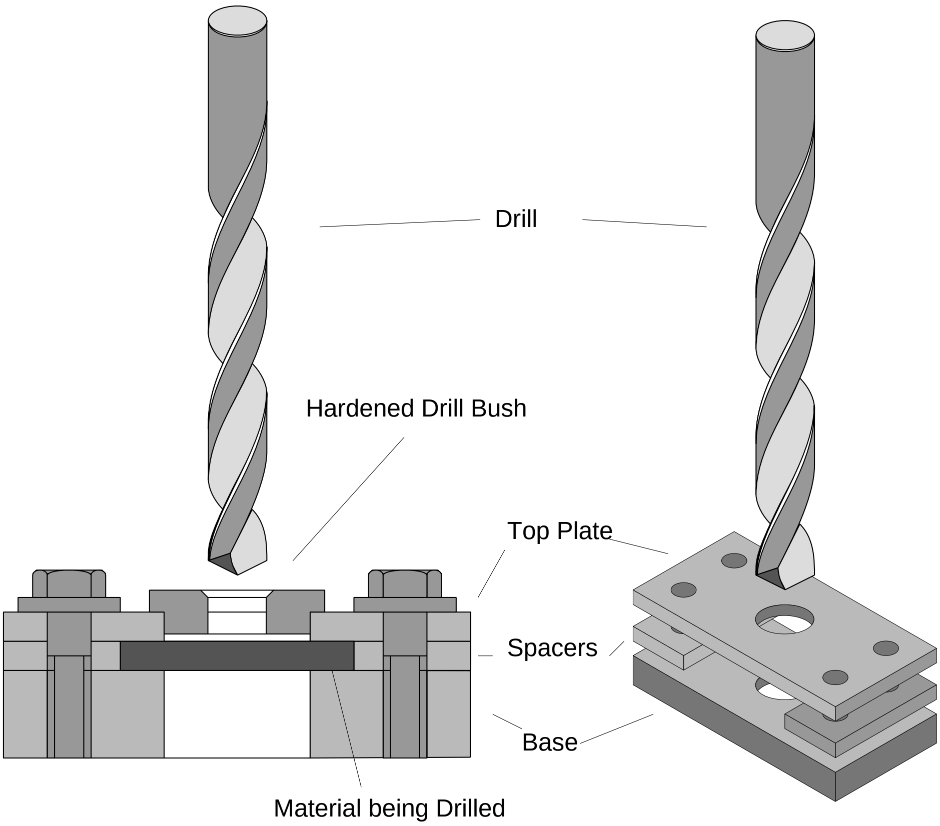

Figure 28: simple drilling jig.

9.6 Steel Casting Mould.

Details of the steel mould for casting aluminium hubs for the Borno Ox-Cart are shown in Appendix 6 of this report.

DTU Working Paper No.44 **December 1995**

The Potential of Cement-Stabilised Building Blocks as an Urban Building Material in Developing Countries

by Dr D E Gooding and Dr T H Thomas

Statement

This Working Paper comprises the *Overview* part of a Report (TDR Project No.D141) to the Overseas Development Administration (ODA) of the British Government which wholly funded the study on which the Paper is based. The Contents List also shows the *Appendices* to the Report which for reasons of economy have been omitted from this Working Paper. Appendices A to I contain the raw survey data acquired during visits to 7 African, 1 Asian and 1 Latin American countries. Individual appendices are obtainable on request from the DTU.

The responsibility for opinions expressed in this Paper rests with the authors and are not necessarily endorsed by ODA. Moreover reference to the names of firms, commercial products and processes does not imply their endorsement by ODA, nor does failure to mention a particular firm, commercial product or process indicate any sign of disapproval.

Abstract

This Paper examines the level of technical achievement in production and the level of social acceptance of cement-stabilised building blocks (alias ‘soil-cement’) currently displayed in 9 developing countries surveyed in early 1995. The survey established that these blocks are currently in common use and are likely to be more widely used in the future. Several technical problems or deficiencies were however identified across the whole area visited, as were new developments pertinent to the advancement of this building technology. These deficiencies and developments are analysed and used to define the research, design and training needed to significantly improve the effectiveness of cement-stabilised blocks as a low-cost walling material in urban areas of developing countries.

J ECONOMIC COMPARISON OF FOUR POSSIBLE PRODUCTION METHODS

SUMMARY

There is a widespread shortage of permanent housing in urban and peri-urban areas of Africa. This shortage is increasing both because of high rural-to-urban migration rates and because of the relatively high cost of permanent urban building materials. The poorest sector of the community is most affected by this housing shortage as it is least able to afford construction materials classified as permanent under prevailing building regulations. This project has focused on building materials for this sector of the population and in particular on cement-stabilised blocks.

Review of objectives

The project leading to this Working Paper falls into ODA’s TDR theme objective U1, "Improving the quality and accessibility of low cost housing and other infrastructure provision in poor urban areas". It forms a preliminary survey to asses the current cost, quality and potential for improvement of cement block making and the viability and value of accelerating the extension of this technology in poor urban and peri-urban areas through the implementation of subsequent programmes of research and design, and of producer training.

It was intended to measure the scale of cement block use, the social acceptability or otherwise of such blocks, whether there is a need for improvement in quality (if so potential interventions were to be identified) and whether it is possible to reduce costs significantly. Using the data gathered it would then be possible to determine whether in combination these factors form sufficient justification for further research to facilitate any potential interventions identified or whether other building materials are more suited to these circumstances and consequently cement block production should not be pursued further. See also Figure 1, "Logical Framework" (overleaf).

Summary of work carried out

Major surveys were carried out in Kenya, Tanzania, Botswana, and Ghana while minor survey were conducted in Sri Lanka Uganda and Mexico. Predominantly urban and peri-urban areas were visited. Discussions were held with governmental and non-governmental organisations involved with building material production, housing construction, planning and building regulation. Poor urban and peri-urban residential locations were visited to assess the current levels of use of cement blocks. Block manufacturers were visited to determine the current quality and cost of the blocks produced and to observe the production methodology in use. Alternative competing building materials were also examined to compare their cost and quality with that for cement blocks. Data was gathered to enable economic predictions to be made to determine the potential block cost reductions which could be made if the process methodology and production equipment were improved. Table 1 summarises this economic modelling overleaf. Potential building material purchasers, private individuals and developers were also visited to determine the acceptability of the available building materials in terms of their cost, quality and social acceptance and the likely acceptability of improved blocks.

Based on observation of the production methodology in use, economic analysis and discussions with local experts, potentially appropriate interventions to improve cement blocks were identified.

Technical results

Cement blocks were found to be a major construction material in both urban and peri-urban areas and are increasingly becoming the basic walling material in these areas. The block quality obtained for a given production cost is much below that which could be achieved. Problems were observed with raw material testing, cement optimisation, mixing, batching, mould filling, compaction and curing. These problems could be reduced if producers were more informed, better skilled, equipped with better production and testing equipment and more diligent in quality control.

It was found that micro-enterprise production of soil-cement can offer cost savings over sandcrete walling. The cost advantage is small (0 to 30%) for built-up walling using current soil-cement block production systems. Soil-cement blocks are usually smaller than sandcrete blocks and consequently are more costly to lay because of the increased laying time and additional mortar required per square meter. Using local cost data for predictions it was found that further savings, in the order of 50%, are potentially possible if impact compaction of larger size soil-cement blocks (equivalent to the size of current sandcrete blocks) were instigated. However it was found that at present soil-cement is disadvantaged by the incorrect perception that it is not a "permanent" building material; it is strongly associated with traditional unstabilised soil construction in the minds of many. It was found that nomenclature was the prime reason for this association and that this may be remedied through the removal of "soil" from the material's name.

The manual equipment used for block production was found to be often poorly designed and its purchasers appeared generally unable to distinguish good design from bad. There was an absence of quality control procedures and in particular of testing equipment to monitor quality.

Implications of results

The implications of these findings for future R&D or training interventions are covered in the last section of this Executive Summary.

This survey found that cement blocks are a major building material for the poor (and the more well off) in the areas of study and that they are increasing in importance as competing materials continue to increase in cost. It is feasible to substantially improve block quality and reduce block costs both for soil-cement and sandcrete. If such improvements were successfully implemented then it is likely that blocks could become both more accessible and more desirable to the urban and peri-urban poor. Consequently it is likely that they could contribute to alleviating the current housing shortage.

Research is required to determine why the present level of process understanding displayed by manufacturers is so low and what improvements could be obtained under current market conditions if operators/owners were better informed and possessed the ancillary equipment to support better quality control.

Current manual compaction machine design is often poor. A wide range of machines are available globally but generally only one machine is available within one country. There is a need to assess the available machines, make public the assessment findings and feed back recommended machine developments to manufacturers and purchasers.

There is sufficient justification for the development, field testing and promotion of the impact moulding process as it offers considerable potential savings in cost and improvements in quality over pressure-moulding.

OVERVIEW

INTRODUCTION

The following report gives details of the result of a four month survey into the use of cement-stabilised[1] building blocks in urban and peri-urban areas of eastern, southern and western Africa, Southern Asia and Central America. The countries of focus for this report were: Kenya, Tanzania, Uganda, Zimbabwe, Botswana, South Africa and Ghana. Sri Lanka and Mexico were also visited to identify practices with potential for future use in Africa. In these countries the building materials used in poorer urban and peri-urban areas were surveyed to determine their price, quality and social acceptance. Particular attention was paid to cement-stabilised building materials and the level of improvement in quality and reduction in cost which could result if a programme to assist block producers were instigated. The data presented in this report was gathered from the field by Dr D.Gooding and Dr T.Thomas[2] between February and May 1995. All prices given are current at this time unless otherwise stated.

Report structure

This report has been arranged so that the central themes and patterns which extend beyond a single country are presented together as an "Overview" which comprises the body of the report. Country specific information is presented in a set of four appendices. In this way repetition of common factors has been minimised.

The Overview has been split into three parts introduction, survey and interventions. The introduction part gives a brief explanation of the differences and similarities between soil-cement and sandcrete blocks, provides the definitions which will be used in this report and outlines the importance of compaction and densification to cement-stabilisation. The second part presents the findings of the survey conducted to establish the current patterns of use, levels of technical production skill and levels of understanding in the 9 countries visited. Also in this part the most commonly observed problems with cement-stabilised building materials are presented. This part finishes with a consideration of the economic value resulting from the use of soil-cement compared to alternative building materials in urban areas. In the third part recent developments in the theory of cement-stabilisation of building blocks are presented and both immediate simple interventions and longer term remedies to the problems observed in part two are suggested. Factors which may affect the advancement of this technology are noted. Research, design and training needs are discussed.

THE TECHNOLOGY

1 THE CURRENT UTILISATION AND QUALITY OF CEMENT-STABILISED BUILDING BLOCKS

1.1 Definition of cement-stabilised building blocks

In this report the term "cement-stabilised building blocks" is used as a generic name to cover a wide range of building materials. A cement-stabilised building block is defined here as one formed from a loose mixture of soil and/or sand and/or aggregate, cement and water (a damp mix), which is compacted to form a dense block before the cement hydrates. After hydration the stabilised block should demonstrate higher compressive strength, dimensional stability on wetting and improved durability compared to a block produced in the same manner but without the addition of cement. This definition includes a range from hand-tamped soil blocks containing only enough cement to enhance their dry strength a little (but not to achieve any long term wet strength) to close-tolerance high-density concrete blocks, mechanically mass produced and suitable for multi-storey construction without a render. The spectrum of cement-stabilised building blocks has been split traditionally into two distinct fractions, sandcrete and soil-cement. Although the terms "soil-cement" and sandcrete/ sandcement/concrete have very different images in

---

1 covering the spectrum of materials from soil-cement to sand-cement or "sandcrete".

2 Both from the Development Technology Unit, a research centre of the University of Warwick.

the public mind in Developing Countries, there is no clear boundary between them. Good soil-cement may be stronger than poor concrete and use "soil" no different in particle size distribution from the so called "sand" used in sandcrete. Provided that the mixtures are "damp" rather than liquid[3] then there is no practical reason to discriminate between soil and sand cement, the production process being the same.

Sandcrete use is widespread and increasing: it has a good popular image. Soil-cement by contrast carries an association or stigma linking it with unstabilised soil and simple adobe construction which has much limited its popularity. However in areas where demonstration production has been undertaken (Arusha, Dar Es Salaam, Nairobi, Taita, Otse, Francistown, Kumasi to mention a few locations) the public has been impressed with soil-cement and the opinion has been repeatedly voiced that it appeared better than the prevailing low quality sandcrete blocks. It is therefore suggested that it is primarily the association of soil-cement with rural adobe building that has restrained its propagation.

It seems appropriate to acknowledge the spectrum of possible cost and quality which cement stabilisation encompasses but to counter the public perception that "sand-cement" blocks are high quality, durable building components, while "soil-cement" blocks are low quality and not as durable. In the country-specific appendices a differentiation has been made between soil-cement and sandcrete because at present, with the exception of South Africa, manufacturers either produce soil-cement or sandcement blocks and identify the materials as separate.

For the purpose of this report soil-cement is defined as a permanent durable material which is produced from a natural or modified soil containing sufficient fines to provide cohesion on densification, sufficient to allow unsupported handling of the freshly moulded block. Good soil-cement blocks may thus be stacked for curing. Quasi-static compaction is usually employed and block depth is typically restricted to 120mm. Using depths greater than this leads to excessive variation in density within the block as a result of high internal friction. Ideally block depth should be 100mm or less.

Sandcrete/sandcement is here defined as a permanent and durable material formed from a washed sand, a natural sandy soil or a modified sandy soil such that cohesion of the freshly moulded block is insufficient to allow unsupported handling or stack curing. Block depth may be greater than 100mm and is typically 230mm. Dynamic compaction is commonly used which produces more uniform compaction resulting in sufficient strength for the block to retain its moulded shape, though not enough for unsupported handling or stack curing.

The key differentiating factors between soil-cement and sandcrete are then cohesion/strength of the freshly demoulded block and the block size. During the course of the survey it was found that block size effectively determined the marketed name, large blocks were sold as sandcrete while smaller blocks were sold as soil-cement. The exceptions to this were in South Africa and Botswana where cement stock bricks are common. However these are typically smaller than soil-cement blocks, 100x225x87.5mm (width x length x depth) compared to 140x290x100mm for soil-cement and 150x460x230mm for sandcrete.

Stabilisation is also possible with alternative cementitious binders such as lime. The following report deals only with ordinary portland cement. At present this is the most widely available and quality-consistent stabiliser and is likely to remain so for at least the next ten years. Even if lime were to become widely available with assured quality, lime stabilisation requires at least twice as long for initial curing. As quick curing has a significant economic value in block production, lime use is likely to remain less common than ordinary portland cement (hereafter cement).

1.2 Methods of forming cement-stabilised building blocks

In all cases blocks are formed by the application of energy to a loose soil/sand-cement-water mix in a mould that determines all but one of the final block's dimensions. The commonest forming processes are

(i) hand-tamping of a moist mix into a wooden mould with no top or bottom, placed on a flat surface; the mould is removed prior to curing the block in situ on that surface. This process was seen in all of the surveyed countries, primarily used for the production of decorative ventilation blocks. Research into the use of this process for labour intensive methods of soil-cement block production has been carried out in South Africa but it is not currently used in the field.

(ii) pressing in a rigid steel mould with a force of up to 10 tonnes (pressure up to 2 MPa) onto the bottom face of the block; the force is obtained by using levers to amplify the pull (say 500N) of an operator; the best

[3] Poured concrete requires compaction to remove air entrained in a viscous liquid which is a different operation to the compression of a damp powder. Moreover such concrete must be contained within a mould until it has hydrated sufficiently to retain its cast shape on removal from the mould.

known machine type operating in this way is the Cinva Ram press. This process was seen in all countries and used exclusively for the production of soil-cement or unstabilised soil blocks.

(iii) pressing with a force greater than 10 tonnes (pressures typically between 2 MPa and 10 MPa) using hydraulic cylinders such as in the Brepack machine. This process has been used in Botswana, Tanzania and Ghana for the production of soil-cement but is no longer in use.

(iv) slamming a hinged and weighty lid onto the exposed top of a mix that has been hand-tamped into a mould. This process was seen in all countries surveyed for the production of sandcrete blocks and also for the production of soil-cement blocks at Camartec in Tanzania.

(v) vibrating a mix in a mould to which some modest pressure or shock impulse is applied towards the end of the process: the vibrator may be powered by electricity or an engine; the blocks may be moulded onto the ground directly by a mobile machine and left to cure there or they may be carried on pallets from a stationary machine to a curing area. This process is used exclusively for sandcrete and was seen in all of the countries surveyed.

1.3 Compaction and Densification

It was shown by Lunt (1980) that higher compaction pressure up to 10 MPa, generated quasi-statically, has beneficial effects on compacted density and cured strength (research conducted on lime-stabilised soil). Subsequently several machines were produced, eg the Brepack, which used a hydraulic circuit to achieve compaction pressures up to 10 MPa. Higher density blocks are easier to handle between moulding and curing, have a higher compressive strength after curing and also an improved surface hardness. The first is important to reduce the incidence of damage during handling and to permit the stacking of green blocks during curing (thereby facilitating good curing and reducing the size of any curing yard). The second is important because standards for building materials are usually expressed in terms of bulk compressive strength. Surface hardness is important as lack of it results in rapid rain or wind erosion or requires a render to be applied to protect the blocks.

By increasing the compacted density of the block, whether soil-cement or sandcrete, the stabiliser content may be reduced for a given strength, thus reducing the cost of the block. However experimental research[4] conducted by the DTU has shown that the cement saving resulting from higher compaction pressures is not enough to offset the increased capital cost of a quasi-static high pressure machine, unless production output is dramatically increased. Additional advantages of high density production were noted by the DTU, namely an increase in the allowable range of particle grading for the material to be stabilised and improved resistance to poor curing as a result of reduced block porosity. These factors do counteract the greater cost of high density compaction but not sufficiently to encourage the use of manual quasi-static high pressure machines.

Block density is not solely determined by the maximum compaction pressure that the forming process could exert. In the case of fixed-volume compaction the amount of soil placed in the mould is highly significant. Too little material and a low density block is produced, while too much material and the machine is over-stressed and liable to jam. Moreover if the material is not compacted at its optimum moisture content, lower density will result. If too little water is present, internal friction is high and densification prematurely ceases. If too much water is added then hydrostatic conditions may be generated where the applied compaction force increases the pressure of the material's pore water but does not result in particle rearrangement and densification. Variable water content causes a further complication as the volume occupied by a damp soil also depends on its moisture content. A dry soil initially expands as water is absorbed, up to a point known as the fluff point, more than this amount of water and the soil volume again decreases.

[4] The relationship between applied compaction pressure, cement content and cured strength was determined empirically in a laboratory setting. This work is described in DTU Working Paper No.40 "Quasi-Static Compression Forming of Stabilised Soil-Cement Building Blocks" (1993).

SURVEY

2 THE TREND TOWARDS INCREASED USE OF CEMENT-STABILISED BUILDING BLOCKS

The traditional building materials common in Developing Countries may be considered to fall into four broad groups; unstabilised soil, fired brick, wood and stone.

Unstabilised soil construction is a widespread construction material in rural areas but is generally seen as undesirable being the bottom rung of the materials ladder. This view is pronounced in South Africa, Kenya and Zimbabwe. Unstabilised soil is not classified as a permanent material under current building regulations which prevents its legal use in urban districts, leaving the home occupier vulnerable to dispossession and the dwelling vulnerable to demolition. None of the survey countries define urban unstabilised soil construction as permanent. Finance organisations are highly unlikely to lend money for the construction of any property built from material not classified as permanent.

Use of unstabilised soil is likely to continue in rural areas where it is freely available (dug on site) and the cost of construction is primarily determined by the cost of labour (which is considered free in a self-build situation). A French organisation, CRATerre has been involved in the promotion of improved architecture to extend the life of unstabilised soil structures, however despite the existence of some admirable demonstration houses unstabilised soil remains firmly fixed in the minds of Developing Countries residents as being second rate. The overwhelming demand in all of the countries surveyed is for "something better than soil". In areas where soil walling is common it is seen as a temporary structure, built because no other alternative material could be afforded. It seems likely that unstabilised soil will remain associated with poor quality and will always be chosen as a last resort by those with limited means. In consequence its use will continue for the foreseeable future in rural areas but not in urban ones.

Fired brick is one of the cheapest building materials where supplies of suitable soil and firewood are present. The quality of burnt bricks was found to be highly variable. In Kampala the soil used has a low clay content and high amount of sand. This is an unsuitable soil for fired brick production, the bricks produced are low quality being porous and even liable to collapse in the rain. These bricks were observed to be highly fissured and bent even before firing. The cost of fuel for a single clamp of bricks in Arusha, Tanzania is 300,000 Tsh (£400). This alone contributes 25% of the final cost of the bricks. Traditionally wood has been the most common source of fuel for brick firing but supplies are rapidly diminishing and have already been exhausted in many areas, in desperation dried cattle dung is now being used by Kenyan artisans south of Nairobi. Work is under way to find alternative sources of fuel; waste wood shavings (Ghana), furnace slag (Botswana and Zimbabwe) and coffee husks (Kenya), all of these are being used with varying degrees of success. In areas where the price of firewood is high, brick production falls in to two categories: high cost bricks produced using adequate quantities of firewood and poor quality bricks using inadequate quantities of firewood with consequent under-burning. It is likely that the use of fired brick will decline in the lower income groups. This trend may be delayed in areas with suitable soil and current reserves of wood but unless the deforestation process is reversed quickly these areas too will see an escalation in cost.

In many areas sawn timber is now one of the most expensive construction materials and consequently one of the least popular, particularly as ongoing preservative treatment to counter the termite threat is expensive. Many squatter settlements are built with waste wood, as seen to some extent in all of the countries surveyed, but this is classified as non-permanent housing and is always vulnerable to demolition by the town authorities. Split bamboo although still widely used in parts of the humid tropics is not an important building material in any of the nine countries visited. Wood will continue to be used for roof support but unless sustainable forest husbandry is successfully promoted its use as a permanent walling material will continue to decline.

Stone is a common building material in areas where soft easily quarried deposits are found. The cost of the material is determined by the labour costs of extraction and dressing and the transport cost of supply to the construction site. Suitable stone is mainly found in Eastern Africa, most notably Nairobi, Kenya where volcanic tuff has been quarried since the 1940s. The early local quarry sites are now becoming worked out and the cost of the material is increasing because the transport costs are escalating as the quarries become more remote. In areas where accessible supplies exist its use is likely to continue, as it is seen as a highly durable material with a low initial purchase price. Stone housing construction by individual home owners has been following an ***extending*** pattern. This pattern of construction has been noted in all of the countries surveyed and is discussed in more detail below in section 2.1.

In all the countries surveyed except Uganda cement-stabilised blocks are becoming the most common urban walling material, despite the increasing cost of cement (a result of internal economic difficulty and structural adjustment programmes). They are steadily displacing the many forms of unstabilised soil, fired brick, wood and stone that have been traditionally used. These blocks owe their popularity to their image of modernity, strength and durability, although at present many of the blocks do not live up to these expectations. They are easy to produce with very little equipment, generally relying more on labour than machinery. Their large unit size compared to stock bricks offsets their higher purchase cost per piece as fewer are required per meter of walling. The large unit size and regularity speeds construction, reducing labour costs and requires less mortar. In all of the countries surveyed current methods for producing soil-cement were found to be capable of producing less expensive block-walling than sandcrete. However soil-cement is currently much less popular than sandcrete because of its stigmatising associations.

At present the majority of these blocks, both soil-cement and sandcrete are not reaching their potential strength or durability, defined by the quantity of cement used in their production. There is great potential for reducing the cost of these materials *and* increasing their quality. Although cement is an expensive industrial product, it is made on a large scale and is widely available, exceptions are remote rural areas such as the Kalahari in Botswana where the price rises dramatically with the distance from supply centres and Ghana where, until recently, supply has been largely restricted to government contracts. With improved production methodology the quantity of cement used in blockmaking and hence the cost of the blocks may be reduced. In contrast, the traditional materials although indigenous are becoming more scarce, particularly firewood, and in consequence more expensive.

There are many possible options for improving the provision of housing, one is to fight against public opinion and promote more traditional building methods, for example improved soil architecture. Another is to promote sustainable forestry to supply wood both for direct use in construction and for fuel for brick firing. A third is to improve the efficiency of cement use in cement-stabilised building blocks. With improved soil/sand selection, more efficient compaction and in particular well controlled curing (see below), the cost of these blocks may be reduced substantially, significantly reducing the quantity of cement consumed per unit of walling, while at the same time maintaining or improving strength and durability.

In the short term at least, it seems likely that cement-stabilised materials will continue to increase their market share. It is generally easier to improve a popular product with an established and expanding market than to revive one with a failing reputation. Moreover it is possible to improve the efficiency of cement-stabilisation through only minor modifications of current production practices. Following the recent rapid increase in cement price in many of the areas visited (the Kenyan price rose from 170 Ksh to 370 Ksh in a matter of months, while the Tanzanian price rose from 1400 Tsh to 4000 Tsh in one year), methods of reducing the cement content per block will be welcomed by the existing manufacturers. It is a more complex proposition to find widespread alternative fuel supplies for brick firing or to implement widespread sustainable forestry practice. As the need for improved affordable housing is current and very pressing it seems preferable to promote methods of reducing the cost of cement-stabilised material now.

2.1 The *Extending* pattern of house construction

In this section the *extending* pattern of construction, common in urban areas of the countries visited, is explained and its influence on materials choice is explored.

Typically a house is built on a grand scale as the owner's "ideal" house. It is not uncommon to let its construction take ten years, divided into many stages of construction and payment, rather than to build an immediately affordable smaller house. Initially a site is obtained and no construction work takes place until the site has been paid for. Then blocks are purchased and stockpiled until enough have been acquired to construct a section of wall whereupon a mason is employed. The stockpiling and block-laying phases are then repeated until the house is ready for roofing. In this way the home owner may use a higher quality material than could otherwise be afforded.

In the particular case of Nairobi where stone is believed to be the highest quality construction material, rough hewn stone is purchased very cheaply and a mason employed to provide the final dressing as and when finance is available. Once enough stone has been purchased and dressed the mason is then employed to lay the blocks and so on. Stone is suited to this pattern of construction as each stage of construction is cheap, even though in total the final cost of the wall may be higher than one constructed from sandcrete blocks.

While the house is under construction the eventual owner is usually renting accommodation elsewhere. The rapidly increasing urban population in many areas is causing the price of rented accommodation to increase rapidly, in Botswana the urban population is increasing at 6.9% per year. Similarly the population of Nairobi is increasing at 7% p.a. In Arusha rent for a 10' by 12' room is currently 7000 Tsh a month, payable for one year in advance (the minimum wage is 15000 Tsh a month). Such high rents are discouraging the *extending* pattern of house building described above. As rent rises so it becomes more attractive to speed up the construction process even if this means a smaller house; the quicker the owner can occupy the house the quicker he/she stops paying rent. Once construction speed becomes an issue then the total cost of the house is considered rather than the cost of its components. For example although undressed stone is cheap to purchase, the cost of subsequent processing and construction is high. Because the stones are irregular, a thick layer of mortar is required and consequently a substantial quantity of cement is used. Similarly a substantial quantity of cement is required for the render. In contrast cement-stabilised building blocks although marginally more expensive to purchase initially, do not require final dressing and are regularly sized using less cement both for mortar and render. As general awareness of the financial drawbacks to *extending* construction increase it is likely that it will become less popular, perhaps becoming replaced by a *core-extension* pattern.

2.2 The *Core-extension* pattern of housing construction

Core-extension housing was observed in the redeveloped squatter settlement of Old Naladie in Gaborone, Botswana. The situation is slightly different in Old Naladie as the future home owner already owns the plot of land and usually occupies a temporary structure on the site. In this case the drive for rapid construction is to allow income to be generated by renting space in the house to third parties. Small twin room houses are initially constructed (using sandcrete), one is occupied by the house owner while the other is rented out. The rental income is then used to provide finance for further extensions to the house which are used either by the home owner or also rented out to generate further income.

Once the advantages of faster construction become more generally appreciated it is likely that both a reduction in the size of the initial construction and an increase in the use of more affordable materials will be seen.

3 CURRENT PRODUCTION OF CEMENT-STABILISED BUILDING BLOCKS: PRACTICES AND PROBLEMS

3.1 Process methodology

3.1.1 Curing procedures

The most detrimental practice seen in all of the countries surveyed was poor curing of the formed cement-stabilised block. Once formed the blocks are frequently left out in the sun to "dry", large areas of sun-dried "curing" blocks were observed in every country surveyed. Cement relies on the presence of water to hydrate, forming an interlocking skeleton of calcium silicate hydrate which gives the material its strength. If the block is allowed to prematurely dry then full hydration of the cement does not occur and consequently only part of the cement used contributes to the strength of the block. Experiments conducted by the DTU at the University of Warwick have shown that the strength lost due to poor curing can easily reduce the final block bulk strength by 20%. As the block surfaces lose water first, strength loss in these regions is still higher. The loss of surface strength reduces both the handleability (edge and corner chipping during transport) and the durability of the blocks. If proper curing were implemented, maintaining the moulding water content for at least seven days, then both strength and durability improvements would be seen. Good curing practice is not followed for one of two reasons. Either the producer is not aware of the need for curing (instances in all countries surveyed) or it is felt that the cost of constructing a suitable curing area is not worth the potential increase in quality. In Kampala where sandcrete blocks are produced by "egg-laying" vibrating machines, producers observed that wet weather, provided heavy rain did not pit the newly moulded blocks, gave better curing. However they were reluctant to use cloths to increase humidity during curing and also indicated that shading the blocks would be unacceptably expensive, given the large area which would have to be covered.

With conventional moulding methods the strength of the green blocks is not sufficient to allow stacking of the fresh blocks and hence a large sheltered curing area is required. Improved compaction produces higher density green blocks which may be stack cured, greatly reducing the area needed. Furthermore a higher density block loses water more slowly as a result of its reduced porosity and consequently is less susceptible to poor curing practice.

3.1.2 Batching

Cement hydration begins as soon as the cement comes into contact with water. In consequence the batch-time, the length of time between addition of water to a cement mix and the use of the last part of a batch, is important. Ingles and Metcalf (1972) suggest that as much as 50% of the final cured strength of cement-stabilised soil may be lost by a delay of two hours before compaction. Experiments conducted by the DTU confirmed a strength loss due to compaction delay but found it to be less pronounced, namely 20% loss after a two hour delay. The significance of batch time was not understood by field producers and consequently batch times of two hours or more were common, in isolated instances batch times up to six hours were found (St Joseph's Mission, Nairobi) which would result in at least a 50% strength loss for blocks produced at the end of a batch. Batch times of 30 minutes are recommended and it is advisable that times do not exceed 1 hour.

3.1.3 Optimum water content

The amount of water added to the cement mix is also important for good compaction during moulding. Moulding at the optimum water content results in the most dense block yielding the greatest strength. If too much or too little water is added the formed block will be less dense. This fact was not fully appreciated by any of the block manufacturers visited and consequently variable moisture contents were used at moulding. This fact also contributes to the argument for shortening batch-times, as water is progressively lost from the mix both in the hydration of cement and also by evaporation.

3.1.4 Raw materials testing

The material, either "soil" or "sand" to be stabilised is not adequately tested and the importance of the fines content is not understood. Thorough soil testing has always been advocated for soil-stabilisation but not for sand stabilisation. It has been found in the field that what is sold as sand, which should contain minimal quantities of material finer than fine sand (0.063mm) frequently contains high quantities of such fines. CSIR in Pretoria, South Africa have found supplies of "building sand" composed of over 50% clay. More commonly contamination is in the order of 25% fines, as observed in Zimbabwe, Kenya, Botswana and Ghana for unwashed pit sand. The proportion of silt and clay (the fines) present in the material to be stabilised plays an important role in determining the amount of cement needed for a given degree of stabilisation. It is the fines, particularly the clay fraction, which expand and contract on wetting and drying and consequently affect the durability of the cured block. Without an understanding of both the effect of the fines and the quantity present it is unlikely that the optimum use of cement will be made.

Although testing is advocated for soil stabilisation it has been found that this rarely happens. In fact in Tanzania the training given by Camartec to purchasers of their block press (Cinva Ram type) does not include how to test the soil. Instead Camartec technicians conduct soil tests on site and report to the producer the quantity of cement required. This is only a very short term solution to the testing problem as the composition of soil is highly variable and unlikely to remain at the tested composition once soil extraction extends from the immediate vicinity of the soil samples taken. Once the composition has changed significantly, the recommended cement content should also change. At present this does not happen and consequently cement use is not optimised.

The soil testing methods reported in the literature have been found to be lacking (see DTU working paper No 38 "Soil Testing for Soil-cement Block Production"), yet these publications usually form the basis for NGO organisations' knowledge. Hence where soil-testing information has been disseminated to block manufacturers by such organisations the information was found to be incomplete, faulty or misunderstood. High quality blocks may be produced with no soil testing whatsoever if adequate trial block production takes place. However without some form of testing and understanding, this process is extremely lengthy and was not observed in any of the countries surveyed.

3.1.5 Quality control

Quality control is usually not appreciated by the block manufacturer, in consequence there is a large degree of variation in quality, both between manufacturers and within the stock of a single manufacturer. Neither testing of the green compact nor testing of the cured blocks was observed. Most NGO projects had tested blocks at the start of production to determine the optimum cement content for the required strength but had not continued testing subsequently. Blocks produced by St Joseph's Mission (Kenya) were recently tested for compressive strength by the Kenyan Standards office and found to be only half of the value expected, 0.7 MPa compared to 1.5MPa. This is not surprising as the production of blocks had begun 12 years earlier, methodology was passed from operator to operator, degenerating over the years, and no quality testing had been implemented to monitor gradual changes.

Testing of the green blocks' density would identify production problems at an early stage, allowing quick remedial action to be taken. Testing of representative sample blocks for cured strength would serve as both an overall check on the production system and a useful marketing tool, namely the adherence of the block to the local building regulations. However although building regulations exist in nearly all urban areas, defining the minimum allowable compressive strengths of walling materials, they are not effectively enforced for low rise construction. Botswanan site inspectors rely on a purely visual assessment of the blocks (source Mr Maititing, Acting Director of the Department of Architecture and Building Services). Moreover the only one of the surveyed countries to have passed a standard relating specifically to soil-cement was Kenya (KS02-1070, 1992), in the other countries either no standard or only an unadopted draft standard exists.

Although the cement-stabilised production process is a simple one, it relies very heavily on tight quality control to achieve good results. The following is a summary of the factors which can cause block defects if not adequately monitored;

- soil/sand composition may vary considerably even if dug from a single pit
- inadequate mixing can produce a highly uneven distribution of cement
- mixing too large a batch of stabilised material at one time can reduce strength due to premature cement hydration

- incorrect moisture content at the time of moulding adversely affects the efficiency of compaction
- variations in the volume of mix placed in the mould for compaction affects the final density of the block and can seriously damage the machine
- inappropriate curing will allow the block, in particular the block surface, to lose the water required for full hydration of the cement, causing low strength blocks with poor surface durability

3.2 Compaction systems

3.2.1 Hand tamping

This method of production was only observed for small, but relatively high value decorative ventilation blocks, carried out exclusively in the informal sector. These are particularly common in Arusha and Dar Es Salaam (Tanzania). It was not observed for larger sized building blocks except in one small Tanzania town and for an experimental investigation conducted by CSIR in South Africa, as the labour cost becomes excessive compared to mechanical compaction.

3.2.2 Low-pressure compaction

The most common compaction equipment used for "soil" stabilisation is based on the Cinva Ram machine, invented in the 1950's. This slowly applies a pressure (usually less than 2 MPa) to the mix. These machines are generally produced in the informal sector although formal production does also occur. Table 3.2.2 details the most common type of machines observed in the African countries surveyed. Machine cost varies significantly with country of manufacture and quality of construction from £63 for a machine produced in Ghana under the supervision of the University of Science and Technology (UST) to £526 for a high quality machine incorporating sealed bearings, the Shelter Press made in Zimbabwe, commissioned by Intermediate Technology (Zimbabwe). The compaction pressure is applied mechanically by transmitting the force exerted by the operator to the contained mix through an over-centre toggle lever arrangement. There are a number of common problems both with the manufacture and use of these machines.

TABLE 3.2.2 Cinva Ram type machines observed in Africa

Organisation	Country	Block size	Compaction Ratio	Novel features	Cost /£
Camartec	Tanzania	140x290 x100mm	1.65:1	none, has poorly aligned mould box	92
Approtec	Kenya	140x290 x115mm	1.7/1.9:1	variable compaction ratio, secondary pivot to ease block ejection, slam-shut lid	321
IT (Zimbabwe)	Zimbabwe	140x295 x120mm	1.6:1	Sealed bearings, sliding mould lid to automate removal and strike off after filling	526
RIIC	Botswana	150x300 x115mm	1.6:1	none, has piston guidance problems	159
UST	Ghana	200x290 x150mm	1.5:1	mould top linked to compaction handle so that removal is automatic	63

The construction quality of these machines was found to be highly variable, some machines are manufactured using jigs to ensure correct alignment of parts (Approtec, IT Zimbabwe and UST) while others are not (RIIC and Camartec). Non-parallel mould boxes and misaligned compaction pistons were the most serious common faults, producing sub-standard blocks and quickly jamming and breaking down, sometimes after only weeks of use (experience of Habitat for Humanity, Botswana). Some of these machines have been modified from the original Cinva Ram design to include useful innovative improvements. A significantly improved machine could be produced by amalgamating the useful features seen individually world wide in many of these machines. However this is unlikely to happen without external assistance as the manufacturers/designers are not aware of machines outside their own locality. Several organisations are currently working separately to improve Cinva Ram type machines, including RIIC, Botswana Technology Centre (BTC) and IT Zimbabwe. If these organisations could effectively liaise then progress would be much faster and duplication of mistakes minimised. Both RIIC and BTC are working independently on interlocking block designs. The organisations are within the same country and less than two hours drive apart but are not currently collaborating.

Most of the machines operate on a fixed compaction ratio (typically 1.6:1), this determines the volume of the mould box at the time of filling. Different soils have different densities at the time of moulding and require different degrees of compaction in terms of the ratio of loose to compacted volume. This necessitates some form of batching to place the correct amount of mix in to the mould; too little and the block is under-compacted and weak, too much and the machine is over-stressed and liable to break. Batch-box filling was not observed in the field, both under-compacted blocks and machine breakdown were common. Overloading of the mould box was by far the most common cause of breakdown yet Approtec were the only organisation to have included the ability to vary the compaction ratio in their machine.

The significance of mould friction is not appreciated by block manufacturers. Research conducted by the DTU has shown that mould wall friction can significantly reduce the effectiveness of any applied pressure. To minimise this the mould should be lubricated with a release oil. This not only improves the compacted density of the block but also improves the block's surface finish and eases ejection. Mould lubrication is not currently common in any of the countries surveyed.

3.2.3 Manual high pressure quasi-static compaction

This type of machine uses the Cinva Ram toggle lever to first provide the majority of the compaction; final compaction to high pressure is then achieved by operating a hydraulic ram which acts on the moving piston. This type of machine is produced only in the formal sector. It is no longer in current use as it is very costly to purchase and has a reduced production speed since the hydraulic ram must be operated in addition to the toggle lever for each cycle. Although savings may be made in the cement used for a given degree of stabilisation the increased capital cost of a high pressure slow-squeeze machine (£ 3000-£4000) outweighs these savings. (See section 5.1 for new developments in the field of alternative high pressure compaction). Powered high-pressure compaction machines are also available but these are much more expensive eg the Ceratec machine seen in Botswana which costs £24,000, excluding ancillary powered mixing and sieving equipment.

3.2.4 Slam-shut low-pressure compaction

The slam-shut compaction machine was found in all of the countries surveyed. The compaction ratio of these machines is very low, a maximum of 1.3:1 if the mix heaped above the top of the mould is included. Consequently the mix is heavily pre-compacted by hand-tamping before repeatedly slamming the mould lid to achieve final compaction. This machine is made cheaply in the informal sector and its origins are unknown. It is less complex than the Cinva Ram and less prone to manufacturing problems. It generally costs slightly more than the cheapest Cinva Ram machine, eg £110 compared to £93 (cost comparison for Tanzania). In Ghana a slam-shut machine costs less than a Cinva style machine, 60,000 C compared to 111,000 C, but 300 wooden pallets are also required at an additional cost of 400 C per piece, increasing the effective cost to 120,000 C. This machine applies a variable compaction energy to the mix, depending on the degree of hand-tamping employed, the amount of mix contained in the mould and the number of blows applied by the lid. Consequently quality and consistency are dependant on the degree of care exercised by the operator. One informed Tanzanian manufacturer, Kunda Co Hardware in Arusha, attempted to ensure quality consistency by closely supervising production, always using the same operators for the same task and ceasing production if one of the team became ill, rather than hire a temporary replacement. Again batch-box mould filling was never observed.

Typically six blows are applied which equates to an applied energy of approximately 1kJ/block[5] (assuming an effective drop height of 30cm, for a mould lid weighing 15kg which is thrown down onto the mix by the operator applying a force of 400N, repeating the operation six times). The energy applied per block falls to 0.5kJ when two blocks are formed at once as is the case for some machines observed in Tanzania. 1kJ is a low level of applied energy. The DTU has found that slow compaction to the low pressure of 2 MPa requires an applied energy of approximately 2kJ (calculated for a block 290x460x100mm).

The low compaction achieved with slam-shut machines results in low density blocks with little green strength. In order to allow transportation from the compaction machine to the curing area the blocks are moulded on a wooden pallet which is then used to carry them. They are too weak to allow stack curing and consequently curing normally follows the "sun dried" pattern. Improving machine design to increase the amount of energy applied

[5] The standard size of block produced by these machines is either 290x460x100mm (4") or 290x460x150mm (6").

would allow the quantity of cement used to be reduced and also increase the green block strength, allowing further savings to be made by facilitating stack curing.

3.2.5 Powered vibro-compaction

In this process machines powered either by electric or internal combustion motors utilise vibration coupled with a very low confinement pressure to compact the mix; some machines finish the compaction cycle with an impact blow of moderate energy. Two types of these machines are common. The moving "egg-laying" type compacts several blocks at once; these are laid directly onto the ground where they are cured without moving (sun dried). The stationary machine produces one or two blocks per cycle which are ejected from the mould on a pallet (a pallet is placed in the bottom of the mould prior to filling) and carried to a separate curing area (sun dried). These machines are produced in the formal sector and are expensive, costing £6000 in Zimbabwe. They require a wetter mix for successful compaction than the impact machines and blocks are prone to slump. The size of the final block is dependant on the wetness and amount of mix placed in the mould and the length of time for which vibration is applied. The mould is filled and scraped off flush. However only volume and not weight of the charge is fixed; block heights were observed to vary as much as 10mm in Harare.

4 ECONOMIC ANALYSIS OF BUILDING MATERIALS COMPETING FOR THE URBAN AND PERI-URBAN MARKETS

Table 4.1 (below) shows the raw data, labour rates, cement costs etc which were gathered in the field and subsequently used to perform the economic analysis contained in the relevant country appendix. It also shows the best case for the costs of built-up walling using respectively, standard-size blocks made by conventional quasi-static compaction of soil-cement to low pressure, large-size blocks made by impact compaction of soil-cement to high pressure, sandcrete blocks, burnt bricks and quarry stone. In the Appendix J four methods of soil-cement production were modelled (using Kenyan costs). The most efficient of these methods, peri-urban micro-enterprise production, was the only method to be used in the subsequent analysis conducted for other countries. The full methodology is detailed in Appendix J and used for the remaining countries examined.

The ratio of labour wage to cement cost, row 14 in table 4.1, was thought to provide a good indicator of the economic viability of soil-stabilisation; however this has proved to be incorrect. Although this labour/cement ratio varies strongly from country to country, the cost ratios of standard block soil-cement walling to sandcrete walling (row 15) and of large block impact formed soil-cement walling to sandcrete walling (row 16) vary little. The results of the economic analyses show that using current low-pressure production, switching from sandcrete to soil-cement will reduce walling costs by between 11 % and 35 %. This is significantly less than the figure of 50% which has been quoted in the past. In previous studies only the cost of the individual walling elements have been compared, whereas in our study the cost of a built-up wall has been used for comparison. Consequently small blocks are disadvantaged. A larger number must be used per square meter of walling (usually considered in earlier analysis), more mortar is required (not normally considered) and they take more time to lay (not normally considered). Although this type of production method is less expensive than sandcrete, a cost advantage of 30% or less is unlikely to encourage the uptake of the technology in areas where social stigma is a factor. It should be noted that for this analysis the two production figures used (200 and 400 blocks per day for low pressure compaction) define the range generally achieved by self help and NGO projects, while the prices quoted for sandcrete are those charged by commercial yards where the production rate is much higher, even if quality is low. For example although 200 and 400 blocks per day was used as the basis for the Action Pack block press output, Approtec believe that with a suitably trained and motivated workforce the daily output could easily reach 800. If such outputs were seen in practice, as should be the case for micro-enterprise rather than self-help production, then this method becomes more attractive.

However with production rates of only 160 and 320 blocks per day, the hypothesised large-size, impact compacted block would cost significantly less than any other available durable walling material. The cost efficiency seen for this type of walling is principally a result of the method of compaction. Impact compaction, resulting in high uniform densification allows a deeper block to be produced which has enough strength to allow hollowing. The hollowing of the block reduces the mass of stabilised material used per square meter of walling. The high block density allows the percentage of cement to be reduced for a given strength. The larger size of the block allows further savings to be made in laying time and the amount of mortar required. Research conducted by the DTU has also shown that impact compaction, by virtue of its superior densification, will also be more tolerant of poor production methodology. It has also shown than a wider range of soils may be economically stabilised and that reduced porosity reduces the rate at which water is lost from the compacted block during curing.

TABLE 1 COSTS FOR LABOUR, CONSTRUCTION MATERIALS AND BUILT UP WALLING IN THE PRINCIPAL COUNTRIES OF FOCUS (figures given are in local currency)

	KENYA	TANZANIA	BOTSWANA	GHANA
1 exchange rate	68.5 (£1)	865 (£1)	4.22 (£1)	1780 (1)
2 unskilled daily labour wage	70 (£1.02)	1000 (£1.16)	5 (£1.18)	1500 (0.84)
3 foreman wage /day	250 (£3.65)	2000 (£2.31)	35 (£8.29)	3500 (1.97)
4 skilled construction labour /day	200 (£2.92)	2500 (£2.89)	35 (£8.29)	3500 (1.97)
5 cement cost /50 kg	370 (£5.40)	4000 (£4.62)	10.95 (£2.59)	6000 (3.37)
6 sand cost /tonne	1000 (£14.60)	4286 (£4.95)	22.6 (£5.35)	7600 (4.27)
7 soil cost /tonne	429 (£6.26)	1714 (£1.98)	1.7 (£0.40)	517 (0.29)
8 machine cost (Cinva Ram type)	22000 (£321)	80000 (£92)	670 (£159)	111625 (63)
9 cost /m^2 for internally rendered wall built with std size soil-cement block	327 (£4.78)	2970 (£3.43)	16.45 (£3.90)	4360 (2.45)
10 cost /m^2 for internally rendered wall built with large size soil-cement block produced by impact	213 (£3.11)	1866 (£2.16)	11.36 (£2.69)	2551 (1.43)
11 cost /m^2 for internally rendered wall built with sandcrete blocks	457 (£6.67)	3341 (£3.86)	25.21 (£5.97)	4880 (2.74)
12 cost /m^2 for internally rendered wall built with burnt bricks	n/a	3454 (£3.99)	19.79 (£4.69)	4796 (2.69)
13 cost /m^2 for internally rendered wall built with quarry stone	418 (£6.10)	n/a	n/a	n/a
14 ratio of labour wage to cement cost	5.29	4.00	2.19	4.00
15 ratio of soil-cement to sandcrete cost std size	0.72	0.89	0.65	0.89
16 ratio of soil-cement to sandcrete cost large size	0.56	0.56	0.45	0.52

INTERVENTIONS

5 RECENT DEVELOPMENTS IN THE THEORY OF CEMENT-STABILISATION OF BUILDING BLOCKS AND PERTINENT INTERVENTIONS

5.1 Compaction, the effects of density on block quality and the superior densification of impact compaction

Research over many years, including that undertaken since 1990 by the DTU, has shown that block quality depends upon three main factors. These are materials selection, densification during moulding and curing. The effectiveness of the first and last of these depends upon the block-maker's skill and the expenditure on cement. Densification depends on the moulding machinery used as well as the moulder's skill. New knowledge in this field relates particularly to the densification process and its consequences: the most recent findings are summarised as follows.

The advantages of increasing the pressure of conventional quasi-static compaction were presented in section 1.3. An alternative method of generating high but transitory forces is through the use of a dynamic lever. A weight lifted slowly through a height gains potential energy. Once the weight is dropped its potential energy is transferred to kinetic energy. When the weight strikes a stationary object all of the stored kinetic energy is released in a very short distance, generating a large force. With quasi-static mechanical machinery the full compaction force must be transmitted through elements which move relative to each other, leading to high bearing wear rates and a short machine life, moreover this force must be transmitted through the body of the machine hence requiring it to be relatively massive. Impact machinery does not suffer these drawbacks nor does it suffer from the complexity associated with the inclusion of the hydraulic circuitry required to achieve compaction pressures above 2 MPa.

Recent research conducted by the DTU has found dynamic methods of compaction, utilising impact blows are also capable of producing high density blocks. Such blocks have a more uniform distribution of density and require lower levels of applied energy than do slowly pressed blocks. For example compaction to a mean density equivalent to that resulting from a quasi-statically applied compaction pressure of about 10 MPa was found to require 43% less energy. Moreover the improved density distribution seen with impact compaction was found to equate to a 24% increase in compressive strength for a given mean density. In combination these factors result in a 50-75% overall saving in the energy required to achieve a given compressive strength. In addition one of the main problems with quasi-static compaction, difficulty of block ejection, is overcome with optimised impact compaction. The dilation and subsequent contraction of the impacted material (which allows the more uniform density distribution to develop) also reduces the final lateral pressure exerted by the mix on the mould walls and consequently greatly eases ejection.

5.2 Possible interventions, immediate

There are thus four prime areas in which improvement may be made to the production of cement-stabilised building blocks; curing practice, production methodology, soil/sand selection and processing/compaction equipment. Crucial to the process of improvement is increased understanding of the pertinent factors both by NGOs engaged in promotional and support activities and the block producers themselves.

The prevalent poor curing practices observed in the field cause a significant under-attainment of compressive strength and durability. This is typically 20% but depends on the degree of adversity experienced by the blocks during curing, the amount of exposure to direct sun, air temperature, relative humidity and wind speed. Improved curing practice to maintain the moulding moisture content for at least seven days is very simple to implement, requiring no additional equipment other than a covering for the blocks. The intervention identified here would be to provide training to block makers, demonstrating the improvement in block quality resulting from good curing practice. Good curing resulting in either a stronger more marketable block or alternatively a cheaper block as a result of the cost saving resulting from cement optimisation if strength was maintained at the current level. Strength is approximately proportional to cement content, so a process-related 20% improvement in strength for a block where cement cost comprises 60% of the total cost could reduce the block cost by 12 % (the cement content may be reduced by 20%).

Similarly immediate improvements, either reductions in cost or increase in quality, will result from improved understanding, used to implement better production practice. Reduced batch times, optimum water content used for moulding, consistent mould filling (batch-box filling) and consistent compaction all increase the quality of the cured blocks.

Correct use of simple soil/sand testing procedures will enable the most appropriate use of the available material to be made, identifying unsuitable soil/sand which should not be used and allowing discrimination between alternative materials. Proper initial use of soil/sand testing can greatly speed the setting up of production while occasional subsequent monitoring can identify changes likely to lead to substandard production.

Improvements to current low-pressure compaction equipment are possible by amalgamating the various refinements seen in individual Cinva Ram type machines. These refinements will increase the production capacity of the individual machines by streamlining their operation and improving compaction consistency. For example a machine with a variable compaction ratio (as is the case for Approtec's Action Pack Block Press, Kenya), once its purpose, adjustment and operation are understood, will result in reduced variation of compacted block density and remove the risk of over-stressing the machine without resorting to batch-box filling.

5.3 Possible interventions, medium term

There are significant advantages in producing blocks of higher density than those obtainable from low-pressure, slam-shut or vibration machines. High-pressure quasi-static compression does not seem to be the answer; as argued earlier it is too slow and the machines are too costly. Impact appears to offer a more economic route to obtaining high and uniform density. Any refined impact machine should find a ready market in competition with the existing slam-shut machines and displace the vibration based machines.

The development of an impact-based machine capable of generating densities equivalent to 10 MPa quasi-static compaction should allow the benefits of high density mentioned above to be achieved in addition to the separate benefits of impact compaction. Any such optimised machine will compact with a much lower energy input than say a hydraulic machine, resulting in less operator fatigue if the machine is manually powered and less fuel consumption if motor driven. The robust simplicity of the slam shut compaction machine and its current popularity with block producers is a good indication that any improvement to this type of machine should find a ready market. A short life and high incidence of mechanical breakdown were the most commonly cited dissatisfactions with the Cinva Ram type machines. The fundamental problems with this type of machine (see section 5.1) are overcome by impact force application. Consequently provided an impact machine's mould box is designed to withstand the fatigue of small repeated shock loading, the machines life and reliability should be superior to the Cinva Ram.

A high-pressure prototype impact machine, the Ranko Block Maker (cost £120), was designed and successfully used by Agas Groth in Botswana in 1985 to produce blocks which were used in the construction of several houses. These houses have now been standing for ten years with no maintenance and are still in excellent condition. They should be compared with neighbouring houses recently built with high density blocks produced using mechanically sieved and mixed soil, compacted with the Belgium Ceratec and South African Hydraform machines which cost £24000 and £14000 respectively. These houses are already suffering from erosion.

6. FACTORS LIKELY TO AFFECT THE UPTAKE OF THE IDENTIFIED INTERVENTIONS

Sandcrete is an established material. The only barrier to extension of its use is its cost. The cost may be reduced through implementing the interventions mentioned. Operators are generally keen to reduce production cost and consequently the uptake of the interventions is likely to be high in this field.

If soil-cement is specifically promoted then there are factors likely to hinder advancement, those mentioned below are the dominant ones which will have to be contended with;

- Soil-cement has frequently been promoted as a low-cost walling material, which it is. However this ignores the social status associated with permanent housing. Namely the owners are prepared to spend ten years building a house rather than use "low-cost" materials because of the social stigma (see below).
- Standards dealing with soil-cement are not yet widespread, consequently soil-cement is not officially recognised as a permanent building material. Therefore planning permission cannot be given for dwellings built from it. Moreover the passing of national standards frequently requires local ratification. Kenya is the only surveyed country where a national standard relating to soil-cement has been adopted (KS02-1070, 1992). Local Kenyan building by-laws are changing but only slowly as these are modified on a district by district basis, frequently hampered by "personal conflict of interest". It should be noted that although standards do exist for sandcrete blocks these are infrequently enforced.
- The need for quality is often not appreciated in the informal manufacturing sector (neither in the soil-cement nor the sandcrete fields) where the majority of block production has taken place. It is one thing to demonstrate a cost reduction resulting from an improvement to a manufacturer's existing production method, which can be appreciated and another to generate interest in training from new manufacturers who believe the process to be simple. Recently a five day course run by Approtec (Kenya) on the proper use of its Action Pack block press machine has had to be shortened to two days in an attempt to increase participation by machine purchasers. The cost of the training course is included in the purchase cost of the

machine so that participants incur no additional fees. The non-attendance of purchasers must therefore be attributed to a lack of appreciation of its importance.

- The literature dealing with soil-cement production methodology is not adequate. Soil-cement is often presented as a simple process while in fact it relies on a significant degree of understanding coupled with a rigorous pre-production testing programme. While the labour force will have been trained in the mechanical operation of the machines which is a simple task, other aspects, such as detailed soil-testing and determining the optimum moisture content have been less rigorously taught and less well understood.
- The field training of existing block producers (both soil-cement and sandcrete) has frequently been conducted by technicians whose knowledge has been gained from the available published literature. This literature is not adequate and consequently the training given to block producers is frequently inadequate. In particular the coverage of methods of soil testing and final block quality are generally not adequate and not sufficiently emphasised.

The soil-cement block must be treated like any other commercial product and subjected to a coordinated marketing strategy. The prime aim of this strategy should be to de-stigmatise the product. Pronounced anti soil-cement stigma was observed in Kenya, Zimbabwe and South Africa. Stigma was also observed in the other countries surveyed but was found to be less pronounced. It is stressed here that at the moment a number of the criticisms which are sustaining the stigma associated with the technology are deserved. The soil-cement blocks currently produced frequently do display poor quality and vary greatly within batches. Although these deficiencies are also commonly shared with informal sandcrete block production it is the blocks marketed as soil-cement which are identified by both the general public and builders as poor.

If soil-cement can be demonstrated to existing sandcrete manufacturers in suitable locations and offered to them as a diversification product to be marketed as a cement-stabilised block, then the uptake of the technology is likely to be sustained (providing that the block quality is maintained). Soil stigma will be averted and the cost of building materials will be reduced. It is recommended that future promotion of both "soil-cement" and sandcrete be combined under the title "cement-stabilised building blocks".

7 TRAINING AND RESEARCH & DESIGN NEEDS IDENTIFIED

Further research is required to determine the most successful method of implementing training and the usefulness of additional ancillary equipment to promote quality control. It is envisaged that three types of training are required, one to provide a proper grounding for employees of NGOs and city councils involved in promoting low-cost housing and two for end users. Of the end user courses one should focus on the practical detail of correct soil preparation and machine operation for foremen/fundis and the other should be for machine owners interested in quality control, cost reduction and marketing.

This training should be fully supported with permanent reference material. The available literature has been reviewed by the DTU and it has been concluded that at present good reference material specifically concerned with cement stabilisation is not available, either to NGO technicians or more importantly to end users. Such literature as there is oversimplifies cement stabilisation: the production process is mechanically a simple one but it requires skill if it is to be cost effective. The soil/sand testing procedures reported in the literature have been found to be misleading and on occasion incorrect. No adequate explanation of the mechanisms underlying stabilisation have been found and in particular the field remains firmly split into separate soil-stabilisation and sand-stabilisation parts.

At present the only NGO/city council orientated training course is run by CRATerre in Grenoble France. This course places an emphasis on CRATerre's own field of focus namely unstabilised soil and improved soil architecture. There is a need for courses focused specifically on cement-stabilisation to be conducted within the developing countries. It is envisaged that a small number of such courses would be well subscribed and have a significant impact, provided that the information presented can be taken away in a permanent reference format.

At present there are almost no end user training courses and those which are available are under attended. The reasons given for the poor attendances were the length of the course and the financial impact to the participant of not working for the course duration. Such courses also have to contend with the additional difficulty of a highly mixed audiences. In Approtec's case (Kenyan NGO) although most of the participants were end users, some of these were foremen/fundis whose prime interest was the machine operation, others were owners whose interest was in optimisation of cost and quality and marketing, while still others were interested in construction methods.

Manual equipment for block production is often poorly designed and purchasers are unable to distinguish good design from bad. To further improve the production process the existing compaction equipment may be improved. The many various designs of machine available worldwide need to be quantitatively assessed. Bad machines must be improved or publicised as being deficient. Generally there is only one common design of machine in each country even if it is produced by several organisations. A competent external agency with no vested interest should be responsible for any such assessment, one outcome of this would be recommendations on simple improvements to individual machines and also if suitable a new amalgamated machine combining the useful features noted on individual machines. The design of any new machine should be circulated to all machine manufacturers.

This survey has indicated that dynamic compaction (impact) can potentially reduce block walling costs by 50%. Hence it appears worthwhile to undertake field testing and promotion of this moulding process. Research is required to develop a commercial "high-pressure" impact machine. Such a design would be based on the experimental research already conducted by the DTU into optimisation of impact compaction and the practical experience gained by Agas Groth with the Ranko Block Maker in Botswana.

PRELIMINARY STUDY OF RAINWATER HARVESTING IN MID-WEST UGANDA

Results of a study undertaken by Dr Terry Thomas in collaboration with Uganda Rural Development Training Programme (URDT) in November 1995.

Introduction

Domestic rainwater harvesting is the collecting of run-off during rains from impermeable surfaces on houses or close to houses, its storage in waterproof vessels and its subsequent use as the water supply of the inhabitants of these houses. The use may be "temporary" (for example during the 24 hours following a rainstorm), "seasonal" (throughout the rainy season) or "permanent" (throughout the year except perhaps in years of exceptionally low rainfall). These three levels of use require in Western Uganda, storage capacities per household of around 80 litres, 1200 litres and 10000 litres respectively. In some places there are opportunities for collecting water from institutional roofs and the roofs of commercial buildings. As commercial buildings in the Target Areas are mostly small shops that also serve as dwellings, they may be regarded as included within 'domestic' rainwater sources.

The most suitable run-off surface in Western Uganda is the corrugated iron roof. Grass roofs are mostly of such loose construction and small size that neither the quality nor quantity of run-off from them is suitable. Grass roofs are also difficult to gutter. Tile roofs are rare in the Area; asbestos roofs are absent. Bare rock surfaces are rarely close to habitations, other ground surfaces give very contaminated and silt-laden run-off.

At present, over the whole area, the majority of the population is using water from contaminated and inconvenient sources, most commonly from waterholes in valleys below their houses. "Temporary" rainwater harvesting, as defined above, is widely practised: most households put out plastic or pottery containers under their roof during rains. However it is rare to find more than 50 litres of such collecting capacity per household. A few households have gutters and storage adequate for "seasonal" water supply, the storage is most commonly a cement jar of 1 to 2 cubic meters capacity. Larger tanks sized for "permanent" supply are rare; there are a few in Kabarole District for example next to dwellings on tea estates, and a few in Fort Portal and Hoima towns. These large tanks are commonly made of galvanised iron.

Roofs and Gutters

Because of the high rainfall, iron roofs are common in Western Uganda and their use is increasing following the national development in recent years. The Uganda National Integrated Household survey of 1992-3 indicated only 31% of households with iron roofs, however it is believed the current figure for Western Uganda is considerably higher.

A survey was undertaken in November 1995 within the 3 Districts. It is clear that the occurrence of iron roofs is strongly influence by type of settlement.

In the two towns of Fort Portal and Hoima over 90% of buildings have iron roofs (auxiliary buildings like kitchens have not been counted).

Along roads of sufficient important to carry taxi/minibus services over 90% of buildings in trading posts have iron roofs and about 70% of isolated buildings close to those roads have them.

Scattered homesteads away from roads have a lower incidence of iron roofs. A number of villages were surveyed, the villages were selected as being at least 2km from significant roads. Very isolated villages were not surveyed but are believed to have very few iron roofs.

Table **Survey of Roofing in Mid West Uganda**

District	Location	Total homes	Iron roofs		% part gutters
			No	%	
Kabarole	Village near Bigodi	40	20	50	0
	Farms in Hakibale county	110	76	70	0
	4 villages (S of Kyenjojo, Mwenge Co.)	454	181	49	30
Kibaale	3 villages near Kagadi (Buyaga Co.)	195	117	60	10
	4 villages in Bwikara sub-county (Buyaga Co.)	394	236	60	50
	2 villages near Rabona (Buyaga Co.)	55	20	45	0
	Migrant settlement near Narweyo	80	5	<10	0
Hoima	3 villages E. of Hoima	220	145	66	6
Total		1548	800	52	

From this preliminary survey and assuming 25% of the population lives in towns or trading posts, the likely availability of iron roofs is 60% (computed as 0.25 x 90% + 0.75 x 50%).

Full gutters are very rare and even partial guttering is uncommon in the Target Area; gutters are only installed for rainwater harvesting purposes. The normal roof overhang is intended to reduce soil erosion or splash damage due to unguttered run-off but this is often ineffective. Trading posts in particular suffer from significant erosion due to roofwater run-off.

Gutters, where present, are usually of corrugated or folded galvanised iron suspended from the roof sheets themselves or from rafter ends. As eaves are low, guttering is often stabilised by props from the ground, for example 2 meter wooden poles. Plastic guttering supported by special brackets from barge boards (as is the European norm) is absent in Western Uganda. This may change with the current expansion of PVC product manufacture in Uganda.

Rainfall, Water Consumption and Storage Requirement

With the exception of a narrow rain shadow (generally under 2 km wide) along the shores of Lake Albert, the whole Target Area has a bimodal pattern of precipitation generally exceeding 1000 mm a year. Over 1200 mm a year reaches much of the Area and in places annual precipitation exceeds 2000 mm.

Taking 40 sq.m. as a minimum roof size, full guttering, 1000 mm rainfall, 85% rainwater capture and 8 persons per household gives an average daily capture of 12 litres per person. This is half the WHO recommended figure of 24 litres per person per day but about equal to current daily consumption of 5 jerrycans per large family.

Using the more typical 1200 mm rainfall and 50 sq.m. gives 18 liters per person per day. This is a considerable increase on current norms and on the levels recorded in East Africa long ago by Bradley and White for communities without piped water.

A recent study by Rugumayo of the Directorate of Water Development (Rugumayo AI, "Rainwater Harvesting in Uganda", a paper presented to the conference on *Sustainability of Water & Sanitation Systems*, Kampala, September 1995, proceedings to be published by WEDC, Loughborough, U.K.) showed a storage requirement of about 22% of annual consumption in bimodal rainfall areas of Uganda. This figure would be slightly reduced if the roof area were oversized for the consumption or if dry season consumption were lower than the annual average. The figure also varies with the level of drought-year security adopted; however it is generally uneconomic to provide sufficient storage to carry water over from wet years to dry ones.

On Rugumayo's evidence, storage for a family of 8 consuming 18 liters per capita per day would need to be around

$$8 \times 18 \times 365 \times .22 = 11{,}500 \text{ liters} = 11.5 \text{ cubic meters.}$$

It is expected that more detailed studies will indicate that 8 to 10 cubic meters is sufficient for most households.

The present cost of 10 cubic meters storage is too high for most households to afford. 1994 prices, collected by RUWASA for Eastern Uganda, indicated the cost of 10 cubic meters storage + fittings to be about

$ 550	for concrete block tanks (with no cover?)
$ 400	for corrugated iron tanks
$2000	for HDPE plastic tanks.

Ferrocement tanks, cheaper than concrete block tanks in Kenya, are probably of similar cost to concrete block tanks in Uganda due to the very high price of steel mesh here. Concrete jars, as currently made in Western Uganda, would cost about $900 to make up 10 cubic meters.

For comparison iron sheets for a typical roof cost $200 to $300.

It is an informed assumption of this proposal that there is scope for substantially reducing water storage costs in Western Uganda by taking advantage of local factors such as stable soil, low water table, cheap bricks etc. Storage costs dominate rainwater harvesting costs and are therefore critically affect economic viability. An 8 cubic meter domed underground tank has just (December 1995) been built at the URDT Institute, Kagadi and a second is being excavated. Their materials cost is under $100 each: their performance will be tested,

Water Supply Alternatives in Mid-Western Uganda

Excluding the two towns with pumped piped water (although the Fort Portal system is currently barely operational) the viable forms of supply in the Area are, in order of current usage:

(i) waterholes, swamps and streams, not protected from contamination,
(ii) shallow wells in valley bottoms made hygienic with the aid of handpumps,
(iii) protected springs,
(iv) man-made reservoirs, with or without in-situ sand filtering of water,
(v) boreholes,
(vi) rainwater harvesting.

(i) Unprotected surface sources give low quality water very cheaply at locations often far from homesteads and nearly always below them: water is carried uphill from them. There are possibilities of partially improving quality (fencing, filtering, pollution control) and convenience (carrying aids).

(ii) Hygienic shallow wells give good quality water at modest cost (e.g. $100 per household) are therefore the basis of most current water improvement activities in the Target Area. Near trading posts the water extraction rate is often inadequate (due to low pump or aquifer flowrates) and long queues form. Location is rarely convenient and effort in water carriage is typically 100 minutes per household per day in addition to queuing time.

(iii) The high permeability of soil in the region results in generally low water-tables and low-level emergence of springs. Well defined spring "eyes" are relatively rare. Springs are normally lower than dwellings, thereby precluding gravity-fed reticulation. Spring protection is currently undertaken in Kibaale and Hoima districts, but good springs are not common enough to offer most communities water within 500 meters (a distance corresponding to the 100 minutes per day carriage time cited above).

(iv) Man-made tanks (i.e. reservoirs behind low dams) are applicable in the drier North East of the Target Area. They may be regarded as a variant on shallow wells, in that a shallow well with pump alongside a tank is the preferred method of hygienic water extraction. Their cost, coupled with the difficulty of minimising reservoir leakage in permeable ground, limits their application to areas where other methods do not work.

(v) The most difficult parts of the Target Area for water supply are those without the topology that permits shallow well construction. A number of boreholes have been expensively drilled in the Target Area. Most have proved difficult to maintain by their user communities and therefore failed during the collapse of centralised maintenance services in the 1970s. Modern designs and procedures (eg. VLOM) solve some of the problems and a few boreholes are being rehabilitated. For scattered settlements it will always be costly to achieve convenient (i.e. very local) supply via boreholes. Moreover deep ground water in the Target Area is usually sufficiently high in iron content that treatment to remove it is desirable.

(vi) Rainwater harvesting is therefore to be compared with the five alternatives above. Its performance is not yet fully known. Storm intensity (that affects gutter sizing), variability of precipitation and dry season length (which affect storage and roof area requirements) and other factors need more detailed local measurement.

Rainwater harvesting has the following advantages in the Area:

- gives very convenient supply, no walking required;
- is largely independent of outside organisation for construction and maintenance;
- gives fairly high water quality which may be further increased by simple means;
- reduces the area of roofing iron required, because of less overhang;
- reduces run-off erosion, especially in townships and urban areas.

It has the disadvantages of:

- rather high cost per household unless cheaper storage methods can be found;
- discrimination against the poor who have grass roofs and insufficient funds;
- storage structures being vulnerable to earth tremors to which the Area is subject;
- vulnerability to drought years.

Further Development of Rainwater Harvesting

Because a strong *prima facie case* can be made for rainwater harvesting in the Target Area yet current usage of the technique is very slight, there appears to be scope for

(i) a programme of design development to reduce the cost of components of rainwater systems - in particular water storage tanks - and to optimize their sizing.

(ii) field studies to identify why there is such an apparent mismatch between potential and actual usage of the technique.

Map

The map overleaf shows, Mid Western Uganda, which is made up of three districts: Hoima, Kibale and Kabarole and the location of the villages and roads surveyed for the presence of iron roofing. The total Target Area is about 15,000 sq'km. However other districts of Uganda, besides the three studied here, have rainfall and soil conditions that seem to favour rainwater harvesting. Much of Kiboga, Mubende, Mpigi, Masaka, Bushenyi, Kasese, Rukungiri, Kisoro and Kabale Districts appear suitable, as do parts of Mbarara, Masindi, Luweso, Ntungamo and Mukono Districts. Outside Uganda, large areas of Eastern Zaire and parts of Kagera Province in Tanzania show similar characteristics.

Operating Strategies for Hydropower Systems Using Unregulated Turbines

Dr. Claudio Alatorre Frenk and Dr. Terry Thomas***

1. Introduction

For micro hydropower systems, say under 100 kW, there has been a growing interest in using turbines having no hydraulic controls. The financial savings from omitting control gear is substantial and further savings are possible if 'pumps', mass-produced in country, are used instead of individually designed turbines, often imported. There is now a considerable literature on the use and selection of pumps-as-turbines.

A common configuration of micro-hydro plant is for there to be very little water storage and therefore for the system gross head to be nearly constant. The speed of the turbine-generator set is held constant by electrical means. Thus the fixed geometry turbines run at constant flow. Unfortunately the river flow is never constant. When it exceeds the total turbine flow there is no problem, but when it is less than rated turbine flow there is a mismatch. The absence of storage (which is too costly) removes the possibility of filtering out river flow fluctuations.

There are three system/operation designs we might use in this context. The simplest way of operating (SO) is to employ a single turbine that runs only when river flow exceeds turbine rated flow. A second option is to employ several small turbines operating in parallel (PO): the number in use is varied to match the variation in river flow. A third option is to intermittently operate (IO) a single turbine fed from a small reservoir (*e.g.* holding only 15 minutes flow). It is the purpose of this paper to compare these three alternatives and to show that the third (IO) has apparent economic advantages over the others. All three alternatives can give higher economic returns in many semi-industrialised countries where, power for power, turbines cost over four times more than pumps.

In making economic comparisons there are a great many system variables and cost factors we might accommodate. To reduce the complexity of the analysis we will restrict ourselves to modelling hydro systems connected to a 'large' electrical grid. This allows us to reasonably assume that all the electrical energy produced will be purchased and that each unit will command the same (daily average) price. Even with this simplification, however, it has been necessary to develop a more flexible economic methodology than is normally used for evaluating hydropower. This methodology, described in section 5, is we hope of value in its own right independent of its specific application here.

The ensuing analysis is a simplified form of that developed in a PhD thesis from Warwick University, U.K. (Ref. 1).

2. Option SO: Simple Operation of a Single Turbine

As observed above, at fixed head and speed an unregulated turbine will draw a constant rated flow, Q_R. Should this flow not be available ($Q_A < Q_R$), there are two operating alternatives. One is to shut down the turbine. The other is to let the water level in the penstock draw down until flow equilibrium is reached ($Q_A = Q_T$, $Q_T < Q_R$): reducing the effective gross head in this way will reduce the turbine flow. Although the second alternative is inefficient, since some head is being wasted and the turbine is being operated away from its best efficiency point (BEP), some power is better than none. Figure 1 shows the advantage of leaving the turbine running at low flow: typically an extra 10% energy can be obtained per year by doing so. In the subsequent analysis we assume alternative (ii) is followed. In practice, to avoid certain operational problems it is sometimes desirable to turn off the turbine flow when Q_A falls below say 60% of Q_R (which corresponds to very little power).

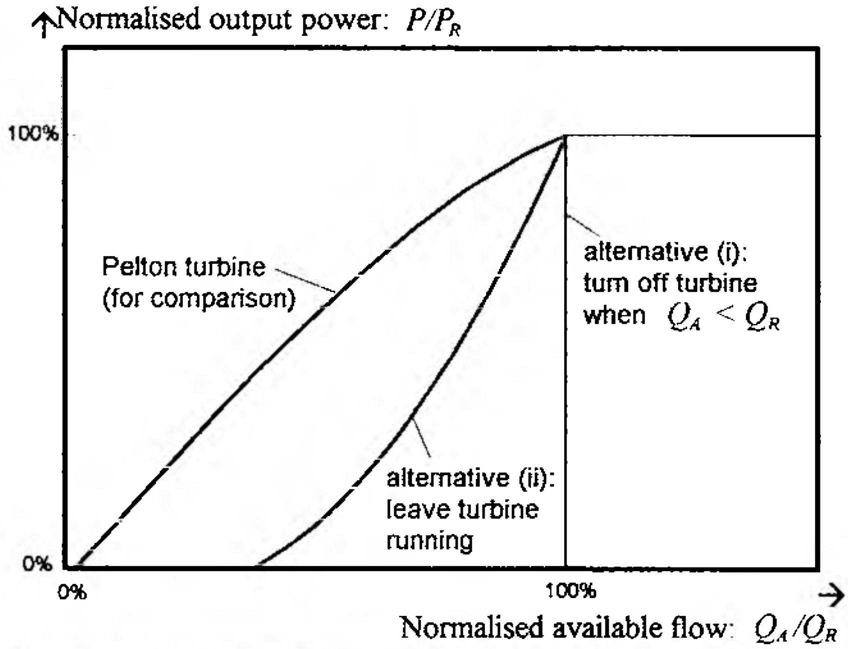

Figure 1: Advantages of operating a PAT with part-full penstock

In the design of this option the key variable is the size of the turbine and hence its rated flow Q_R. Increasing Q_R will increase the capital cost of the system. Up to some limit it will also increase the energy output. Using the economic model described later, by trial and error an optimum Q_R can be identified. It is such an optimised SO system we will later compare with optimised PO and IO systems.

3. Option PO: Several Turbines Operated in Parallel

If two or more PATs are operated in parallel, they can be switched on and off according to the available flow. Parallel operation (PO) of up to 7 machines has proven to be more cost-effective than a single conventional hydraulic turbine of comparable capacity, according to the literature (Ref. 2).

The machines can be different or identical to each other (for example, in a two-PAT scheme, the turbines can handle either ⅓ and ⅔ of the full flow, or one half each). The first option increases the energy generation, as it enables more combinations (in this case ⅓, ⅔ and ³⁄₃); the latter restricts the combinations (½ and ²⁄₂), but makes maintenance easier, as the same set of spares can be used in all machines.

Figure 2 shows the power output of a 5-turbine system. The solid line indicates some of the available flow is being spilled; the dashed line indicates where the penstock is not full; the numbers show how many machines are actively connected to the penstock. The shared penstock and equality of turbine sizes are common features of PO. The optimum number of machines is not however always 5 but depends, *inter alia*, on the variability of the river flow. In optimising a PO system we therefore need to find best values for two parameters: turbine number (n) and total rated flow Q_R.

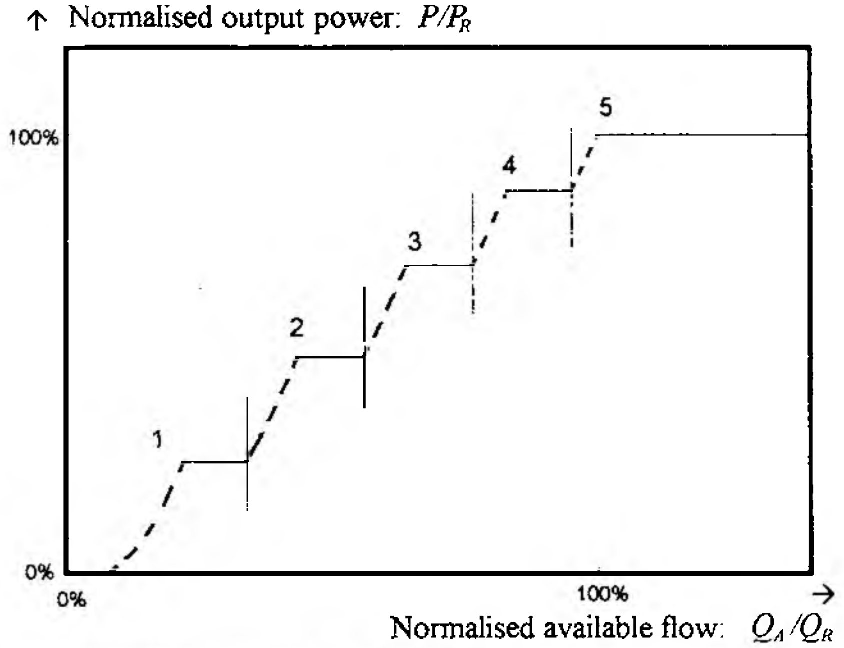

Figure 2. Parallel operation of five equal machines with common penstock.

4. Option IO: Intermittent Operation of One Turbine

When the river flow Q_A is less than the flow Q_R drawn by the turbine in operation, we might operate the turbine intermittently for a fraction Q_A/Q_R of the time. We will need a reservoir (in practice an enlarged forebay tank) whose level falls while the turbine is running and rises when the turbine is shut off. Figure 3 shows the cyclic operation. Although in theory the penstock could be opened and closed using a valve, in practice a quick-priming double siphon (see Fig. 4) would be used. Such siphons have no moving parts and can operate very swiftly.

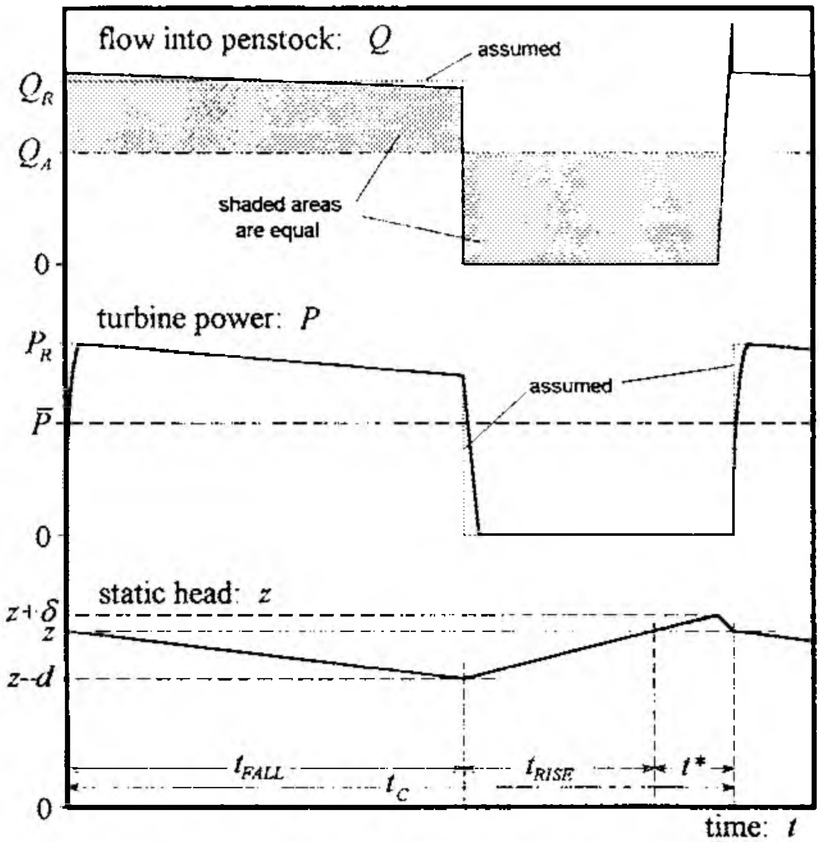

Figure 3. Schematic representation of the intermittent operation using a siphon (with d, δ, etc. exaggerated).
(t^* is the time to surcharge the reservoir with the water needed to refill the penstock.)

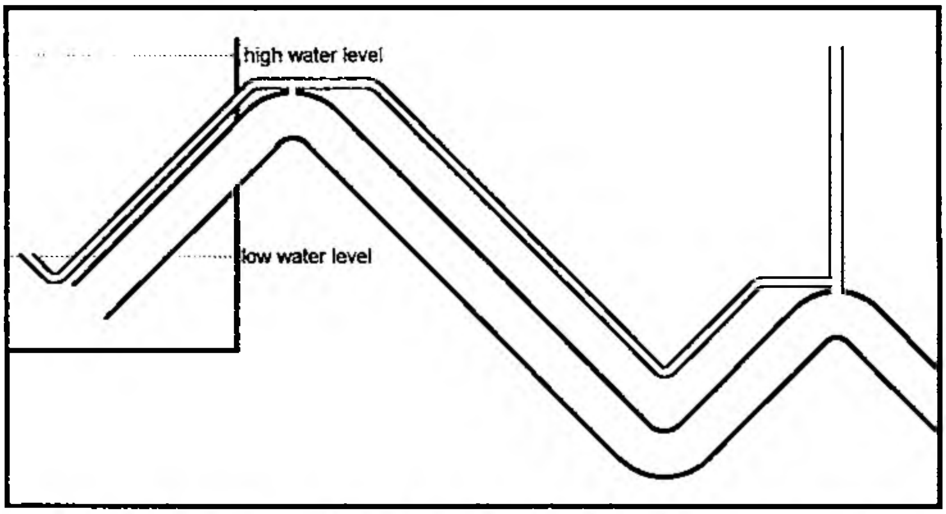

Figure 4. Schematic layout of a double-siphon, developed from a design described in Ref. 3. Performance and design procedure analysed in Ref. 1.

Technically therefore intermittent operation requires us to design an appropriate siphon and a penstock that will tolerate the sudden and frequent changes in flow. Using economic models we need to optimise three variables, namely the turbine size (Q_R), the drawdown (d) of the forebay tank and its effective surface area (A).

There are three regimes under which the system can operate. Where Q_A is greater than Q_R (regime ①) the turbine will run continuously at full power P_R and the tank will be both full and overflowing. Where Q_A is much less than Q_R (regime ②) the siphon will operate cyclically, the power output will be intermittent and the water level in the tank will fluctuate between height $z+\delta$ (rated gross head plus the small surcharge height δ) and height $z-d$ (see Fig. 3). If however Q_A is only slightly less than Q_R, we may observe regime ③ in which the turbine runs continuously but at a reduced head and flow: the water level will be steady somewhere between heights z and $z-d$.

This third regime is unfortunate as it may give less output power than when the flow is slightly lower (regime ②). Fortunately, with typical small values for drawdown ($d < .05 \cdot z$), the system spends very little time operating in regime ③ and to simplify the discussion we can neglect it. Figure 5 shows the power output of a typical system.

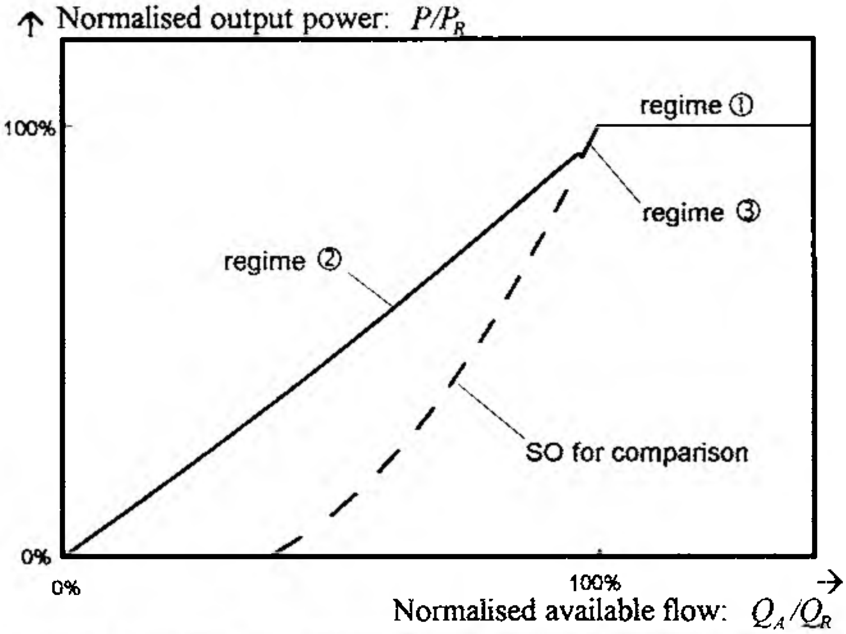

Figure 5. Power *versus* flow for intermittent operation.

The drawdown height (d) and the corresponding drawdown volume ($A \cdot d$) affect the power output during regime ②. A full analysis is given in Ref. 1 and is complex. Fortunately the optimum value of d is such a small fraction of gross head that we can use an approximate analysis in which

- Q is assumed to remain constant at Q_R as the tank level draws down
- the mean gross head during turbine operation is not z but $z-d/2 = z(1-d/2z)$
- the ideal cycle time $t_C = t_{FALL}+t_{RISE}$ is extended an extra period t^* during which the tank overfills by volume V^* which is effectively lost each cycle. As an approximation we can equate V^* to the penstock volume.

The effect of the last assumption is that the cycle time t_C is increased by factor X and the mean power correspondingly decreased.

$$X = \frac{t_{FALL} + t_{RISE} + t^*}{t_{FALL} + t_{RISE}} = \frac{\dfrac{dA}{Q_R - Q_A} + \dfrac{dA}{Q_R} + \dfrac{V^*}{Q_R}}{\dfrac{dA}{Q_R - Q_A} + \dfrac{dA}{Q_R}}$$

$$X = 1 + \frac{V^*}{dA}\left(1 - \frac{Q_A}{Q_R}\right) \qquad [1]$$

So mean power is

$$\overline{P} = \frac{P_R\left(1 - \dfrac{d}{2z}\right)}{1 + \dfrac{V^*}{dA}\left(1 - \dfrac{Q_A}{Q_R}\right)} = P_R \frac{1 - \alpha d}{1 + \dfrac{\beta}{d}} \qquad [2]$$

We may decide to choose d to simply maximise power regardless of its influence on cost. If so, differentiating the function of d in Eq. [2] and setting to zero gives

$$d_{\text{MAX.POW}} = \sqrt{\beta^2 + \frac{\beta}{\alpha}} - \beta$$

$$\frac{d_{\text{MAX.POW}}}{z} = 2\sqrt{\alpha^2\beta^2 + \alpha\beta} - 2\alpha\beta$$

then, since $\alpha \cdot \beta \ll 1$ typically,

$$\frac{d_{\text{MAX.POW}}}{z} \approx 2\sqrt{\alpha\beta}$$

$$d_{\text{MAX.POW}} \approx \sqrt{\frac{2zV^*}{A}\left(1 - \frac{Q_A}{Q_R}\right)} \qquad [3]$$

This power-maximising drawdown varies with flow from 0 at ($Q_A = Q_R$) to $\sqrt{\dfrac{2zV^*}{A}}$ at no flow. Although a variable drawdown siphon is feasible, it will normally suffice to use a fixed drawdown for all flows, choosing a flow of *e.g.* $Q_A = 0.8 \cdot Q_R$ to get close to the flow-averaged optimum. Alternatively we can employ a 'hill-climbing' search, using a spreadsheet version of the full economic model, to optimise all three variables d, A and Q_R.

5. Economic Modelling

There are many economic measures we might use for comparing alternative hydro system designs for a particular site. They all combine the initial cost, any running costs and the income earned through the life of the system into a single measure. The most usual measures are internal rate of return (IRR), benefit-cost ratio (BCR), payback time (PB) and net present value (NPV). IRR, BCR and PB reflect the financial return per unit of money invested, whereas NPV reflects the return "per site"; a system sized to maximise the latter will be larger than one sized to maximise the former three. As hydropower systems are capital intensive and microhydro schemes are particularly vulnerable to capital shortage,. we choose the return-per-unit-of-money-invested approach, *i.e.* the former three measures. Moreover, as we are dealing with systems whose expected incomes per year remain constant over their lives, and whose lives are long, it can be shown that the economic ranking of alternative designs will be the same whichever of the three measures (IRR, BCR or PB) we choose. As the calculation of BCR and PV (and NPV) requires the prior choice of a discount rate, we prefer the IRR as our measure and the ratio of their respective IRRs as our criterion for comparing two alternatives. IRR is the solution of:

$$\frac{\mathrm{IRR}(1+\mathrm{IRR})^{N}}{(1+\mathrm{IRR})^{N}-1}=\frac{\mathrm{NAI}}{\mathrm{CAP}} \qquad [4]$$

where N is project life, NAI is annual income net of running costs and CAP is capital invested. As we are normally interested in IRR values greater than 15% and system lives of over 25 years, we can approximate Eq. [4] within 3% error to:

$$\mathrm{IRR}\approx\frac{\mathrm{NAI}}{\mathrm{CAP}} \qquad [5]$$

The net annual income is equal to gross annual income minus the annual operating and maintenance costs. These O&M costs are usually a function of capital costs. However, for the sake of simplicity, we will assume that they are a fixed multiple of the gross annual income. The error incurred will be negligible since O&M costs in microhydro are minor. This leaves the task of estimating gross annual income (GAI) which is affected by river flow. The flow can be described by a hydrological probability function

$$F_{Q_A}=\mathrm{Prob}(Q<Q_A) \qquad [6]$$

The relationship between output power and flow varies from design to design and is expressed by the technical function of each

$$P=\mathrm{T}(Q_A) \qquad [7]$$

(See Figs. 1, 2 and 5 as examples.) At a given output power, an economic function determines the rate of earning money

$$R=\mathrm{E}(P)=\text{typically } K_E P^{\Gamma} \qquad [8]$$

The parameter Γ can be taken as 1 for grid connected systems so K_E becomes the economic value of 1 Joule and gross annual income is

$$\mathrm{GAI}=\int_0^{\infty} K_E'\,\mathrm{T}(Q_A)\,dF_{Q_A} \qquad [9]$$

(Where $K'_E = K_E \times 3.16 \times 10^7$ s.) The following hydrological probability function (proposed in Ref. 1) fits very well the typical flow-duration curves in the range of interest for micro-hydro (*i.e.* the range of flows smaller than the average annual flow):

$$F_{Q_A} = e^{\lambda Q_A^{-\mu}} \qquad [10]$$

The numerical integration of Eq. [9] using a distribution such as [10] gives us income. We now need a flexible expression for capital cost.

Let

$$\text{CAP} = C_T + C_P + C_S + C_R \qquad [11]$$

where the cost components represent respectively turbomachines, penstock, storage and the rest of the system.

Noting the economies of scale in machinery manufacture, we get

$$C_T = k_T q_R^\theta = k_T q_R^\theta n^{1-\theta} \quad \text{for } n \text{ machines} \qquad [12]$$

(Note the need to change to a normalised flow $q_R = Q_R / \overline{Q}_A$ to keep the coefficient k_T dimensionally simple.) The elasticity θ is typically 0.55 to 0.7.

Penstock size will depend upon flow and the penstock efficiency η_P we choose. Penstock cost can be shown to have the form

$$C_P = k_P (1 - \eta_P)^{0.4} q_R^{0.8} \qquad [13]$$

Storage costs only arise in the case of intermittent operation. Assuming that storage volume ($d{\cdot}A$) is chosen as a large fixed multiple of penstock volume we can use

$$C_S = k_S C_P \qquad [14]$$

Finally we have civil and electrical costs dependent respectively on flow Q_R and power P_R. As power is proportional to flow and treating all equipment as having the same cost-scale elasticity

$$C_R = k_R q_R^\theta \qquad [15]$$

We have in equations [11]-[15] the means of evaluating the changing cost of a system as parameters such as Q_R are varied.

6. Comparison of Options SO, PO and IO

Having optimised the IRR of each of the options by finding the best values for Q_R and other parameters, the three options can be fairly compared. A reference scenario was defined as follows:

$\mu = 0.8$, $\theta = 0.6$, $k_T/k_R = 0.3$, $k_P/k_R = 0.3$, $k_S/k_R = 0.001$

Figure 6 shows the rated flow Q_R, the gross annual income GAI, the capital invested CAP and the relative IRR for PO and IO, taking SO as reference. It can be seen that both PO and IO lead to larger schemes whose internal rates of return are higher than for SO. In the case of intermittent operation IO, the economic advantage is sufficient (10%) to justify considering this alternative. Similar advantage was observed across a representative range of scenarios.

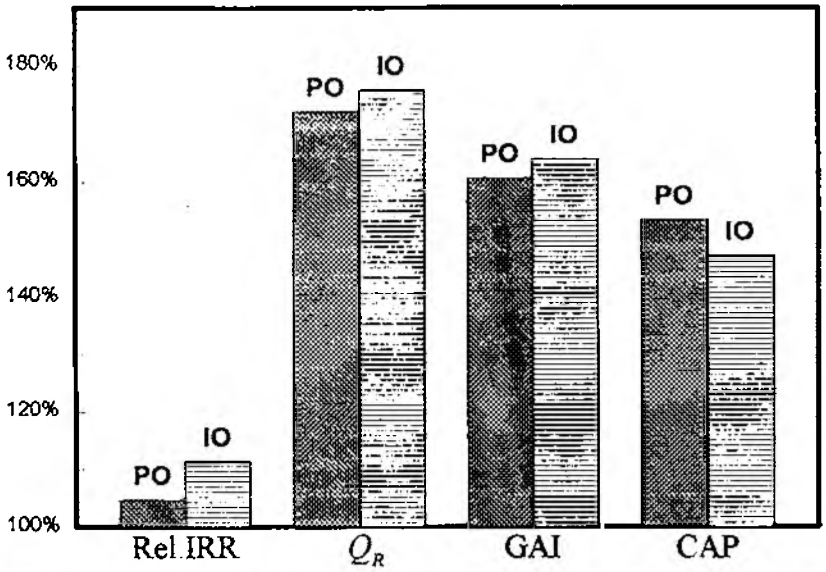

Figure 6. Comparison between IO, PO and SO.

Finally, the effect of varying the different economic and hydrologic parameters is analysed in Ref. 1. One example, relating to the hydrological parameter μ, is shown in Figure 7, confirming that IO and PO are especially attractive for small systems.

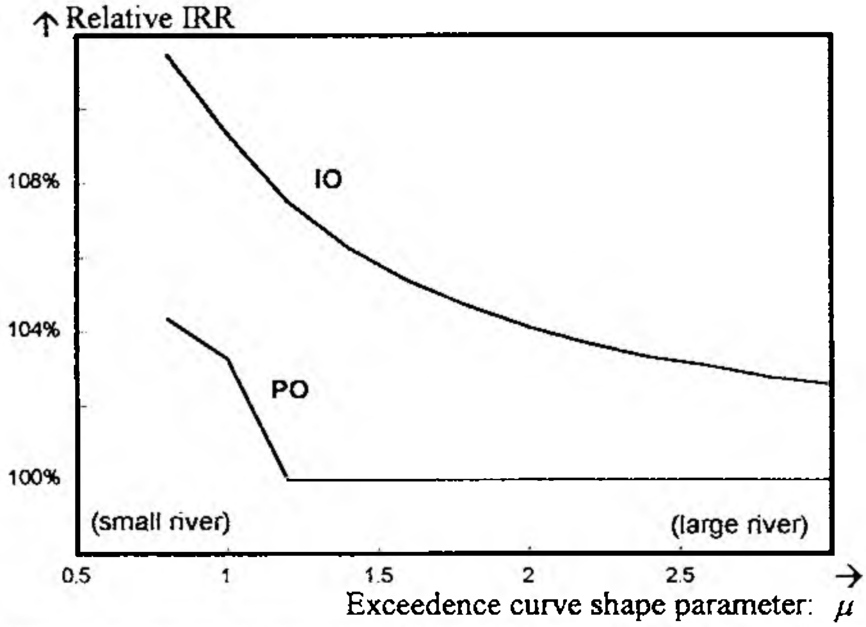

Figure 7. Relative IRR of PO and IO (SO as reference) when varying μ.

DTU Working Paper 52 **February 2000**

DESTRUCTIVE EFFECTS OF MOISTURE ON THE LONG TERM DURABILITY OF STABILISED SOIL BLOCKS

by A G Kerali

1. INTRODUCTION

This working paper describes the summary of the research conducted at the University of Warwick during the 1998/99 academic year. The purpose of the research was to investigate the main mechanisms responsible for the deterioration of compressed stabilised earth blocks, hereinafter referred to as blocks, and to propose remedial measures for their improvement. The scope of the working paper at this stage is limited to the study of the influence of moisture on the durability of blocks.

A working paper describing the influence of moisture on the durability of blocks has been long overdue. A compressed stabilised earth building block may be defined as one formed from a loose mixture of soil and/or fine aggregate, a stabiliser and water in a damp mix which is compressed to form a dense block before the stabiliser hardens (Gooding and Thomas, 1995). After hardening the block should be able to demonstrate higher compressive strengths, better dimensional stability even on wetting and improved durability, than a similar block produced in the same manner but without the addition of the stabiliser. However, since the blocks are produced from soil as the bulk constituent, and given the poor resistance of soil to water, the long term behaviour of the blocks are dependent on the environment and on time (Fitzmaurice, 1958). For this reason, since the introduction of blocks a few decades ago, interest has been growing in understanding the critical factors governing the long-term durability of the material. The durability of blocks is likely to remain a major concern in the foreseeable future. Blocks may be popular and widely used in developing countries, but aggressive environmental conditions such as cyclic changes of moisture content, temperature and pressure over prolonged periods have tended to result in the unexpected shortening of their working life. This has been facilitated either through production shortcomings, or through irreversible changes in the microstructure of the material leading to failure (Tibbets, 1982). This working paper recognises the fact that although in practice several causes of deterioration my occur simultaneously, with synergy and a cumulative effect, it is nevertheless important to identify the most critical mechanisms, understand the processes involved, and propose remedial measures. This paper suggests that moisture, resulting from driving rains, rising damp, or the condensation of vapour is the most serious factor influencing the deterioration of blocks. If blocks are to become more widely accepted in future as alternative durable building material, then they must be seen to overcome the major drawback of their inability to resist prolonged exposure to moisture (Fitzmaurice, 1958; Agarwal, 1981; Spence and Cook, 1983; Odul, 1984)

The paper examines the experimental work done so far to explain the processes of moisture-linked deterioration. According to literature examined so far, it would appear both that no previous extensive research has been done in this area and that there is a substantial gap in our understanding of the problem. It is hoped that this working paper will contribute towards the orderly progression required to provide a satisfactory theory to assist in understanding the exact nature of the problem, and thereby pave the way for the generation of possible solutions.

The working paper is presented under five main sections namely; introduction, deterioration of blocks, tests and experiments, results and discussions, and conclusion. A list of references used in the preparation of the working paper is presented at the end of the report. Comments, suggestions, and contributions from other researchers, academics, practitioners and users are particularly invited and will be welcome and gratefully acknowledged.

2. DETERIORATION OF BLOCKS

2.1 **Basic Wall Characteristics**

In order to understand better the deterioration process, it is necessary first of all to appreciate the most important basic wall characteristics. For any new material, it is important to identify, evaluate and understand the basic standard criteria that will be used to analyse the ability of the material to maintain its essential initial qualities (Jennings, Kropp and Scrivener et al, 1994). It is necessary to begin with an evaluation process that will require positive answer to a set of given basic standard criteria. The four key and likely variables to which basic criteria of assessment could be applied include: relevant material properties, easily measurable properties, initial performance standards for use, and any set durability thresholds during the lifetime of the material (BS CP3 1950; Baker et al, 1994). We therefore seek to answer four questions.

Firstly, what are the primary and secondary properties of the material in relation to the particular application to which it is being designed for? In the case of wall construction for which blocks are produced, the required basic characteristics include strength, dimensional stability, and durability (Spence and Cook, 1983; Caroll, 1992). Important secondary characteristics include weather-proofness, fire resistance, thermal insulation, acoustical insulation and satisfactory appearance (Rigassi, 1995). These wall properties are to a large extent governed by the characteristics of the blocks from which the walls are built (Atkinson, 1970). Good initial block properties are therefore an important consideration in the study of the deterioration of blocks. Secondly, can the relevant properties be measured? Measurement of relevant properties should ideally be possible as and when required. It should be possible to take measurements through immediate tests (surrogate tests) in the case of compliance testing, through medium term tests (accelerated tests) in the case of laboratory experimentation, and through long term performance testing (exposure field tests) in the case of long term performance testing. What numerical limits and thresholds should be attached to the results? Thirdly, do the initial properties of the block fulfil the basic requirements at all in terms of specifications? Fourthly, will the blocks fulfil the requirements during the lifetime of the structure? It is worth noting here that the durability of blocks is closely related to the block properties but are not constant during the lifetime of the block.

It has been suggested in the literature on stabilised blocks that the durability of blocks is closely related to the block properties which in turn are not constant during the lifetime of the block (BS CP 3, 1950; Fitzmaurice, 1958; Atkinson, 1970; Ingles and Metcalf, 1972; Spence, 1975). Despite this potential problem, however, blocks have to be initially strong and remain with adequate strength to carry vertical or lateral loads for the service duration of the wall structure. The blocks have to be durable and weatherproof to exclude any undesirable influences of the environment such as rain, winds, rising damp or other severe weather conditions of exposure. Dimensional stability is necessary to avoid or contain undue volume changes due to expansion or shrinkage. Volume changes, especially under conditions of restraint such as within a wall structure, often induce undesirable cracks and fissures in walls. These have to be avoided if the service life of the block is to be prolonged.

2.2 Defining Durability and Deterioration.

The terms durability and deterioration are perhaps the two most commonly used words in the field of construction materials. A discussion of what these two words really mean and how they can be assessed in the context of compressed stabilised soil building blocks is necessary for a deeper understanding of the subject.

The underlying assumption driving this research is that durability is probably the most important quality for any construction material since adequate performance over a long time is expected, and implied. According to British Standards, durability is a measure, albeit in an inverse sense, of the rate of deterioration of a material or component (BSI, CP3 1950). For the purposes of this research, durability will be defined as the ‘measure of the ability of the block to endure or sustain its distinctive characteristics of strength, dimensional stability and resistance to weathering under conditions of use for the duration of the service lifetime of the structure’ after Baker et al, 1990. This definition would seem to suggest that the block must be able to maintain satisfactory performance throughout its service lifetime even under the adverse influence of the natural environment. It further suggests that although blocks may initially have suitable and desirable properties, the continued influence of adverse natural environment may alter these properties for the worse. When such alterations lead to substantial failure of the block ahead of, or within its planned lifetime, then the durability of the material can be brought to serious question. Fortunately however, although most construction materials will alter in one way or the other with time, their durability is not always brought to question. This appears to emphasise the fact that durability is not only related to time, but also to the expected function of the material, and conditions of exposure. Conditions of exposure greatly influence the degree of alteration that the block will witness over time.

The alteration process leading to failure may be termed deterioration. The term deterioration will be defined here as ‘the time related loss of quality of the block under the direct or indirect influence of the environment' (Atkinson, 1970). The term as defined may be used to distinguish failure due to the inability of block to fulfil its basic engineering functions from the alterations and possible eventual failure during the lifetime of the block. This term as defined suggests that durability may be taken to be the ability of the block to resist deterioration. It seems very likely, however, that the durability of the block may not be constant. This suggests that due to deterioration, the durability of the block may change considerably. For example, the water absorption and permeability properties of the block may be directly related to the structure and density of the block. However, the structure and density of the block may alter appreciably due to weathering (deterioration). This alteration may considerably increase the water absorption and permeability levels of the block thus accelerating degradation by softening the loose uncemented matrix of the block, and thereby inducing other degradation mechanisms. In short, deterioration and durability influence each other mutually but negatively (Jennings et al, 1994).

The premature degradation of blocks, and the rate at which this may occur, remain of major concern to most researchers (Hammond, 1973; Uzomaka, 1978). A certain length of time is normally required before deterioration starts. This period may be referred to as the initiation stage, which is later followed by the propagation stage when deterioration is progressing. This suggests that the service life of a block structure could be considered to have an initiation phase and a propagation phase which eventually lead to an unacceptable level of deterioration. The service life of the block is therefore the sum total of the duration of the initiation phase and the propagation phase (Baker et al, 1990).

It should however be pointed out that it is very difficult to define precisely a criterion for unacceptable deterioration. This is because such a level of deterioration may depend on a number of factors such as the nature of the use of the structure, the design and the consequences of failure. In moderate climates, The propagation phase is believed to be short in comparison to with initiation phase and hence the service life can be approximated to the duration of the initiation phase. After the initiation of loss of material, the erosion process might proceed at a rate depending on the degree of exposure of the block surface, the bulk resistance of the block, and the stabiliser type used in the production of the block. There is unfortunately still very little literature and data on the subject since no single long-term studies have been conducted. Several methods may exist for the prediction of the service life of construction materials. These include estimates based on experience, deductions from the performance of similar materials, accelerated testing, mathematical modelling based on the chemistry and physics of degradation processes, application of reliability and stochastic concepts, and through the use of neural networks (Baker et al, 1990; Jennings et al, 1994; Sjostrom et al, 1996). Despite the existence of all these methods it is still important to note that not all deterioration mechanisms are well understood.

2.3 **Mechanisms of Deterioration**.

The durability of blocks is affected by both surface and block factors. It is therefore important to understand in each case the source of the action, nature of the action/ reaction, the propagation processes, and the measuring techniques available to quantify their effect on the block over time. The most common influencing mechanisms in the performance of blocks are:

- ♦ Moisture related deterioration- in areas of seasonal, cyclic or continuous alternate wetting and drying which lead to the block retaining sufficiently high amounts of moisture to have deleterious effects. The softening and abrasive action of moisture leads to erosion of exposed surfaces (Fitzmaurice, 1958; Wischmeier 1958; Ingles and Metcalfe, 1973; Lunt, 1980; Stulz and Mukerji, 1988; Ola and Mbata, 1990; Gooding and Thomas, 1995).

- ♦ Temperature changes- in areas of high ambient temperatures causing dimensional changes, which when resisted by restraints of the wall results into splitting, warping, crazing, and cracking. Temperature variations may also induce reversible physical properties like strength, hardness, and rigidity. The retention of moisture and loss through evaporation are dependent on the surrounding temperature. A weakened block then becomes more susceptible to further damage from internal stresses since the maximum load it can carry reduces (Atkinson, 1970; Lunt, 1980; Spence and Cook, 1983)

- ♦ Freezing and thawing-in regions where the environmental conditions allow frost action on exposed blocks under restraints of the wall structure can cause deterioration. The moisture content of the block may near or reach saturation from thawing water or other sources. A block subjected to repeated cycles of freezing and thawing, coupled with the effect of the ice growth in the voids, and the associated development of both hydraulic and osmotic pressures, result in the build up of expansive forces within the pore system. This leads to disruption, loosening and breakdown of particles (Ingles and Metcalfe, 1973; Houben and Guillaud, 1994)

- Chemical agents- where present in the soil like sulphates, calcium hydroxide, soluble salts and acids could potentially react or instigate reactions with the cement bonding component in the block. Sulphate attack is common in clayey soils in terrains of high ground water levels containing sulphates. Exposed blocks, which absorb or permit the passage of water or moisture, enable the calcium hydroxide present in the hardened cement mix to be removed by dissolution, a process also known as leaching. Soluble salts such as sulphates and chlorides entering the pores within the blocks and crystallising within the pores may induce internal stresses leading to cracking. Acid attack on the cement element of an exposed block surface leads to direct disintegration of the hydrated cement mix. Chemical attacks may be prevalent where the blocks are used in foundation level applications, but similar attacks have been rare in the case of above ground use of blocks. The presence of moisture in the block facilitates and speeds up most of the chemical reactions (Neville,1986; Houben and Guillaud, 1996; PCA, 1971; PCI, 1970; Spence, 1975)

- Physical action –mostly occur through adhesive, abrasive, and erosive wear of the block surface, especially the corners and edges. Adhesive wear occurs when two solid surfaces slide against one another under high pressure leading to the removal of material from the surface of the block. Abrasive wear may occur when material is removed from the block surface by contact with, and cutting action of other hard particles. Erosive wear may occur through the impingement and softening action of fast moving liquids leading to loss of material. A block saturated with high levels of moisture over prolonged periods is more susceptible to further damage by physical action (Houben, Rigassi and Garnier, 1996; Lunt, 1980)

- Volume changes- may take place within the block due to the drying shrinkage, variations in temperature, and moisture variations. When the change in volume is resisted by internal or external restraints, cracking results. The block is inherently sensitive to moisture variations due to the presence of clay as its constituent component. The determination of the amount and type of clay present in the soil for block production is of paramount importance. The presence of moisture does have the potential to disperse the clay wafers (Scot, 1963; Van Olphen, 1977; Lunt, 1980; Torraca, 1988).

From the above summary list of possible deterioration mechanisms, the direct or indirect presence and action of moisture is a common denominator in influencing the degradation processes. The potential damaging effect of moisture on the long-term performance of blocks could now be recognised as the most critical processes affecting the durability of block structures (Ola and Mbata, 1990; Spence, 1975; Ingles and Metcalf, 1972; ILO, 1987; Houben and Guillaud, 1994). This research paper therefore focuses on attempting to understand the nature of the action of moisture that would for example lead to loss of material from the block. Mass loss is chosen as the performance criteria because it is more amenable to measurement than for instance strength loss, swelling or expansion, and cracking. The theory likely to explain the phenomena satisfactorily will be presented, and experiments that simulate the damaging processes conducted.

2.4 **Critical Moisture Action**.

As previously noted, changes in the properties of blocks leading to unacceptable levels of deterioration may result from both surface and bulk factors. Weathering through the abrasive and erosive action of moisture often leads to severe loss of material for exposed surfaces of blocks. It is therefore important to identify the sources of moisture, nature of its action, the transport mechanics and the measurable parameters. The inputs that could affect the performance of the block are wide ranging. The most significant of these however include the exposure level to environmental elements (in this case rain) and the manufacturing processes (stabiliser type and content, compaction pressure, clay content and mineralogy, moisture content, curing time, mixing, vibration etc). Both of this result into time varying product properties (density, porosity, permeability, water absorption and retention, etc). The research effort in this case is focused on the examination and quantification of the loss in mass from the block due to the action of moisture from external sources.

Driving rains, rising damp and condensation are the main sources of moisture that could potentially be detrimental to blocks (Torraca, 1988; Agarwal, 1981; Lunt, 1980; Houben and Guillaud, 1994; Norton, 1997). The cyclic wetting and drying of blocks often ensures that there is sufficient moisture to have a decrepitating influence. The durability of the block appears to depend to a great extent on the water absorption capacity, permeability and porosity properties of the block on the one hand, and on the nature of the moisture action, and the capacity of the block to resist disruptive forces on the other. Permeability and porosity appear to play a major role in the entry and retention of pore water, and its mobility inside the block. The actual destructive action of moisture once the block has been penetrated could largely be through adsorption resulting in surface energy changes, dissolution and softening of loose particles, disruption of loose bonds or through pore pressure generation resulting in disruptive internal stresses (Fitzmaurice, 1958; Wischmeier, 1958; Franklin and Chandra, 1972; Ingles, 1972; Darve, 1990). The capacity of the block to resist the disruptive action of moisture will determine the rate and extent to which weakening, softening, swelling, shrinkage, or complete disintegration and loss of material will occur. This analysis would appear to imply that a block which is either impermeable, has a high intergranular strength, and is non-reactive to softening, would be very durable. The question to ask is; given the present fragmented knowledge, can such a block be made? Impermeability and high intergranular strength are directly related to the microstructure of the block, an area rarely covered in stabilised soil literature to date but through which major advances have of recent been made in the improvement of comparable building materials.

According to the literature (Ingles, 1962; Herzog and Mitchel, 1963; Lea, 1976; Houben and Guillaud, 1994), in a compressed cement-stabilised block, the cement binder undergoes a three-phase reaction with the clay component of the soil. This three-phase reaction results into a three matrix mix comprising; an inert sandy matrix bound with cement, a matrix of stabilised clay, and a matrix of unstabilised soil. Assuming that the matrix of unstabilised soil represents the greatest constituent of the block, and yet is also the most vulnerable of three matrices to softening and erosive loss, one would be inclined to predict that the continued exposure of the block to moisture would lead to irreplaceable loss of material from the block over time largely due to the unstabilised matrix.

Other possible mechanisms that may arise from the action of moisture could include ion exchange in the clay minerals, capillary effects, and stress relief (Franklin and Chandra, 1972). Clay bearing blocks are especially susceptible to moisture weakening. Among the several mechanisms that may account for this behaviour, ion exchange appears to be dominant. Clay minerals in the block are surrounded by an atmosphere of adsorbed cations, usually hydroxyl ions that are still loosely bound (Torraca, 1988). The particles can be dispersed in water solution containing negative ions, or can be flocculated by positive ions. The ionic dissociation of the dispersing solution as measured by its dielectric constant controls the efficiency of the dispersion, but the type of clay used also matters. Sodium clays are the easiest to disperse then potassium, magnesium and barium clays. Some clays, for example illite and montmorillonite, contain inter-layer potassium ions that favour hydration. In this instance, the swelling of the crystal lattice may well assist in the dispersion process. Capillary effects, due to the presence of pores in the block microstructure, are likely to play an important part in moisture degradation. Water menisci in the block increase their radius of curvature as the block becomes saturated, so that capillary tensions at grain contacts, and at the tips of cracks are reduced. Also water that is drawn into the block by the action of strong capillary forces may compress entrapped air in its path, resulting in the disruption of the block. Stress relief is probably also an important mechanism, since compressed clay bearing soils subjected to diagenetic forces, are likely to store elastic strains that will be released if intergranular bonds are weakened by the repeated action of water.

In order to quantify the loss of material as a result of the action of moisture, it is necessary to establish a good scientific yardstick of measurement and comparison. There are at present a number of durability tests in use, but with scant application. These include the wet-dry-cycling test, the abrasion test, the rain erosion test, the freeze thaw test, and the immersion test (BSI 4315, 1970; Lunt, 1980; Spence and Cook, 1983; Houben and Guillaud, 1994; Rigassi, 1995). These tests attempt to measure weight loss but cannot be said to measure the resistance of the block to weathering, which is what would be useful. A test is therefore required that would measure the resistance of the block sample to weakening and disintegration resulting from an accelerated abrasion, wetting and drying cycle. The test could be fairly simple, practical, accurate and replicable in application. An index test that would not only measure loss of material but also provide an indicatiobn of the comparative degree of alterablity of the block would be more useful. This working paper proposes such a test in Section 3.

3. TESTS AND EXPERIMENTS

3.1 Need For Tests

Stabilised blocks used for external walling have been widely reported in the literature as being prone to deterioration through weathering i.e., softening and erosion leading to loss of mass. The blocks have also been reported to experience lower wet compressive strength and larger dimensional changes than walls made of other comparable masonry materials such as concrete blocks and fired or burnt clay bricks exposed under similar conditions of service (Fitzmaurice, 1958; Lunt, 1980; Spence and Cook, 1983; RILEM, 1987; ILO, 1987; Stulz and Mukerji, 1988; Houben and Guillaud, 1994). The personal experience of the author who built several dwelling units using the same material in East Africa would also add testimony to this premise (Kerali, 1996). The problems have tended to be more serious in tropical upland climates and humid wet climates which experience more seasonal and very intense rainfall than in the more arid hot dry climates (Eaton, 1981; Spence and Cook, 1983; Ola and Mbata, 1990). Prolonged periods of wetness due to continued exposure from double or triple rainy seasons could be of particular concern

Tests and experiments on blocks on blocks are necessary firstly to measure the block properties upon which durability is dependent like strength, water absorption, micro- and macro-structural changes, and secondly to monitor the blocks performance in conditions which simulate the cause of the deterioration. The tests will provide experimental results and data from which general and localised trends could be identified, and from which comparissons can be made with theoretical predictions or other available data. The tests also would provide an opportunity with which the validity of currently held beliefs could be tested, and any agreements or departures from the norm spotted. The literature on stabilised soils still has scanty and/or little information and data on the influence of moisture on the durability of blocks (Gooding, 1995; Spence, 1975). Translating the experimental data into information to facilitate the potential improvement of the durability of blocks would be the broad objective.

3.2 Selection of Tests to be performed

Four separate tests and experiments, all of which have direct bearing with the investigation of the effect of moisture on the durability of blocks, were selected and conducted. The tests include the wet compressive strength test, the water absorption test, the slake durability test, and microstructural analysis of block samples. Although the wet compressive strength test and the water absorption tests are both now standard performance tests widely described and used for stabilised soils, they were originally developed for concrete blocks and fired bricks. The wet compressive strength of blocks has to be known because it is on the value of the wet compressive strength that structural designs are based. The compressive strength values also give an overall picture of the quality of the block and are an indication of the hardness of the hydrated cement paste that binds the various particles together. In most of the climates where the wall will be wet most of the time, it is critical to know the wet compressive strength values for design and compliance purposes. Moisture, it has been stated in several parts of this report, is responsible for most of the damage in blocks. Through the water absorption test, it should be possible to determine the ability and extent to which blocks can absorb moisture. Knowledge of the water absorption levels of blocks could serve as useful criteria for setting limits and for investigating possible ways of reducing the same in order to improve on the durability of blocks. The slake durability test may not yet be a standard test for stabilised soils, but it remains a standard durability test for measuring the resistance of clay bearing rocks to alteration from the accelerated action of moisture (Franklin and Chandra, 1972). The test was adopted for use with blocks in this research because of its several attractions over existing methods such as the wet-dry-cycling test, the abrasion test, the rain erosion resistance test, the freeze thaw test and the immersion test. All existing methods are non-standardised, fragmented and limited in approach, and rely heavily on the operator for results. A test was sought that would be simple, controllable, reproducible, practical, accurate, and reliable. The slake durability test was able to measure not only the loss in mass but also provided some information by way of an index to show the degree of alterability of the block when subjected to controlled cyclic wetting and drying, erosion and abrasion. The test was also easily applied to test concrete block samples and fired brick samples, and the results compared to those obtained from blocks. Interest in examining the microstructural characteristics of blocks, an area not covered anywhere in stabilised block literature, emanated directly from the results obtained from the standard and adopted tests in an attempt to understand the nature of the distinct phases and the degree of connectivity of the block constituents. The test procedures and operations are presented in the section 3.4.

There are several manufacturing variables that could affect the performance of blocks. These include soil type, cement content, compaction pressure, moisture content, and curing regime (Rigassi, 1995). In the experiments conducted it was decided that of these several variables, only the cement content be varied while all the other parameters would remain fixed. The reason for this decision and approach was based on the fact that it was the stabiliser content which, according to the literature on stabilised soils, was significantly responsible for the improvement in strength, dimensional stability and durability of blocks. Although compaction pressure could contribute towards increasing the densification and thereby reducing voids, it is the stabiliser content that is responsible for binding, sealing, reinforcing and imparting flexibility to the block (Stulz and Mukerji, 1983). By binding the soil particles tightly together, the stabiliser the stabiliser may increase the compressive strength and impact resistance of the block, as well as reducing its tendency to swell and shrink; by sealing all voids and pores and providing a waterproofing film, the stabiliser may prevent or reduce water absorption; by imparting a degree of flexibility which allows the soil to expand and contract within limits, the stabiliser may help to reduce cracking; Conversely, by reinforcing the soil, the stabiliser may reduce excessive expansion and contracting. The effect of stabilisation is greatly increased when the soil is compacted (Ingles and Metcalfe, 1972; Stulz and Mukerji, 1983; Spence and Cook, 1983; Thomas and Gooding, 1995). In the experiments conducted all blocks were compacted prior to curing to a compaction pressure 10 MPa, a value considered to be high enough to produce the best possible quality blocks. In practise however, compaction pressure values much less than 10 MPa are used. In subsequent experiments to follow, both the compaction energy and the cement content will be varied. The stabiliser used in these experiments was ordinary Portland cement conforming to BS 12: 1972. This is because of all known stabilisers currently on the market, it is only ordinary Portland cement which is widely available and used in most parts of the world. It is likely to remain the stabiliser of choice due to its well-established reliability, availability and quality record.

3.3 Specimen Preparation

The preparation of specimens was considered to be one of the most important stages in the execution of the experiments. Extra care had to be taken with the soil, cement mix, moisture content, compression, curing, and sizing of the samples. The high levels of accuracy, reliability and consistency demanded by the experiments be maintained throughout the testing regimes, and for all the different types of tests conducted. Specimen preparation describes the raw materials used, the mix proportions, addition of moisture, the compression method used, the curing regime, and the dimensions of the samples.

For the raw material, an artificial soil for laboratory testing purposes was prepared by mixing ordinary builders sand and potters powder clay of the kaolinite type (grade E). Kaolinite clay was selected for its known non-expansive nature (Craig, 1987; Das, 1983; ILO, 1987; Webb and Lockwood, 1987; Lunt, 1980). Preparing the soil raw material in this way was found to be necessary in order to ensure that the soil mix was a fixed variable for all the different kinds of experiments envisaged. This would also facilitate consistency and repeatability in the research. For purposes of this study, the soil will henceforth be described as 'Soil S'. The proportioning of the ordinary builders sand and the clay powder followed the recommendations obtained from the literature to the effect that an ideal soil would have an optimum raw materials composition of: sand 75%, fines (silt and clay) 25% (Fitzmaurice, 1958; United Nations, 1964). Of the fines, at least not less than 10% has to be clay. The actual mix then used consisted of;

Sand 75%
Silt 13.5%
Clay 11.5%
Total 100.0%

A shrinkage test and a simplified sedimentation test were used to confirm the limits for the different constituents (Houben and Guillaud, 1994). The sand and clay were thoroughly mixed together using the Hobart Machine mixer until a uniform colour was achieved. Proportioning the mix of the soil raw material with the cement stabiliser was done in varying quantities, by percent weight of cement from 3% by weight in 2% increments up to 11% by weight of the soil as follows: 3%, 5%, 7%, 9% and 11%. A total of ten blocks of average dimension 290x140x100mm were subsequently made in this manner. An extra block, the eleventh, was also produced but without cement stabilisation. For each of the experimental blocks, a fresh mix of the soil S was prepared.

The optimum moisture content was determined, or more precisely, estimated by trial and error (ILO, 1987; Stulz and Mukerji, 1988). To the already prepared soil S mix with cement was added approximately 4% by weight distilled water. The entire mix was left overnight for 24 hours in order to homogenise and get absorbed evenly. After the twenty-four hours, a further 4% to 5% more distilled water was added. To approximate that the optimum moisture content had been near achieved, a drop test was used to ascertain the same (Smith and Webb, ILO/UNIDO Technical Memorandum No. 12, 1987). The constituent parts of the mixed soil preparations were separately weighed using an accurate and sensitive electronic weighing machine to plus or minus 0.05g. To improve on the degree of mix, a mechanical mixer, the Hobart machine, had to be used.

To produce the blocks, a pre-installed BREPAK machine designed on the quasi-static compression principal was used for all the samples. Before filling the mould for each compression, the mould lining was lightly oiled with used engine oil. The soil was carefully poured into the mould in three equal amounts, all pre-weighed, packed and sealed in light transparent plastic bags. After each pouring, the soil was levelled in the mould. The use of the BREPAK machine was based on the operational manual of the machine (Webb and Lockwood, 1987).

The blocks were compressed by the pumping action of the side pump up to 10MPa (517Psi). The machine is equipped with a pressure gauge, which was found useful in confirming the pressure excerted. Each block took approximately 50-60 strokes of the hand pump, as opposed to the recommended 40 in the manual. The last 2-3 strokes of the hand pump however required some excertion. The hydraulic pressure was released using the flow valve screw causing the handpump to become slack. The mould cover was then rotated sideways to expose the green block, which was, then demoulded. The green blocks were then carefully removed using two flat 20mm plywood base plates, and immediately placed in plastic bags and left to cure in the laboratory. The dimensions of the green blocks were recorded and so were the combined weight of the blocks and plywood base plates.

Curing of the blocks consisted of two distinct phases described herein as primary and secondary phases (Webb and Lockwood, 1987). The curing time, temperature, duration, and moisture conditions were of particular interest to the experiment. Primary curing, whose purpose is to ensure that moisture is retained in the block, and not lost rapidly, was done for a period of five days. Laboratory dry conditions were used with curing temperatures of 22-24 C. After the five days, the blocks were noticeably lighter in colour than when demoulded. Each of the blocks were marked using permanent ink markers in each case to clearly show the percentage cement content, moulding pressure, date and time of production, and an identification number (BRE OBN, 1980). This decision to mark individual blocks was to be found very useful later on. In order to enable the blocks to further achieve strength, secondary curing was allowed to continue for a further twenty three days. The clearly marked blocks were placed side by side and covered with a large polythene sheet. This was done to slow down evaporation and to protect the blocks from external interference. The blocks were then left to dry in this manner under laboratory dry conditions.

After a total of twenty-eight days, the blocks were carefully weighed, and demarcated for cutting into smaller 100x100x100mm cubes. The dimensions of the left overs, together with their individual weights, were also taken using callipers and an electronic weighing device. All this information was marked onto each sample individually. The samples were then ready for further testing.

3.4 Tests and Procedures

3.4.1 Compressive Strength Test

The compressive strength of blocks is perhaps their most important property. The main aim of the compressive strength tests was to determine the wet compressive strength values of the blocks. It is the wet compressive strength value, which is normally lower than the dry compressive strength, that is used in the structural design of buildings. The compressive strength test done is a standard test based on BS 6073 Part 1, 1981 and on BS 3921, 1974.

After the 28 days curing period, the blocks of average dimension 290x140x100mm were cut using the concrete lathe machine to reduced cube sizes of approximate dimensions 100x100x100mm. The main compression equipment used was the Denison Concrete Testing Machine 7229/T91081 with a maximum load of 100KN. The machine was certified to grade one calibration for the test duration. Attached to the machine is an automatic electronic input and output recording device. Figure 1 shows a photographic record of the compressive strength test taken during the experiment.

Figure 1. Compressive strength testing of block samples.

Two blocks in each category of varying cement content from 3% in increments of 2% up to 11% were tested for wet compressive strength. Each block sample of dimension 100x100x100mm was soaked for 24 hours or overnight in ordinary tap water. They were then removed and kept aside for 30 minutes to let the extra surface water to drip off, then capped with two 100x100x20mm thick plywood pieces. The capped samples were then carefully placed within the set marking pins of the compression-testing machine. The crushing load was then continuously applied without shock to the sample at a rate of 15 KN/min till failure, and in this way the maximum crushing load was obtained for each sample. The computerised device of the testing machine then generated all the input and out information namely, reference, sample type, date, time of test, loading rate, sample dimensions and maximum crushing load for each individual test.

The wet compressive strength was then calculated in each case from the ratio of the maximum load and the cross sectional area of the block in N/mm2.

3.4.2 Water Absorption Test

The aim of the water absorption test was to determine the percentage moisture absorption capacity of the block samples. Cut block samples were weighed when laboratory dry, immersed in water for 24 hours, removed and weighed again. Samples of concrete blocs and fired bricks were also treated in the same manner and under the same conditions for future comparison purposes. An accurate electronic weighing machine was used in case, to an accuracy of 0.05g. The percentage moisture absorption by weight was calculated from the formula:

$$Mc = \frac{Ww - Wd}{Wd} \times 100 \ (\%)$$

Mc = percentage moisture absorption (%)
Ww= mass of wetted sample (g)
Wd= mass of dry sample (g)

The apparatus consisted of an accurate weighing balance, a stop clock and a water trough with a capacity to hold up to 5 fully immersed blocks (Rigassi, 1995). The entire test took two days to complete mainly due to the overnight soaking of the block samples in water.

3.4.3 Slake Durability Test

The aim of the slake durability test was to provide an index that could help show the degree of alterability of the block samples when subjected to continuos wetting and loss of material through softening and erosion. This is a pioneering test on blocks modified after a similar type of testing regime previously used for clay bearing rocks (Franklin and Chandra, 1972). Samples of concrete blocks and fired bricks were also tested. Figure2 shows the diagrammatic illustration of the slake durability testing equipment.

Figure 2. Slake durability testing equipment.

The equipment mainly consists of a drum 140mm in diameter and 100mm long with 2mm-sieve mesh forming the cylindrical walls. Four block sample pieces with a combined total weight of between 450-500g were loaded into the drum. The drum was then rotated at 20 revolutions per minute for 10 minutes through a container or more accurately a bath filled with distilled water. After 10 minutes of the slow rotation, some percentage of the block samples were retained inside the drum, while others were dissolved or suspended in the distilled water filled bath. The block samples were removed, dried overnight in the oven, and then weighed. The slake durability index was then calculated using the formula:

$$SDI = \frac{Mf}{Mi} \times 100$$

SDI= slake durability index (%)
Mf = final mass (g)
Mi = initial mass (g)

After drying, the moisture absorption test was done as before. The test was then repeated for a further 10 minutes cycle, and the slake durability index determined again. The water absorption was also determined again as before for each sample tested.

3.4.4 **Micro-structural Examination.**

Specimen of the block samples made from varying cement content as before and compacted at 10 MPa were examined using the Optical Microscope and screened at magnifications ranging from x10 to x63 (Brandon and Kaplan, 1999). Samples of fired bricks and concrete blocks were also examined in the same manner. The samples which were representative of the whole in terms of features were first observed while in a dry state using the attached binoculars and then their images recorded using the photographic high speed and high resolution cameras also attached to the equipment. The exercise was repeated for the same samples after overnight soaking in water till saturation.

The ultimate good resolution of the recorded pictures was a result of careful sample preparation, imaging in the optical microscope, and individual recording. The optical microscope was selected for the examination of the microstructure because the visual impact of the magnified image would be immediate, and the interpretation of the spatial relationship of the phases would be familiar even to the casual observer. Of major interest to were the inhomogeneity i.e., spatial variation in features and their distribution and the morphological anisotropy of the samples i.e., orientation variations. Since the literature on stabilised soils does not mention any previous work done in investigating the microstructure of blocks by any of the researchers whose works have been assessed so far, it would be reasonable to state that this test has been a pioneering and pace setting contribution to knowledge. The results are presented in Appendix I, and discussed in Section 4 of this report.

4 RESULTS AND DISCUSSION

4.3 Wet Compressive Strength

The results of the 28-day wet compressive strength values obtained are presented in a tabulated form in Appendix A and in a graphical form in Appendix D. From these results general and localised trends can be discerned.

According to the tabulated results in Appendix A, it would be reasonable to predict that for a given constant compaction pressure, an increase in absolute wet compressive strength can be achieved by increasing the cement content. From the graphical presentation of the results shown in Appendix D, the rate of increase in strength can be approximated. The graph reveals that the absolute increase in wet compressive strength appears to remain constant but then increases less at the lower cement contents but more at the higher cement contents. For instance, when the cement content is doubled from 3% to 6% at constant compaction pressure, a wet compressive strength increase of 130% is achieved; further doubling of the cement content from 6% to 12% would produce a projected increase in wet compressive strength of up to 145%.

The results also show that all the blocks produced at the varying cement contents from 3% in increments of 2% up to 11% but at constant compressive pressure of 10MPa, have 28-day wet compressive strength values well above most of the recommended minimum values for use in structural work. According to the literature, several different values of 28-day wet compressive strength, all above 1.0 MPa are proposed; 1.2Mpa (Houben, Rigassi and Garnier, 1996), 1.4 MPa (Lunt, 1980), 1.0MPa to 2.8 Mpa (ILO, 1987). According to the

1987 ILO Report, the 1.0 MPa 28-days minimum wet compressive strength values are recommended for dry arid zones while the 2.8 MPa minimum 28-day wet compressive strength values are recommended for the wet rainy zones. The high wet compressive strength values obtained in the tests can be explained by the use of a high compressive pressure of 10MPa, which was used to produce the blocks. In practice, however, compressive pressures of less than 10 MPa are adequate.

The behaviour of the block samples tested for wet compressive strength showed that although blocks may be considered as hard and rigid materials, they remain brittle and fragile under the action of extreme loading. The most notable visual observation made during the tests was the fact that damage tended to start from the block edge and corners, and extend to the centre and inner parts. It would also appear from the tests that if the load were removed, the samples would not fully recover their initial shape and configuration. This appears to suggest that blocks are not elastic but could be plastic from their behaviour on removal of the tress. The explanation for this could stem from the fact that blocks are heterogeneous materials composed of many different crystals and particles, held together through contacts and joints with variable degrees of strength. Some of the joints or particles start to start to break up well before others, causing irreversible deformations that remain even after the removal of the stress.

4.4 Water Absorption

The experimental results of the water absorption test are tabulated in Appendix B, and shown in a graphical form in Appendix E and Appendix F. Appendix E shows the effect of cement content increase on the water absorption capacity of the block. Appendix F shows the effect of bulk density increase on the water absorption property of blocks.

According to the tabulated results in Appendix B, the 28 day mean water absorption values for the various samples tested range from 5.3% for the 11% cement content samples to 8.1% for the 3% cement content samples. The recommended maximum water absorption value is 15% (ILO, 1987). Houben, Riggassi, and Garnier, 1996 proposed the maximum value of 20% water absorption for blocks. During the same test, samples of fired bricks and concrete blocks were also examined for purposes of comparison. The results, also shown tabulated in

Appendix B, reveal mean water absorption values of 9.1% and 3.4% for the fired brick samples and concrete block samples respectively. These results appear to suggest that blocks compacted at 10MPa but with varying cement contents from 3% to 11% have water absorption values which fall within the recommended limits, and which compare well with water absorption values of similar materials like concrete bricks and fired bricks. The fired brick samples actually absorb more water than any of the block samples tested. Does this mean fired bricks are more porous than blocks? Do fired bricks have more voids than blocks? Are the voids more interconnected? Are the values obtained significant in any way for blocks? Why do the fired bricks absorb more water yet are considered to be more rigid and durable? An investigation of the microstructure of blocks and comparable materials is called for. The issues to be determined include the interconnectivity of the pores, the pore size distribution and the total porosity. The results do show that in ambient conditions, the blocks do have a potential to retain significant amounts of moisture.

According to Appendix E, an increase in cement content has the effect of reducing the water absorption value of the blocks produced at constant compaction pressure. A doubling of the cement content from 3% to 6% results into a reduction in mean water absorption of 22%. A further doubling of cement content from 6% to 12% is projected to reduce the mean water absorption by 15%. This shows that the increase in cement content results into a reduction in water absorption, and the reduction is more at the lower cement contents but less at the higher cement contents, eventually becoming constant above the 9% cement content level.

According to Appendix F, an increase in bulk density from 2055Kg/m3 (3% cement content) to 2082Kg/m3 (11% cement content) results into a reduction of water absorption of up to 35%. Above the 2079Kg/m3 density value (9% cement content), any further increase in cement content does not correspond to any further reduction in water absorption. Below the 5% cement content level, an increase in density from 2055Kg/m3 (3% cement content) to 2060 Kg/m3 (4% cement content) results into a reduction in water absorption of 20%. Above the 5% cement content level, an increase in density from 2065Kg/m3 (6% cement content) to 2067Kg/m3 (7% cement content) results into a reduction in water absorption of 2%. Further incremental increase in cement content would result into no further reduction in water absorption. This appears to suggest that a further increase in density would not necessarily eliminate water absorption by the block. The block would still be able to absorb significant amounts of moisture.

In practice, water can gain access to the block either in liquid phase in the case of rainwater infiltration or suction from a wet surface, or in the vapour phase in the case of condensation or adsorption, but leaves the block almost exclusively in the vapour phase through evaporation. Therefore the water content of the wall should be determined not only by its contact to water sources but also with its water vapour balance i.e., evaporation minus condensation and adsorption. Given that the block undergoes s seasonal cycle with maximum water content in the rainy season and minimum water content in the dry season, such cycles constitute an added complexity in analysing the moisture balance and therefore any remedial steps that could be taken. Would plastering the wall, which in effect hinders evaporation, be useful or harmful? It would be recommended that a test of moisture conditions should follow the entire wet- dry cycle, and be repeated annually. There is currently no known test in stabilised soil literature that corresponds to this. Further studies will need to be conducted in this area as well as in respect of water penetration, mobility, retention and solubility of constituents.

4.5 Slake Durability Test Results

The results of the slake durability test are tabulated in Appendix C, and shown in graphical form in Appendix G and Appendix H.

According to the tabulated results in Appendix C, the mass loss in blocks stabilised with varying cement contents from 3% cement content to 11% cement content ranged from 37% to 7% respectively. Fired brick samples and concrete block samples were similarly tested with results showing mean mass losses of 1% and 4% respectively. This shows that despite the significant water absorption capacity of the fired brick and the concrete block, the integrity of the two materials when subjected to alternate wetting and abrasion, were upheld. One of the three fired brick samples showed integrity of 100% against wetting and abrasion. Does the answer to integrity lie in strong interparticle bonding? Blocks stabilised at 11% and 9% cement content experienced mass losses of less than 10%. Blocks stabilised at 7% and 5%

cement content experienced mass losses of below 20%. Blocks stabilised below the 5% cement content level experienced mass losses of between 21% and 37%. Recommendations encountered in the literature for acceptable limits of mass loss set the maximum at 10%(Spence and Cook, 1983; Fitzmaurice, 1958). Apart from these two references there appears to be complete silence to the possibility and degree of mass losses in blocks. The most significant aspect of this experiment, which attempted to simulate the combined effect of accelerated wetting, softening and abrasion of blocks, was to confirm that blocks do indeed lose mass faster than comparable materials. The answer to redressing this potential problem would probably lie in understanding the degree of bonding, sealing, flexibility and reinforcement capacity of the binder and the contribution of compaction pressure. Why is the integrity of the fired brick, which absorbs more water than the blocks, almost total? The microstructure of the two materials will need close examination if the shortcoming is to be solved. Therein could lie the key to the strengthening of the inter-particle bonds in blocks while continuing to expose them to moist conditions and thereby increase their desirability in the developing countries.

The general trend shown by the results plotted in Appendix G is that an increase in cement content would result into a reduction of mass loss. A doubling of the cement content from 3% to 6% results into a mean reduction in mass loss of 62%. Further doubling of the cement content from 6% to 12 % results into reduction in mass loss of 57%, i.e. only 5% improvement. By extrapolation, would higher cement content of above 15% approximate a zero mass loss? Would further cycles of the slake durability test result into further disintegration of blocks? After how many cycles would the mass loss become constant, or would a weakened block disintegrate?

As with the case of wet compressive strength, it is possible to relate mass loss variation to density variation, with the latter depending mostly on the cement content variation. According to Appendix H, the general trend that emerged showed that an increase in density from 2055Kg/m3 (cement content 3%) to 2063Kg/m3 resulted into reduction in mass loss of 54%. A further increase in density from 2063 Kg/m3 (cement content 5%) to 2067 Kg/m3 (7% cement content) resulted into a lesser reduction in mass loss of 30%. Does this suggest that the higher the density i.e., the lesser the voids, the lesser the mass loss? At a density of above 2085Kg/m3, approaching the zero voids line, would the mass loss be nil? Would it be possible to achieve this through better processing methods like more vibration before compaction? This aspect, together with the microstructural nature of blocks, will need further investigation.

From the results of these experiments, the slake durability test which combines wetting and abrasion of blocks has the advantage of allowing fast comparisons to be made between blocks made from the same batch, different batches and even different materials to be compared efficiently and reliably. Unlike other durability tests that rely heavily on the actions and senses of the operator, the slake durability test was found to be simple, practical, reproducible, controllable and repeatable.

Among the various factors that could influence the results, the following could be of importance; the apparatus (sieve, drum size, speed of rotation), the sample (size, shape, weight, microstructure, and storage, drying), duration of slaking, nature of the slaking liquid (chemistry and temperature). All these factors are common to most standard tests but could be simplified and and adopted. The need to develop a classification of block methods that are quantitative and independent of block dimensions is long overdue. No previous durability tests done in the past have been able to achieve the degree of reliability and controllability made possible through the slake durability test.

4.6 Microstructural Characterisation

The photographic records of the microstructural investigation of blocks and samples of fired bricks and concrete blocks are presented in Appendix I and Appendix J.

According to the images in Appendix I which show the microstructure of a wet block sample and that of a dry block sample both stabilised with 5% cement content, the volume fraction of voids appear quite prominent. In the wet block sample, films of water, which have filled the pores, are evident. The interparticle bond appears to be basically light contact bonds possibly with weak connectivity. It is difficult at this stage, without the benefit of further tests, to discern the distinct different constituents of the block microstructure, such as clay and cement. The larger particles that are visibly prominent due to relative size could be sand particles. What this apparent weakness in bonding and connectivity have on strength may not be possible to discern at the moment but their implications on softening, dissolution and disintegration could be serious. This is a pioneering investigation in as far as research on stabilised soils is concerned. This investigation also has the potential of revealing contamination or unwanted inclusions in block samples due to inadequate processing techniques. The fact that the wet samples reveal complete saturation with absorbed moisture could have a bearing on the future performance of blocks. Would it be possible to device processing methods that can reduce the level of the presence of moisture in blocks? Would it be possible to establish relative quantities of the three mixed constituents comprising the block namely, the inert sandy matrix bound with cement, the matrix of stabilised clay and the matrix of unstabilised soil? Which of these three matrices is more prone to softening, dissolution, and erosion? Does stabilisation affect all the sand particles? Further research is required in all these areas. The literature on stabilised soils does not cover these pertinent and critical questions.

The fired brick samples and the concrete block samples appear to have exceptionally high degree of connectivity, almost approximating strong covalent bonding. In the fired brick sample, the clay crystals appear to have melted into a continuos mullite and quartz structure. A hard and non-crystal porous mass appears to have been formed. It would be reasonable to suggest that the higher the firing temperature, the stronger the brick formed. The recommended wet compressive strength of fired bricks is in the order of 5.2 MPa (BS 3921, 1974). The concrete block sample reveals a hard porous but brittle material. The degree of connectivity of the constituent particles also appears to be much stronger than in comparable stabilised blocks. The recommended wet compressive strength of concrete blocks is 2.8 MPa (BS 2028, 1968).

The limitations of this investigation could arise from the fact that the samples used were not as flat and coated as would have been required. No chemical enchants solvents or differential imaging agents were used. The focusing of the images also relied on the use of the eye before imaging. Nevertheless, reasonably good images discernible to the casual observer were obtained. Future research into the differentiation and separation of the different phases that could offer a quantitative approximation of the different constituents should be done.

5 CONCLUSION

The conclusions that could be made from the results of these exploratory tests and experiments are wide ranging, and include;

- The wet compressive strength of a block is a valuable indicator of its quality, and by implication, its durability. Increase in cement content results in an increase in the wet compressive strength value of blocks made at the same constant compaction pressure. The increase in absolute strength remains constant but increasing less at the lower cement content levels but more at the higher cement content levels. Increase in cement content could be a more effective method of increasing wet compressive strength values, and by implication the durability of blocks than an increase in compaction pressure. The final wet strength reached by a block is much more sensitive to variations in the cement content than to densification.

- The moisture absorption capacity of the block could be significantly correlated to its durability. Increase in the cement content of block results into a reduction of its water absorption capacity. Further progressive increase in cement content beyond about 9% however only results into a reduced but constant water absorption by the block. The water absorption value of a block reduces with an increase in density, but a further increase in density results into a constant water absorption value. The ability of the block to expel moisture should also be studied in trying to arrive at the moisture balance of the block, and in analysing its potential damaging effects.

- Blocks made with the highest possible standards of manufacture can still be capable of absorbing water and losing mass when subjected to continued wetting and drying, and therefore softening and erosion. Current durability tests are fragmented, non-controllable and hardly reproducible. A standardised test that can approximate the action of wetting, drying and abrasion is required. An increase in cement content results in a reduction in mass loss, but the least depreciation of blocks would require cement contents approaching 15%. This would be highly uneconomical, so more stringent durability thresholds are needed for lower cement contents especially in wet areas of use. A quick predictive durability test has not yet been developed for blocks.

- The microstructural characterisation of block samples revealed the presence of a large volume fraction of voids, which could be detrimental to the durability of blocks. The characterisation of blocks in this manner could be of tremendous potential in essaying to understand the nature and degree of bonding of the particles inside the block. Its use could be further extended to analyse the strength of interparticle bonding and/or inter phase connectivity in blocks.

Deliberate further research will still be needed to test refine and validate the findings contained in this report with a view to developing a reliable long-term durability model. Improvements to the durability of blocks can only become possible when most of the currently unanswered questions are settled. The most probable likely answer will lie in ways to achieve higher interparticle bonding and the exclusion of the damaging effects of moisture. Comments and contributions to any aspect and findings of the research report are invited.

Dynamic Compaction of Soil for Low-cost Building Blocks

by David E Montgomery and Terry Thomas

Table of Contents

Abstract

This paper reports the results of experiments carried out on the process of dynamic compaction of stabilised soil blocks. The interest in this area has been fuelled by the previous research that has shown the dynamic technique of compaction has significant advantages over quasi-static compaction. During the experiments emphasis was placed on determining the wet compressive strength obtained after curing of the formed material. The results lead to a greater understanding of the different factors that affect this strength and suggest a means of predicting the strength without applying a destructive test. The “green” density of the newly formed material was found to be a good surrogate for its subsequent wet compressive strength.

The discovery that density was a good indicator for strength led to further investigation into the factors affecting the achieved density. It was noted that the moisture content of the soil mix was an important variable. The concrete and the soil literatures both give very inappropriate guidelines for a suitable moisture content; around 6% water by mass was found to be optimum for the production of stabilised soil samples. The energy used to compact the material is another key factor in generating a high density. The same energy applied via dynamic and quasi-static compaction was found to achieve similar densities, a disappointing result as larger scale tests indicated dynamic methods uses less energy for compaction than quasi-static methods. The lower efficiencies could however be a result of non-optimum dynamic compaction as the variables within the method of energy transfer, were not specifically optimised for the small (200g) samples used.

Finally, the different findings have been interpreted into a possible machine specification for the dynamic compaction of stabilised soil blocks. The most notable advantage that dynamic compaction has over quasi-static is its potentially lower machine cost. The impulsive blow to compact a soil sample does not exert massive forces for sustained periods of time during the compaction process. Consequently dynamic compaction has shown to be possible with thinner mould walls and using low-tech mechanisms than hydraulically assisted high-pressure quasi-static compression, yet to achieve similar levels of densification (and subsequent strength). It is therefore envisaged that a machine capable of producing high-strength building blocks can be made at a tolerable cost whilst also requiring a tolerable input of human energy into the production process.

Nomenclature

Aggregate: Pieces of crushed stone, gravel, etc. used in making concrete.

Brick: An object (usually of fired clay) used in construction, usually of rectangular shape, whose largest dimension does not exceed 300mm.

Block: A larger type of brick not necessarily made of fired clay, but stabilised in some way, sometimes with central cores removed to reduce the weight.

Bulk Density: Density calculated including any moisture present in the material.

Cement: Ordinary Portland Cement (OPC).

Clay: The finest of the particles found in soil, usually of less than 0.002mm in size and possesses significant cohesive properties.

Concrete: The finished form of a mixture of cement, sand, aggregate and water.

Dynamic Compaction: A process that densifies soil by applying a series of impact blows to it.

Fines: General category of silts and clays.

Gravel: A mixture of rock particles ranging from 2mm to 60 mm in diameter.

Green: Describing the state of material containing cement and water before it reaches the critical time, after which further plastic deformation hinders the final set strength.

Green Density: The density calculated immediately after ejection prior to any curing, drying or soaking.

Inferred Dry Density: The calculated density at ejection assuming no moisture is present in the formed sample, only solid matter.

Permeability: Describing a material that permits a liquid or gaseous substance to travel through the material.

Porosity: A measure of the void volume as a percentage of the total material volume.

Sand: A mixture of rock particles ranging from 0.06mm to 2 mm in diameter.

Silt: Moderately fine particles of rock from 0.002mm to 0.06mm in size.

Soil: Material found on the surface of the earth not bigger than 20mm in size, not including rocks and boulders and predominantly non-organic. If soil is to be used for building material it must not contain any organic material and it can be a natural selection of particles or a mixture of different soils to attain a more suitable particle distribution.

SSB: Stabilised Soil Block

Stabilised soil*:* Soil which has been stabilised (treated to improve structural characteristics) by using one or more of the following stabilisation techniques: mechanical, chemical and physical.

Religious dedication

Sometimes at the beginning of a publication one finds a dedication to a certain person or member of the family who has been an influence in the author's life either in general or specifically in generating the work in question. There is one person in my life that immediately springs to mind who is worthy of such a dedication. Furthermore, my experience with this person is not unique as millions of others have found him to be a great inspiration, comfort, guide and friend. "What's his name?" you may be asking yourself and, "Why haven't I heard of this incredibly influential person". The sad thing is that you probably have, but you have never accepted him as such or welcomed him into your heart and life. Well, now you have an opportunity to do just that. Please read on.

The man's name is Jesus and although he was born nearly 2000 years ago his testimony still remains and his power to save is just as great. "Save from what?" you may ask, sin and the consequences thereof, or more specifically, your sins and the consequences you face when you die. As humans we demand justice to be done, and justice will be done, but on a perfect scale and to a perfect standard. That leaves us all falling short and without hope when we come face to face with a holy God. But, God in his great love towards us send his only begotten Son into the world that the world through him might be saved. Jesus Christ died for you so that you would not have to be punished for what you have done wrong. You can be spared eternal punishment in hell and enjoy love and peace in the presence of God forever. Today the choice is yours. Reject God's free gift of love at your peril, accept it and who knows you too may have the joy of writing a dedication such as this someday. Please ponder the verses below and make your choice carefully, it will be the most important decision you ever make.

David Montgomery

"*For by grace are ye saved through faith; and that not of yourselves: it is the gift of God: not of works, lest any man should boast.*" Ephesians 2:8,9.

"*For God so loved the world, that he gave his only begotten Son, that whosoever believeth in him should not perish, but have everlasting life.*" John 3:16.

"*For whosoever shall call upon the name of the Lord shall be saved.*" Romans 10:13

"*He that believeth on him is not condemned: be he that believeth not is condemned already, because he hath not believed in the name of the only begotten Son of God.*" John 3:18.

"*Jesus saith unto him, I am the way, the truth, and the life: no man cometh unto the Father, but by me.*" John 14:6.

1. INTRODUCTION

This report describes the experiments carried out that investigate the characteristics of soil samples stabilised by different methods of compaction. The effects of such variables as water content, compaction energy, mixing delays and method of compaction are examined. Particular emphasis is given to the dynamic compaction method of soil stabilisation.

1.1 Motivation for this work

It is well documented that there is a massive and growing shortage of low-cost housing for the urban and peri-urban poor in developing countries. Several technological solutions that use local soil as the basic building ingredient have been proposed to help alleviate this problem. Currently two devices are widely available for the manufacture of stabilised soil blocks (SSB), namely high and low pressure block-making presses. The high-pressure (e.g. 10 MPa) press is capable of achieving sufficient densification to allow the quantity of stabiliser (cement) to be reduced to a low level (<6%) while still achieving adequate block properties. Low-pressure (<2 MPa) machines do not achieve such high densification and consequently the quantity of stabiliser in each block needs to be increased to a higher level (8-12%). However, the saving in cement when the high-pressure machine is used does not outweigh the significantly higher machine cost. What the market requires is a machine that achieves the same level of densification as the high pressure machine whist costing little more than the low-pressure one. *Dynamic* compaction of soil samples has in the past been shown capable of achieving high levels of densification and promises to provide a basis for designing the required machine.

1.2 Dynamic compaction

The basic principle behind dynamic compaction is the simple one of using a fast impact to transfer the energy of a falling mass into the object being hit. One can cite the parallel of the superiority of impact over pushing when driving a nail into a piece of wood. How the energy is transferred is however quite complex to describe as it depends on the characteristics of both the impactor (falling mass) and the object hit. Furthermore, the energy transfer will not be 100% efficient as other outputs such as noise, vibration and air resistance will subtract from the total energy delivered into the object being hit.

Dynamic compaction of building blocks is of interest to us for a number of practical reasons. We believe that it has some significant advantages over the existing method of slow squeezing (‘quasi-static compression’) of soil blocks that greatly outweigh the potential problems within the process. The first and perhaps most important advantage is that dynamic compaction doesn't require the same level of machine cost or complexity as high-pressure quasi-static compaction does. The absence of large levers, associated bearings and a hydraulic circuit represent a significant savings in machine cost. Furthermore the forces transmitted through the press are less, so that the machine can be made from thinner sections of steel and consequently be lighter and cheaper. The disadvantages of the process are that the safety implications of a falling mass are significant and the time taken to deliver a number of dynamic blows may be longer than a 'slowly' applied quasi-static force.

The instantaneous force generated during a dynamic blow can exceed, by a factor of up to 1000, the weight of the mass used for the blow and hence the force needed to lift it. We therefore have a sort of 'dynamic lever' capable of turning the pull of a human operator into a force of many tonnes. With these possibilities in mind, research into the dynamic compaction of soil for low-cost building began in the 1980s. This chapter reviews where the research in the field had reached prior to the commencement of this project and the current goals of the project.

1.3 Previous research at Warwick

Research has been carried out world-wide for many years into both the process of *quasi-statically* compacting stabilised soil blocks (SSBs) and that of *dynamically* compacting unconfined soil for the civil engineering industry. Unfortunately a bridge between these two spheres of activity did not seem to exist and there was virtually no information on dynamic compaction of constrained soil in order to produce building blocks. Other researchers at Warwick had noted this and hence dynamic compaction of blocks became an area of interest for the DTU. However almost no research into the technique has been identified elsewhere.

In 1984 Agas Groth carried out a final year student project investigating the potential of compacting soil within a mould by dropping weights onto it. The research included varying the mass of impactor and the drop height, but keeping the energy transfer and the material constant throughout the project. He aimed to achieve (with a 95% confidence) a block density of 1870 kg/m^3, a density that corresponded to a cured dry compressive strength of 3 MPa. With his particular soil type, he found he had to apply at least 1.63kJ to form a standard size block of $290 \times 140 \times 90$mm (mass ≈ 6.8 kg), i.e. about 240 J/kg. Using the technique, Groth subsequently built two houses in Botswana which after 15 years are still in good condition.

Bearing in mind the limitations he faced, some comments can be made on his findings. Several blocks must have been made, but there was no record of their characteristics after compaction, only the method of transferring the energy into the block. The recorded density is not defined as wet or dry density, which with 12% moisture would make a significant difference. However, the research did pave the way for future research to be carried out on the process of dynamic compaction.

Dominic Gooding undertook research for his PhD during 1993-6, looking at methods of soil stabilisation for low-cost building. He investigated how various aspects of quasi-static SSB production affect the output characteristics of the block. Factors such as mould wall taper, mould wall surface smoothness and whether single or double-sided compaction were used were examined and all found to have only a minor effect upon densification. He also generated a pressure/cement/strength relationship for his quasi-statically compacted samples.

However the main thrust of his work was an investigation into the dynamic compaction of approx. 1.6kg cylindrical samples. Like Groth he kept the energy transfer constant and varied the method of applying the energy to a given quantity of soil. The results indicated that there were optimum arrangements for transferring the energy into the soil with respect to the number of blows applied and the mass and velocity of the impactor used. They also showed that impact was a more energy-efficient method of compaction than slow squeezing.

None of the dynamically compacted samples that Gooding produced were stabilised with cement. Moreover the soil he used for his tests was recycled several times and that may have caused unintended variations in block properties (subsequent testing indicated the soil had progressively lost most of its fines content). After graduation, Gooding undertook a review of SSB production in 6 developing countries.

David Montgomery (the author) continued this research during another undergraduate project, whose emphasis was upon the design and development of a test rig to manufacture full-size dynamically compacted blocks. The design kept in mind the developing country environment in which such a block press might be both manufactured and used and employed an appropriately low level of technology. Applying a number of blows from a 36kg impactor produced several blocks with varying characteristics. Density was the main measurement made of the finished blocks as they were also unstabilised to conserve materials. The primary discovery was that the impacting process and Gooding’s findings could be extrapolated onto full size samples (approx. 8kg) with a high degree of confidence. Even at full size the impacted blocks required much less energy to form (to a specified density) than quasi-statically pressed blocks.

1.4 Current Goals

The present (PhD research) project can be divided up into two distinct parts; a materials science part and a manufacturing process one. The materials part started with a review of criteria for selecting a suitable soil and such a soil was selected for research purposes and for comparing dynamic compaction with quasi-static compaction whilst a number of variables where manipulated. The objective of this was to gain a better understanding of the material and to determine which variables are of greatest influence in the production of compacted samples.

The manufacturing process part of the project will take the findings from the material analysis and develop a systematic method for block production using the beneficial aspects of dynamic compaction. Variables discovered to be of importance will either be optimised to a single value or will be kept as alterable variables within the production regime where it is possible to do so. This part of the project will involve the design and manufacture of a machine capable of producing full-size dynamically compacted blocks. The design will be selected to ensure that it is appropriate for SSB producers in developing countries to manufacture and maintain.

Another aspect of the whole research project is to clarify the actual physical processes underlying dynamic compaction, as these are still poorly understood. Several process models have been suggested already but none of these have proved to be very accurate. Dynamic compaction of unconfined soils has been modelled as a one-dimensional problem (Scott & Pearce, 1975), but the theories within his paper do not cover compaction of confined samples as is the case in block production. Some analysis of the dynamic forces will be required for the machine design but full analysis of the dynamic compaction process may be outside the scope of this project.

2. VARIABLES OF SIGNIFICANCE IN THE MANUFACTURE OF SABILISED SOIL BLOCKS

The production of blocks suitable for low-cost building involves many different stages from the extraction of raw materials via block manufacture to the transportation of the finished blocks to the building site. The purpose of this paper is to look only at block formation (compaction), its associated constraints and the resultant block characteristics. Selection, extraction of raw materials, pre-processing of them, curing techniques and transportation constraints will be considered either briefly or not at all.

Blocks manufactured from different materials and by different methods have significantly different characteristics. Below is a table showing some common building materials and their respective key characteristics. Unfortunately the large range in values makes useful comparison difficult.

Property	Fired clay Bricks	Calcium Silicate bricks	Dense concrete blocks	Aerated concrete blocks	Lightweight concrete blocks	Stabilised soil blocks (SSB)
Wet compressive strength (MN/m^2)	10 to 60	10 to 55	7 to 50	2 to 6	2 to 20	1 to 40
Reversible moisture movement (% linear)	0 to 0.02	0.01 to 0.035	0.02 to 0.05	0.05 to 0.1	0.04 to 0.08	0.02 to 0.2
Density (kg/m^3)	1400 to 2400	1600 to 2100	1700 to 2200	400 to 900	600 to 1600	1500 to 1900
Thermal conductivity (W/m°C)	0.7 to 1.3	1.1 to 1.6	1.0 to 1.7	0.1 to 0.2	0.15 to 0.7	0.5 to 0.7
Durability under severe natural exposure	Excellent to very poor	Good to moderate	Good to poor	Good to moderate	Good to poor	Good to very poor

(International Labour Office, 1990)

Desirable block characteristics are:-

- a high wet compressive strength – to permit both single and multi-storey construction,
- a low moisture movement – to lessen expansion/shrinkage potential,
- a low density – lighter blocks to make construction easier,
- a low thermal conductivity – for greater dwelling comfort and
- a high durability – securing a long-term investment.

The last column above shows the characteristics for SSB’s and the very large ranges that each characteristic has for SSB’s. During the research reported here, the wet compressive strength was taken to be the key characteristic and production sought to maximise the strength achievable with tolerable physical effort and machine cost.

During the production of an SSB many different variables will be of importance. We will regard as ‘independent’ those variables that can either be controlled by the operator, such as moisture content, or are a result of environmental conditions, such as temperature and can be monitored. The ‘dependent’ variables are values that are determined by interactions between the independent variables. From the viewpoint of the SSB manufacturer, several of the independent variables, including cement content, are of major concern; whereas to the end-user only the dependent variables, such as durability and strength, are of any great interest. For the purposes of this research both the dependent and the independent variables were monitored. The research endeavoured to identify which independent variables have the greatest effect on the dependent ones and what might be the optimum values of controllable variables. The aim of this was to minimise the demand on the manufacturing inputs without compromising the desired block characteristics.

2.1 Dependent variables of interest

This section discusses five key *dependent* variables, identifying values for them that are achievable and desirable in the production of SSB’s. Since they are associated with different stages in the production and use of a block, they are presented in ‘chronological’ order.

De-moulding force – After compacting an SSB in a mould it must be successfully removed from the mould without damage. Moulds that come apart in some way to easily release the finished block are more complex to manufacture and take more time to open and close than simple straight-sided moulds: they are therefore unattractive both from the complexity and time aspects. The compacted material can instead be pushed up out of a cheaper fixed mould, however a certain de-moulding force will needed to overcome the cohesion/friction between the SSB and the mould walls. The size of this force will depend on the mould’s surface finish, the moisture content of the material, the level of compaction achieved and the method with which the energy was transferred into the SSB. For manufacturing purposes we desire the de-moulding force to be as low as possible to make the production of the block easy. Currently a full-size block quasi-statically compressed with 10 MPa requires a de-moulding force of slightly under 2 tonnes. For a human to generate such a force a significant leverage must be employed. Reducing de-mould forces well below this 2 tonnes would be advantageous to both the machine designer and the block manufacturer.

Ease-of-handling – A freshly formed block has a low ‘green’ strength and must be handled with care. If the block had a greater ‘ease of handling’ there could be a lower rate of block breakage both before and after curing. Furthermore high ease-of-handling would permit green blocks to be stacked immediately upon demoulding, which in turn helps to reduce the floor area required for curing. Stacking also reduces the surface area for moisture-loss from the freshly formed block and thus helps to ensure a good curing regime. This ease-of-handling of a block is not a characteristic that can readily be measured directly. However it correlates with green strength which can be measured. A penetration test is usually used to determine the green strength of a formed block. This involves pushing a rod a specified distance into the surface of the block and recording the force required (or conversely measuring the penetration distance resulting from using a specified force). The green strength of the block will not depend on its cement content as the cement particles will not have had time to hydrate and add any strength to the material. The green strength is largely dependent on the particle size distribution (soil type), the moisture content and the level of compaction achieved. These factors work together to give the material the cohesion that enables ease of handling.

Green density – In the same way that the green strength is of interest to the block producer, the green density is another characteristic that can be easily and quickly measured immediately after production. This measurement can serve two purposes, firstly it checks that the block passes a certain standard prior to curing and secondly it can be part of a longer term feedback loop to improve control of the manufacturing process (discussed in Chapter 4). Where a known amount of material has been used to generate a sample, measurements are taken on the overall size of the sample after compaction has taken place. Several different density calculations can be carried out (as is discussed later) but usually either the ‘bulk’ or the dry density is recorded. The bulk density is always higher than the dry density due to the presence of water in the block and so it is important to record which of the two has been calculated. Bulk densities between 2000 and 2200 kg/m^3 are considered to be excellent for SSB manufacture (Houben & Guillaud, 1989). A number of the process inputs (independent variables), but most specifically the energy transfer and the method of compaction, influence the green density of the block. Other factors such as moisture content and cement content have a lesser effect on it.

Wet compressive strength – This characteristic is high on the list of user priorities. Existing low-cement SSB’s manufactured by low-pressure compaction have compressive strengths adequate for the majority of low-rise structures *provided that* water penetration is kept to a low level. Using an external render or paint, both of which require regular maintenance, will reduce the moisture penetration considerably. However, when saturation of SSBs has occurred it has often proved to be too harsh for the material to withstand whilst maintaining a load: surface flaking or even collapse has followed. If the wet compressive strength can be improved then environmental effects such as running water will not cause such early failure to occur in the building material. The wet compressive strength is measured by placing a cured and water-soaked sample into the jaws of a compression machine and slowly squeezing the sample until the maximum load applied is reached. After the maximum the sample has been crushed and will no longer support a load of that magnitude again: it has been tested to destruction. The predominant factors that affect the wet compressive strength are cement content and the level of compaction achieved during moulding. The strength achieved by the cement content depends in turn on the moisture availability for cement hydration and curing regime applied to the finished block. Wet compressive strengths of over 2 MPa are considered to be excellent for SSB’s (Houben & Guillaud, 1989).

Durability – The most desirable of all the dependent variables is durability, taken to be the measurement of how long the material will survive before environmental attack jeopardises the integrity of the building material or renders it unsightly. Unfortunately no measurement of SSB durability is currently available, as real long-term tests need to be carried out. Current literature describes durability via the terms ‘poor’ to ‘excellent’, hardly a quantitative approach. Other research currently underway at Warwick is exploring durability. However it is generally accepted that the durability of stabilised soil blocks is closely linked to their wet-compressive strength: blocks with higher wet-compressive strengths last longer.

2.2 Controllable independent variables

This section briefly describes the different controllable variables that are involved in the SSB manufacturing process. A summary will be given of the ranges used for the controllable variables in previous work and mechanisms by which they might affect the dependent ones will be outlined.

Soil type – In the field this can vary considerably and it is known that some soils are more suitable than others for the production of SSB's. The United Nations guideline for suitable soils for SSB production requires "a well graded soil consisting of 75% sand, the remainder being fines of which more than 10% is clay". Soils with more than 30% clay will be very expansive with the addition of water and hence will exhibit excessive dimensional variation with the seasons. To counteract this a larger degree of stabilisation than normal is necessary, either by extra compaction or by increasing the amount of cement. Very high clay contents (over 50%) are unsuitable for stabilisation with cement, so either lime has to be used or sand must be mixed with the soil to reduce the clay fraction. There is therefore a literature about soil selection for block making. For the purposes of the research reported in this paper, the soil type has not been treated as a variable but instead been kept constant. All the experiments have used the same soil, one selected to be quite suitable for SSB manufacture.

Moisture Content (MC) – Different sources gave conflicting information about the selection of suitable moisture content for the process of SSB manufacture. A drop test is usually given by the SSB manufacturing texts as an approximate method for checking that the MC is suitable. For research purposes a better definition is required.

The *soil mechanics* literature indicates that maximum density is achieved if compaction occurs at what is termed as the Optimum Moisture Content (OMC) but we should rename *Density Optimising Water Content* (DOMC). Compaction tests need to be carried out to determine what the DOMC is for each soil used: values around 11% are typical for the soils of interest.

The *concrete* literature (Neville, 1995) - which however effectively assumes use of a 'soil' having a total absence of fines - indicates that for ideal compaction the Water/Cement (W/C) mass ratio should be extremely low. For practical levels of compaction, W/C ratios of 0.3 to 0.5 normally yield the greatest strength. For the low cement contents (<6%) characteristic of SSB manufacture, such ratios corresponds to around 2% water content. Thus the DOMC and W/C criteria give widely differing values for optimum water content, and a compromise needs to be made. A further complication with SSBs is that too high a moisture content (say >9%) so reduces the "green" strength of the block that its ease-of-handling becomes inadequate and post-compaction breakage rates become intolerable.

Cement content – Cement is usually the dominant variable cost in SSB production, so the reduction of its quantity is very desirable. How much cement is necessary depends on three factors, the clay content of the soil used, the degree of compaction during moulding and the required wet compressive strength of the finished block. The higher the clay content the more cement is required and conversely the higher the compacting effort (as measured by the densification achieved) the less cement is required for adequate stabilisation. If a higher wet compressive strength is necessary then either the compacting effort or the cement content will need to be increased. To some degree increase in the one can be traded for a reduction in the other - a fact that has driven a trend towards increasing the moulding effort in SSB manufacture. Previous stabilised soil research (Rigassi, 1995) has indicated that cement contents below 2 or 3% will not actually enhance the wet compressive strength or improve stabilisation. Consequently 5% by weight is probably the smallest amount of cement practical to employ for SSBs.

Energy transferred – This is a highly significant variable as it can have a marked effect on the final material strength regardless of the route by which the energy is applied to the material. Dynamic compaction has consistently proved to be more efficient in improving SSB properties than quasi-static compaction using the same energy transfer. Previous experiments with dynamic compaction kept the energy transfer, or the energy transfer per unit mass, constant. This generated samples with varying characteristics from the same energy transfer. Producing samples with fixed characteristics via different compaction methods and energies was not carried out. However, it is to be expected that different amounts of energy will be required to produce samples with similar characteristics via the two different compaction methods (dynamic and quasi-static).

Quasi-static compaction involves a certain pressure being applied to the ends of the material confined in a mould of either rectangular or circular cross-section. The pressure can be applied in one or more cycles and the speed of compression can also be varied (5-100mm/min). (Speed of compression is only varied for convenience and accuracy to ensure a good result in a short cycle time.) Previous research indicates that the increase in compaction achieved by having more than one compression cycle is so small that it is not an efficient use of energy (Gooding, 1993), five pressure cycles only increase the density by less than 2%. Generally the applied pressure is calculated in MPa and samples created between 8 and 12 MPa are of most interest for comparison with dynamic compaction.

Dynamic compaction uses the energy from a falling mass to compact the sample. The process entails a number of variables but these can easily be summarised as the number of blows and the impactor momentum per blow. The number of blows applied to the sample can be varied within a pre-determined optimum range of 8 – 32 blows. The impactor momentum ($mv = m\sqrt{2gh}$) and the impact energy ($e = mgh$) both depend on the mass m of the impactor, and the height h through which it is lifted. The lifted height will control the final velocity of the impactor at contact with the soil. Previous research showed that impact velocities of over 2 m/s were potentially damaging to the compacted material as the initial compressive shock wave could reflect at the bottom of the mould into a tensile wave, whose subsequent travel upwards can shatter the sample.

Mould-wall thickness –The mould-wall thickness required for dynamic compaction is different to that needed for quasi-static. It is found that for comparable energy transfer and densification, the forces applied to mould walls during dynamic compaction are smaller and of much shorter duration than those occurring during quasi-static compaction. If mould-wall thickness is chosen on the basis of achieving a particular strength safety factor, the dynamic moulds can be significantly thinner and therefore lighter than quasi-static compaction moulds. For example for highly-densified full-size blocks, the respective mould-wall thicknesses might be 8 mm and 25 mm respectively. This difference is economically significant, since one of the barriers to the take-up of quasi-static presses operating up to 10 MPa pressures has been their excessive weight and cost.

Size and shape – A standard block size is 290 × 140 × 90 mm whereas the standard sample size for compression testing is either a 150mm or a 100mm cube. Previous research has also been carried out on 100mm diameter cylinders with an approximate height of 100mm. All these different sizes and shapes will have an effect on the apparent characteristics of the finished sample. For research purposes it is inconvenient to manufacture full size blocks to check every little variable and characteristic. Furthermore the dynamic compaction of a full size block requires strict safety procedures to be followed and these become much less stringent if the sample size is smaller. For these reasons the research was performed using smaller size samples. Extrapolation of findings to full-size blocks is not straightforward, however the *ranking* of alternatives at one scale is likely to be the same as the ranking at a different scale.

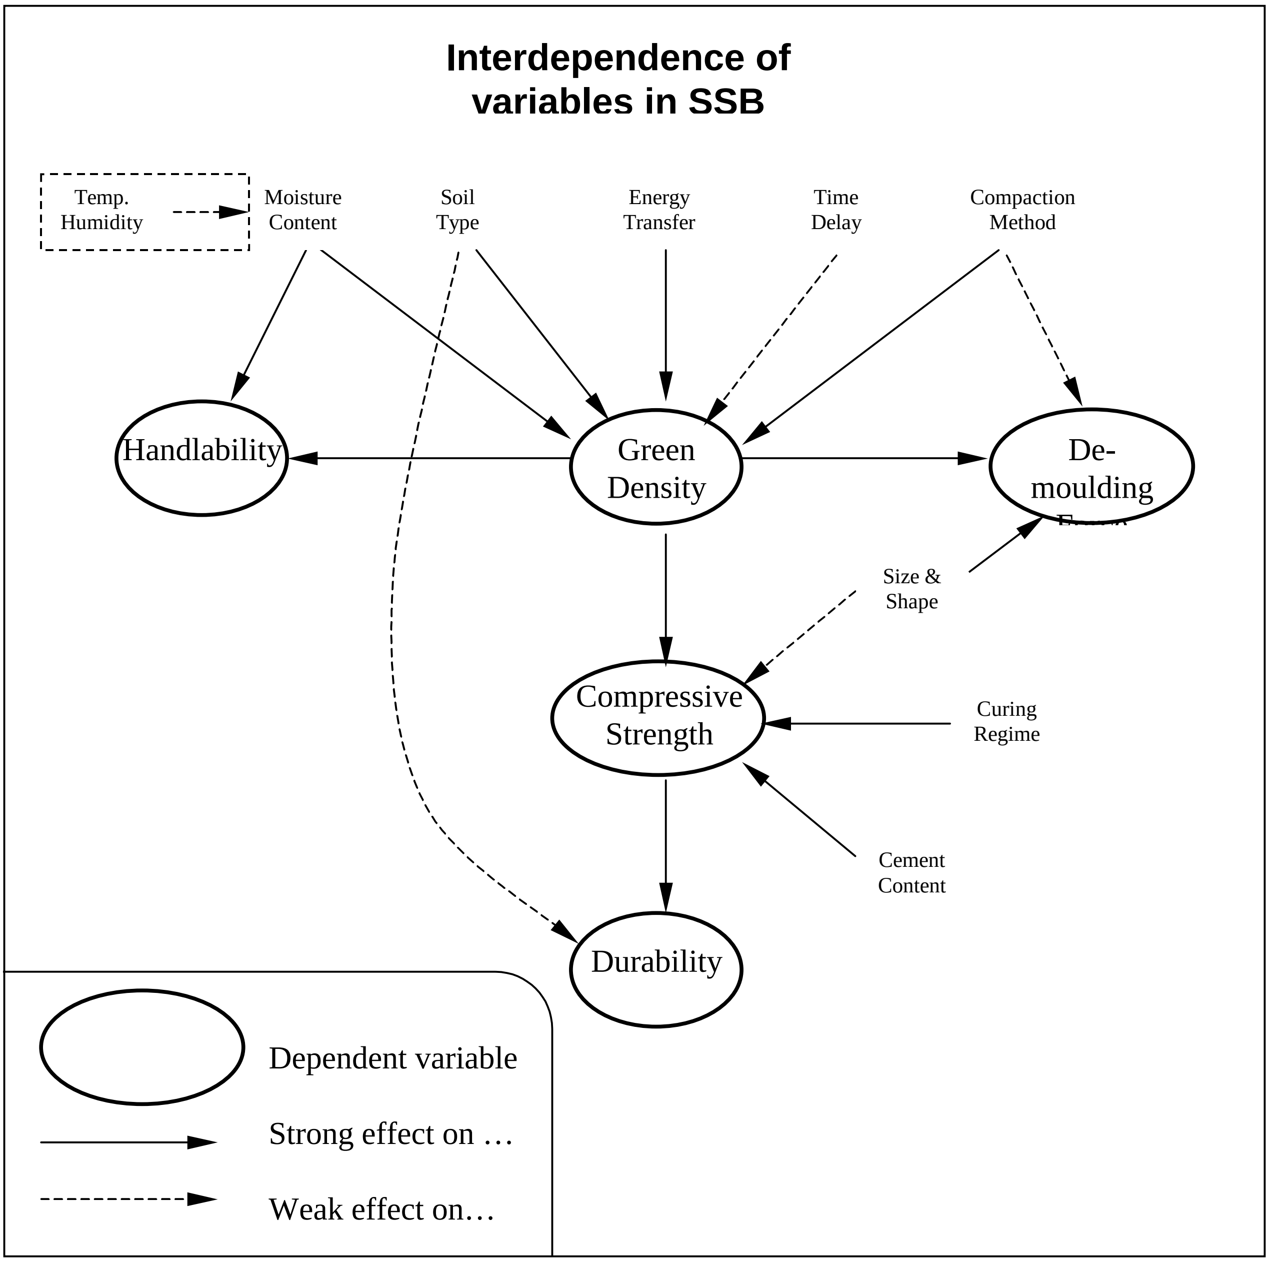
Delay before compaction – As soon as moisture is added to the dry soil/cement mixture the cement will begin to react with the water. As the cement begins to hydrate the moisture levels in the soil available for lubrication becomes less, hindering the compaction process. Meanwhile the crystallisation that is beginning to occur with the cement after the critical period has passed (roughly defined as 15 minutes after adding water) further hinders the compaction. Following the manufacture of a batch of material some parts of the batch are made into blocks before other parts. This variable delay between mixing and compaction has an effect on the ejected density. The order of production within a batch will thus have an effect on the final sample characteristics and while this is not large it is a factor that requires addressing. Indeed it is very useful to know whether a significant loss-of-strength penalty is incurred when a period as long as say 1 hour elapses between mixing a batch and using all of it.

Curing period – Ideally the compacted samples should be left to cure for an adequate time in an environment of nearly 100% relative humidity. The normal period for concrete curing is 28 days, although test data also records 3 and 7 day strengths as well. In reality SSB production seldom includes block curing for 14 days: 7-day or even shorter curing is more normal. Water scarcity and poor understanding of curing concrete often leads to blocks being left out and allowed to dry in the open. This is a very poor production practice as keeping blocks moist in a humid environment will improve their final strength significantly. The majority of previous experiments have been carried out under laboratory conditions, typically at 20°C and with a low relative humidity. During this research samples were cured in sealed bags containing water-saturated air.

2.3 Summary of variables and their interactions

Each independent variable has *some* effect on every dependent (output) variable. Below is a schematic chart that attempts to illustrate the this dependence of the outputs on the inputs. The term ‘significant’ is used to denote a output-to-input sensitivity commonly exceeding unity.

In order to check this interdependence a significant number of different samples needed to be manufactured. As full-size block production was not viable, for reasons rehearsed above, a smaller sample size had to be chosen. In fact a small sample, an approximately 200 gram cylinder, was selected. This permitted fairly rapid production even up to quasi-static pressures of over 10 MPa using existing laboratory facilities. An existing mould with an internal diameter of 54.4mm was found and was used as a standard for other moulds. The sample height was chosen to give the same ratio of mould-wall surface area to compaction (top surface) area ratio as a full-size block has.

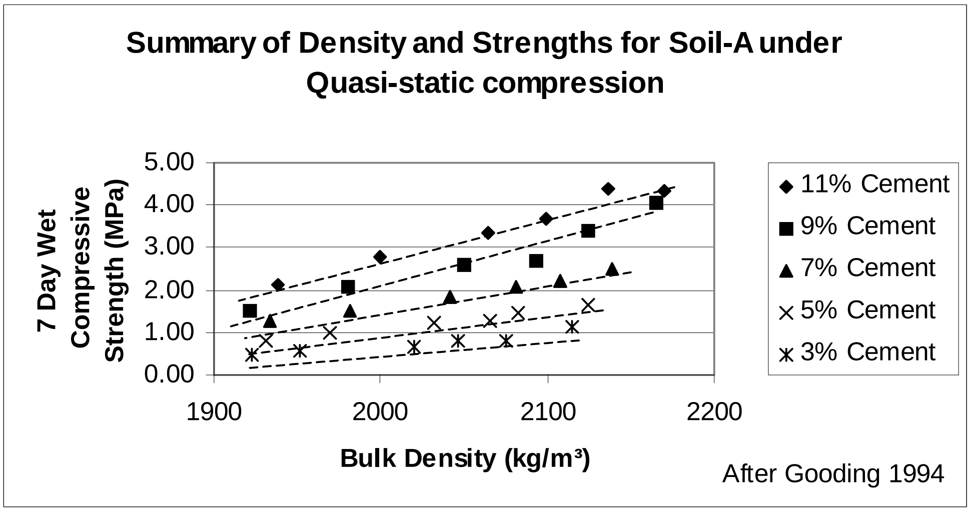


3. FACTORS AFFECTING THE STRENGTH OF CURED BLOCKS

One of the most important characteristics of an SSB is the durability of the finished product. Durability may, as discussed earlier, be thought of as how long the block will be able to support a load whilst experiencing normal environmental attack. Since durability measures do not currently exist for SSB's and the durability is closely linked with compressive strength, then determining the strength of an SSB is probably the best available indicator for its durability. Unfortunately compressive strength can only reliably be measured by rather complex and destructive testing of blocks prior to their incorporation in a wall. This is inconvenient both for research and for quality control in manufacture. Moreover compressive strengths of materials such as we are using here are inherently somewhat variable. As we shall see later, *block density* (which can be measured non-destructively) may sometimes be considered a surrogate for wet compressive strength in research work. In production a simpler modulus-of-rupture (flexural) test may be used instead of a crushing test although both are equally destructive in nature.

The flow chart in Section 2.3 showed the main factors that affect the strength to be the cement content, the curing regime and the green density. If the cement content and the curing regime are kept constant then the only factor affecting the strength should be the density achieved during moulding the block. We already know that the cement content and the curing regime have a significant effect on the final strength, but we don't know fully how other factors affect the green density.

Gooding established that the 7-day wet compressive strength of pressed blocks is directly related to the cement content and the compaction pressure applied to form them. He developed an equation to determine the expected strength if a known pressure and cement content were applied to a specific soil with a moisture content of 8%. Below is a summary graph of his results for wet compressive strength tests on 50mm diameter x 100mm long samples made from his 'soil-A'.



E_D_E_QS_gooding

Although cement content is not one of the variables that have been addressed in this paper, Gooding's work clearly illustrates the significant gain in strength that can be achieved by adding extra cement. The graph above also illustrates that increasing moulding pressure increases both density and strength. Each locus, representing a particular cement content, has 6 points representing moulding pressures of respectively 1, 2, 4, 6, 8 and10 MPa. Not unexpectedly the lowest pressures resulted in the lowest densities and strengths. Another feature visible from this graph is that the sensitivity of the wet strength to cement content is much higher than it is to moulding pressure.

A number of new experiments were carried out, in each of which the wet compressive strength of the sample was measured after compaction and subsequent curing. The effect on strength of varying (a) moisture content, (b) compacting pressure *or* number of fixed energy dynamic blows and (c) time delay before moulding was measured. Other factors such as mould wall thickness and energy transferred were also investigated for their effect upon green block density but not upon cured block strength.

Certain variables were kept constant (at realistic values) during the production of samples, partly because there are too many variables to consider and partly because some of them have already been investigated. The cement content was set at 5% by weight. Rather than vary the type of soil a large batch of stable (and reproducible) soil was manufactured that could be used for all of the experiments. This research soil is gap graded with 80% builder's sand and 20% kaolin clay and is called Soil-B. All samples were cured for a total of 7 days in a humid environment that included a 1-day soaking period followed immediately by wet crushing. Unless otherwise stated the selected sample size was a cylinder of 54.4mm diameter with a dry soil mass of 200g. Moulding and strength testing were conducted in the laboratory at temperatures around 20^{o}C and relative humidity levels around 60%.

3.1 Inherent variability of strength

Two seemingly identical concrete samples will have slightly different strengths. The different arrangement of the particles and the cementitious bonds that join them create a variation in the strength of the material. In order to determine this inherent variability an experiment was carried out in which almost every independent variable was held constant and the coefficient of variation of wet-strength was estimated. This indicated the inherent variability of strength so that future results could be assessed more accurately and sample sizes chosen wisely. For practical reasons, one input variable was allowed to vary, namely the time elapsed between mixing the soil mortar and compacting it. The results were processed in a way that allowed this variability to be compensated for.

During the experiment 35 samples were produced, 18 via quasi-static compaction and 17 via dynamic compaction. The quasi-statically formed samples were compressed to 10MPa and the dynamically compacted samples received 16 blows of a 5kg impactor falling through 200mm. The quasi-static samples received approximately 100J of compaction energy whilst the dynamic samples received 157J (i.e. 0.2m×9.81×5kg×16 blows). Both sets were manufactured at 6% moisture content and in the 54.4mm diameter mould with an 8mm wall thickness. A batch of material was made up to produce three 200g samples and the order of production of each sample within the batch was recorded.

Each batch consisted of a 'first', 'second' and 'third' sample manufactured at different times. Six of each were produced for each (dynamic and quasi-static compaction) process. The strengths of the firsts, seconds and thirds can all be compared and analysis carried out on the results.

Below is a table of results from the dynamic compaction tests.

Table 3.1a

Number	Position	Bulk density			7-day wet strength		
of samples	in Batch	mean kg m^{-3}	s.d. kg m^{-3}	Coef of var %	mean MPa	s.d. MPa	Coef of var %
5	1st	2140	8	0.38	2.38	0.14	6.1
6	2nd	2131	5	0.26	2.23	0.15	6.5
6	3rd	2118	5	0.24	2.12	0.18	8.3

E_D_E_DS_den-ref

It is immediately clear that there is a very low variation in the bulk density (under 0.5%) but a more significant variation in the wet compressive strength (6 to 8%). From this we infer that either strength is highly sensitive to density or that there is an inherent variation in the compressive strength of identically formed materials.

Below is the table of results from the quasi-static compaction tests.

Table 3.1b

Number	Number	Bulk density			7-day wet strength		
of samples	in Batch	mean kg m^{-3}	s.d. kg m^{-3}	Coef of var %	mean MPa	s.d. MPa	Coef of var %
6	1	2067	9	0.44	1.76	0.09	5.3
6	2	2054	13	0.65	1.61	0.13	7.8
6	3	2050	9	0.44	1.63	0.11	7.0

E_D_E_QS_den-ref

The same feature can be noted in these results: a very low variation in the density and a larger variation in the compressive strength. Despite the lower densities and strengths of these samples, the coefficients of variation of strength are similar to those for the dynamically compacted samples. This suggests that variability in strength is not closely related either to the density achieved or to the method of compaction. The above results indicate that the strength coefficient of variation will be not more than 8% under normal conditions or not more than 5% if the average of 3 samples is taken. Consequently a sample size of 3 was adopted and any averaged change in strength of more than 10% was be considered to be significant - i.e. the result of a change in an input variable.

3.2 Effect of moisture content on strength

Early on in the project some full-size blocks were manufactured using a “Bre-pak” high-pressure block-making machine. Three blocks were manufactured from old ‘soil A’ at each of the moisture contents: 4, 5, 6 & 7%, making a total of 12 blocks. All the blocks were stabilised with 5.2% cement by weight and their production and curing cycles were virtually identical. Their measurements were taken at ejection and the bulk density was calculated for each block prior to curing it in a humid environment for 7 days. To make the compression tests comparable with standard concrete tests each block was cut in half and each half was cut to the size of a 100mm cube. This gave 24 samples for compressive testing instead of 12. Then each half of the same block was subjected to different tests. One half was soaked for a day whist the other half was left to dry out for a day prior to crushing. This gave a ‘wet’ and ‘pseudo-dry’ compressive strength test for each of the blocks.

It should be noted at this time that blocks continue curing after being removed from the humid curing environment. This resulted in a curing period of one day more than intended. A block crushed after 7 days curing and one day soaking or drying will have effectively been curing for 8 days total because the core moisture will not evaporate entirely in 24 hours. The concrete literature (Akroyd, 1962) suggests an adjustment of around -7% should be applied to an 8-day strength figure to generate the corresponding 7-day strength. The figures given below have been adjusted in this way to standardise them into 7-day wet compressive strengths.

Table 3.2a

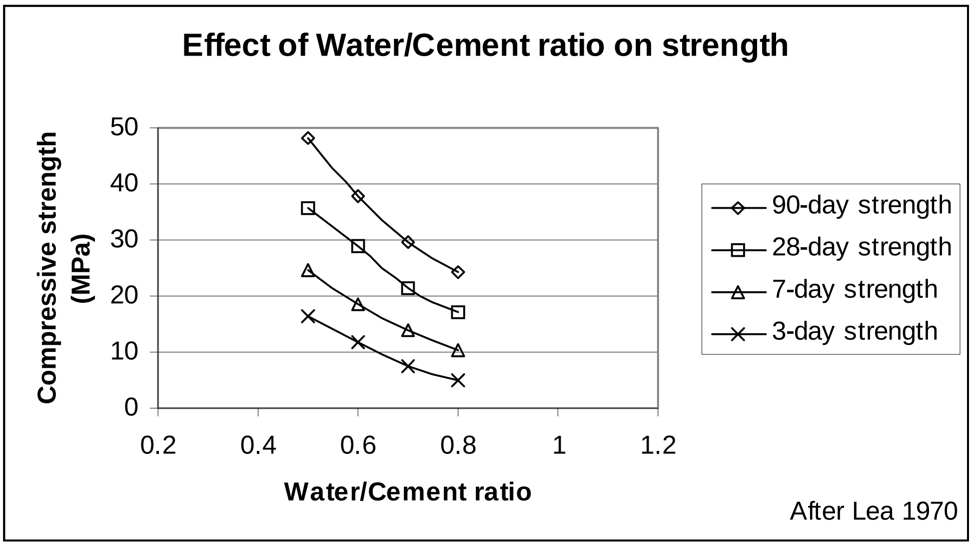
Moisture content % by wt	Bulk density mean kg m^{-3}	s.d. kg m^{-3}	Coef of var %	7-day wet strength mean MPa	s.d. MPa	Coef of var %
4	1943	3	0.15	0.86	0.04	4.41
5	1971	14	0.72	1.40	0.03	2.40
6	1995	2	0.09	2.10	0.08	3.87
7	2020	11	0.56	2.32	0.10	4.13

E_D_E_QB_strength

The above results seem to be consistent with the soils literature in that as the moisture content is increased up towards the DOMC the density also increases. These results follow that trend very well since 7% moisture is still below the DOMC for the soil (discovered to be between 9-10% moisture). The greater variability of wet compressive strength compared to that of bulk density can be seen here again. If we were to ignore the effect of the cement present we would be excused for thinking that the increase in strength is caused solely from the increase in bulk density resulting from compaction closer to the DOMC. This assumption cannot be made and consideration of what is happening between the cement and the water must also be included.

The cement literature suggests that a Water/Cement (W/C) ratio of between 0.3 – 0.5 is the best for concrete strength, provided that the mix is "fully compacted" (i.e. that all air is expelled). The above results unfortunately do not confirm or contradict that statement. The increasing *density* at higher water contents brings about an increase in strength; this may outweigh the loss in strength caused by the W/C ratio being too high. An alternative explanation is that (given the high water-affinity of the clay fraction of the soil) the higher moisture content mix has more free water to hydrate the cement and this, combined with the increase in density, helps to generate a higher compressive strength.

Data taken from (Lea, 1970) on the water-cement ratio and resulting strength (of sand-cement-water mixes containing no fines) is shown below.



E_D_MCTesting

For the experiments done only one of the above W/C ratios could be matched. One sample had a cement content of 5% and a moisture content of 4% giving a water-cement ratio of 0.8. It is obvious from the graph above that reducing the W/C ratio below this 0.8% should increase the strength, whereas the experimental data presented earlier showed strength *increasing* as W/C ratio was raised above 0.8. It must therefore be assumed that the W/C ratios recommended by the concrete literature are inappropriately low for soil stabilisation - either because of the presence of fines in the mix or because of the unusually low cement levels used in SSB manufacture.

In order to try and illustrate the effect of the water on cement curing for very low moisture contents (supposedly best for concrete strength) the 'pseudo-dry' strength was also measured. 'Pseudo-dry' is defined as removing the sample from the humid curing environment and allowing the free water to escape to the atmosphere in the laboratory for 24 hours. This does not dry the block entirely as much of the core moisture is still present. The table below shows the compressive strengths of these samples.
Comparing Tables 3.2a and 3.2b enables us to compare 'wet' and 'pseudo-dry' 7-day compressive strengths over a range of water contents. One normally expects a wet block to be weaker than a dry one, because there is more lubrication between particles

and a slip plane can develop more easily causing failure at a lower stress level. The above results are initially contrary to this assumption. For the 4% M/C case the wet strength (0.86MPa) was actually higher than the corresponding pseudo-dry strength (0.77MPa). This difference is statistically significant (>95% as the difference in the sample means exceeds twice the standard error of difference). One possible explanation is that the extra water available during the soaking process preceding the wet-strength test so advanced the cementitious reaction that it overcame the loss in strength due to the sample being wet. This suggests that the cement had been starved of moisture and more moisture would have been of greater benefit.

Table 3.2b

Moisture Content %	'Pseudo-dry' compressive strength Mean MPa	s.d MPa	Coef of var %
4	0.77	0.02	2.79
5	1.36	0.11	8.08
6	2.12	0.18	8.29
7	2.48	0.16	6.64

E_D_E_QB_strength

For the 4% MC condition the significance test is as follows:

Standard error (wet) = $\frac{0.04}{\sqrt{3}} = 0.023$

Standard error (pseudo-dry) = $\frac{0.02}{\sqrt{3}} = 0.011$

Standard Error of Difference (SED) = $\sqrt{0.023^2 + 0.011^2} = 0.025$

Difference of Means (DoM)= 0.86 – 0.77 = 0.09

DoM/SED = 0.09/0.025 = 3.6 (3.6 > 2 $\therefore$ significant)

Penetrometer tests were also undertaken to determine the surface strength of 'green' blocks. Greatest penetrative resistance, and hence the greatest ease of handling, was found at moisture contents between 4-6%. Penetrative resistances above 0.4MPa were achieved in this moisture range but the penetrative resistance was found to reduce significantly where the water content was increased above 6%. Consequently, 6% water was selected for many of the experiments carried out.

3.3 Effect of 'Effort of moulding' on strength

Densification of material increases the effectiveness of stabilising additives like cement. This densification can take place in many ways, but for the purposes of this paper only two methods will be considered: quasi-static and dynamic compaction.

Quasi-static compaction can be most easily defined by the peak pressure applied to a block causing densification, whereas dynamic compaction can more easily be defined by the number of blows applied and the momentum of each blow. (For purposes of directly comparing the two methods however a common measure may be calculated, namely moulding energy applied per kilogram.) This sub-section will be looking closely at the difference between the two types of effort applied and how they respectively affect the strength of the sample created.

3.3.1 Quasi-static compaction

Different compacting pressures have been selected in the past for the stabilisation and densification of soil blocks. Low-pressure machines apply between 1 and 3 MPa via a lever mechanism, whilst high-pressure machines would apply between 8 and 16 MPa using a lever and a supplementary hydraulic circuit (Houben et al., 1994). The experiment carried out here looked at the effect of pressures within the high-pressure range on the wet compressive strength of samples produced.

Below is a table showing the summary of results from the compression tests of small samples (200g) produced by quasi-static compaction in a cylindrical mould with 8-mm walls and with a soil moisture content of 6%. The soil used was Soil-B stabilised with 5% cement.

Table 3.3a

Compacting Pressure MPa	Bulk density mean kg m^{-3}	Bulk density s.d. kg m^{-3}	Bulk density Coef of var %	7-day wet strength mean MPa	7-day wet strength s.d. MPa	7-day wet strength Coef of var %
8	2047	12	0.57	1.48	0.05	3.60
10	2067	14	0.69	1.75	0.23	13.07
12	2102	15	0.69	1.92	0.30	15.78

E_D_E_DS_density2

As the results from Gooding showed (Chapter 3) the strength increases as the pressure is increased for a given sample and these results also follow the same trend. What is interesting to note is that a 50% increase in pressure (from 8 to 12 MPa) yields only a 30% increase in strength, giving a mean sensitivity of strength to pressure of 0.65. (Gooding, operating with a slightly different range of variables, found doubling the strength requires a tenfold increase in compacting pressure, i.e. a mean sensitivity of only 0.3.) This is a fair return providing the machine is designed to withstand the higher pressures. The significant variation of strength for an insignificant variation in density can again be seen in these results.

3.3.2 Dynamic Compaction

Previous research had already indicated that dynamic compaction was more efficient at increasing the density of a sample for the same energy transfer, but that research did not include any strength testing of the samples produced. Consequently a series of small samples (200g) was produced by dynamic compaction in a cylindrical mould with 8-mm walls and with a soil moisture content of 6%. The soil used was Soil-B stabilised with 5% cement. These were manufactured in the same manner, as the quasi-statically compressed samples described in the previous section. The method of densification and the energy transfer were the only variables altered. The aim was to try and achieve the same density via different methods and to see if the resulting strength was significantly different.

One of the negative aspects of the process of dynamic compaction is the large number of blows that often need to be applied to the sample to achieve sufficient densification. If this number could be reduced then the processing time for making a block would be shortened. Clearly this is desirable, but sacrificing strength to accomplish it is not acceptable. Direct comparison with quasi-static compaction suggests that 16-20 blows should be sufficient to achieve the same strength as using 10MPa quasi-static compaction. This experiment set out to confirm this. Three blocks were manufactured at each of the following number of blows: 8, 12, 16, 20 & 24, making a total of 15 samples. Each blow is from a 5kg impactor falling through no more than 200mm. An analysis of energy transfer will be considered in later chapters.

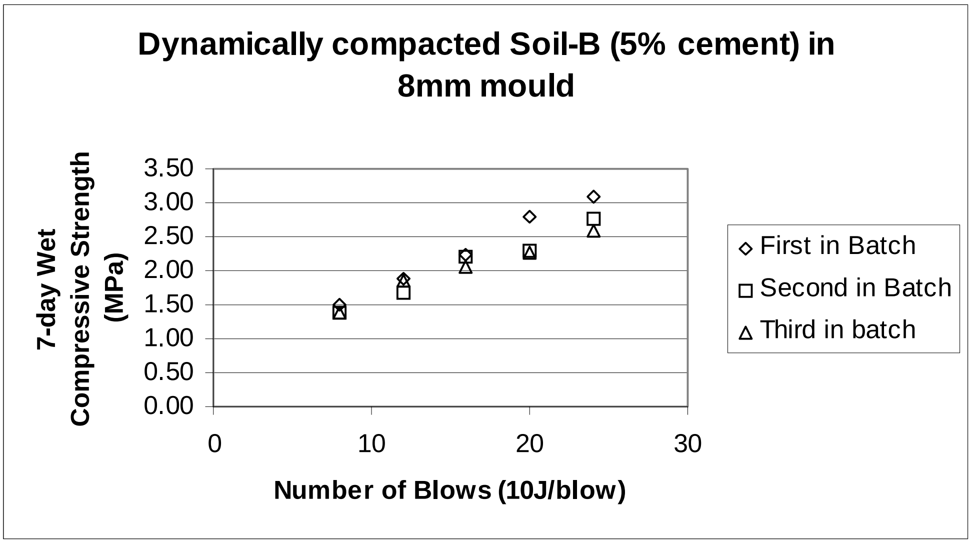
Table 3.3b

Number of Blows	Bulk density mean kg m^{-3}	s.d. kg m^{-3}	Coef of var %	7-day wet strength mean MPa	s.d. MPa	Coef of var %
8	2053	18	0.86	1.43	0.07	4.76
12	2097	13	0.61	1.81	0.11	6.19
16	2113	16	0.75	2.17	0.10	4.79
20	2133	13	0.59	2.44	0.29	11.98
24	2162	19	0.86	2.81	0.25	9.06

E_D_E_DS_density2

As the blow number, and hence moulding energy, are increased the bulk density and wet strength also increase. As noted previously, density is less variable than strength. Increasing the number of blows applied by 50% (from 8 to 12 or from 16 to 24) generates an increase in strength between 25 to 30% - giving a mean sensitivity of strength to effort of 0.6. This is a good return especially considering the machine design does not need to be altered to accommodate the higher number of blows.

These results are represented in the graph below with indicating the order of production for each batch. The graph shows another feature that may be of interest. The strength achieved seems to be related to the position within the batch, with the first sample produced being the strongest and the last generally the weakest. This trend seems to become more pronounced as the number of blows is increased, possibly due to the longer production time necessary for more blows to be applied.



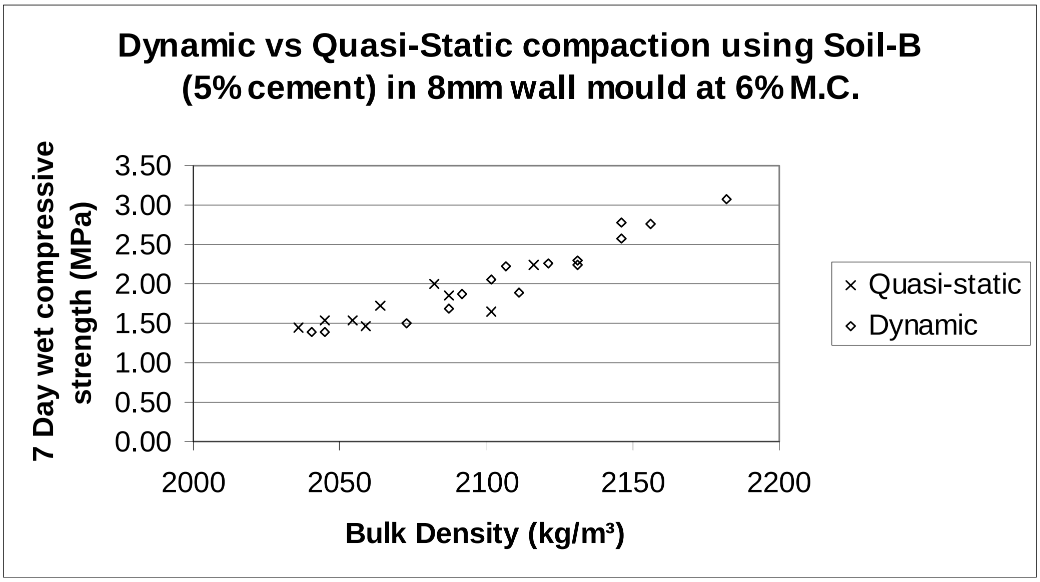
E_D_E_DS_density2

A direct comparison between the dynamic and quasi-static compaction results, show that dynamic compaction is significantly better than almost all of the compacting pressures. The strength achieved with 12 or more blows exceeds the strength achieved with 10MPa pressure. Looking at the highest applied pressure of 12MPa a resulting strength of 1.92MPa is achieved whilst the 12 and 16 blow samples achieve 1.81 and 2.17MPa respectively. A quick significance test shows that there is no significant difference between the 12MPa sample and either of the 12 or 16 blow samples, (E_D_E_DS_den-ref). Consequently it can be suggested that the strength achieved by quasi-static compaction to 12 MPa is the same as the 12 and 16 blow dynamically compacted samples.

These results suggest that the goal of replicating the strength achievable with a 10MPa press should be possible with in order of 14 dynamic blows. This is a very pleasant discovery as Gooding showed that for a constant energy transfer the optimum number of blows is around 16.

3.4 Effect of method of compaction on strength

One of the important tests that needs to be carried out is whether or not the method of compaction makes any difference to the strength of the sample compressed to a similar density. In order to check this, a set of results from dynamic and quasi-static compaction tests were compared. Everything except the method of compaction and the corresponding moulding ‘effort’ is the same for these results, summarised in the graph below.



E_D_E_density2

The graph immediately shows the similarity in the results given by the two methods. What is also of great interest is that the two methods of compaction seem to lie in a similar region on the graph with the dynamic results extending beyond the scope of the quasi-static results.

If we look at the results that overlap (i.e. where density does not exceed 2120kg/m^3) then we find the results for quasi-static pressures between 8-12MPa and dynamic blows between 8-16 are remarkably consistent. A significance test carried out on these results shows that there is no significant difference in the density-strength relationship between the two compaction methods. (In fact the difference is very low indeed with the Difference of Means/Standard Error of Difference equalling only 0.43). These results show that over the region of interest (for any given density in the range achievable by 10MPa compression) the strength achieved via either moulding method is highly similar.

3.5 Time delay between mixing and moulding

In the production regime of block manufacture it is customary to mix materials up into batches from which several blocks are moulded. The time delay between mixing and moulding will therefore increase from the first block made from the batch to the last one; this variation may be reflected in differing strengths of the blocks. As time passes the cement is progressing through the curing process and compaction should take place as soon as possible and certainly not after the critical time. (This critical time is defined by the concrete literature as the time after which working the cement mix causes damage to the cement crystals that have already formed.)

It is possible to see if the time delay has a significant effect on the characteristics of the finished sample by looking again at the results from the reference set of dynamic and quasi-statically compacted samples. For the production of these samples the time delay was in the order of about 15 minutes between the first sample and the third sample of the batch. The first sample in the batch was compacted after the moisture had been mixed into to the soil for about 3 to 4 minutes. Therefore the total processing time for a batch was around 20 minutes.

Below is a table of results from the dynamic compaction tests.

Table 3.5a

Number of Samples	Position within Batch	Bulk density mean kg m^{-3}	Bulk density s.d. kg m^{-3}	Bulk density Coef of var %	7-day wet strength mean MPa	7-day wet strength s.d. MPa	7-day wet strength Coef of var %
5	1st	2140	8	0.38	2.38	0.14	6.09
6	2nd	2131	5	0.26	2.23	0.15	6.53
6	3rd	2118	5	0.24	2.12	0.18	8.26

E_D_E_DS_den-ref

Below is a table of results from the quasi-static compaction tests.

Table 3.5b

Number of samples	Position within Batch	Bulk density mean kg m^{-3}	Bulk density s.d. kg m^{-3}	Bulk density Coef of var %	7-day wet strength mean MPa	7-day wet strength s.d. MPa	7-day wet strength Coef of var %
6	1st	2067	9	0.44	1.76	0.09	5.26
6	2nd	2054	13	0.65	1.61	0.13	7.84
6	3rd	2050	9	0.44	1.63	0.11	6.99

E_D_E_QS_den-ref

In both tables the mean wet strength falls with position within the batch. For the method of dynamic compaction there is a statistically significant difference between the first and third sample, but an insignificant one between the first and second or between the second and third samples produced. The quasi-static compaction results are slightly different as there is a significant difference between the first and second or third samples, but not between the second and third samples. (E_D_E_DS_den-ref).

These results seem to indicate that there is a significant drop in strength if a sample is produced more than 15 minutes after adding water to the soil/cement mixture. This poses some serious production problems and will need to be addressed and double-checked on the full-size block production to see if the same limitation exists.

The significant drop in strength could be a result of a variety of effects, some of which are as follows. (i) Some of the free water (useful for lubricating the particles causing better densification) has been absorbed by the fines content of the soil and partially used in the generation of the cement gel; (ii) there could be active cement crystallisation already occurring and this hinders the compaction process sufficiently to reduce the final strength; (iii) the compaction process actually breaks already-formed cementitious bonds. The last effect is probably of greatest concern as the crystalline growth is being damaged and wasting potential cement strength. The lack of lubrication or compactive effort could be remedied easily, but destruction of crystalline growth should be avoided if possible.

4. DENSITY AS THE SURROGATE FOR STRENGTH

The last chapter described the many tests carried out to determine how different factors affect the final strength of an SSB. We can now state with a degree of confidence that many of the independent variables affect both the cured strength and the green density of blocks. The understanding of the relationship between density and the strength can enable us to know how accurately and under what circumstances density at demoulding can act as a surrogate measure for the potential strength of a sample.

If density is to be the surrogate for strength it is important to decide which density should be used. Several different densities can be measured or inferred during the production of an SSB. Below is a summary of them. As in every case density is taken as a mass divided by a volume, we define different densities by which mass and which volume each uses. In practice we use weight as the source of mass.

Green bulk density – weight is that of material (*including* water) placed into the mould for compaction; volume is that measured upon removal of the green block from the mould. This density is the most commonly used as its calculation is easy to accomplish using simple measurements taken at the time of moulding.

Inferred green dry density – weight is that of material (*excluding* water) placed into the mould for compaction; volume is that measured upon removal of the green block from the mould. This density is not commonly used but is helpful when determining the comparative compaction of different samples with different moisture contents as the moisture variation is removed from the density calculation.

Pre-ejection dry density - this is a similar measure to *inferred green dry density* except that the volume is based upon a block's dimensions prior to its ejection from its mould. This measure is suitable for exploring density variations during moulding and is used in Chapter 5 below.

Cured bulk density – weight is that of the block after the curing process has just been completed, it includes the free water in the block as well as the absorbed water used in the curing of the cement; volume is as measured earlier on demoulding. Other current research has indicated that this density calculation may be the best indicator of the final strength of the finished sample.

Post-cure dry-density – weight is measured after both curing and driving off excess moisture (e.g. in a low-temperature oven); volume is measured at the same time. This is a difficult density to record during a research cycle of curing and subsequent crushing as time is taken to dry out the sample during which some curing is permitted to occur. Furthermore, the subsequent soaking prior to determining the wet strength (by crushing) will permit even more curing to take place, changing the characteristics of the sample.

Post-cure wet-density – uses the weight and volume measured after curing and then soaking for 24 hours (i.e. just prior to crushing). One can determine the voids ratio of the material by comparing the *post-cure wet* and *dry densities*. Their difference is due to the mass of the water filling any voids present.

For the majority of the experiments carried out the *inferred green dry density* was used as a working guide of densification, particularly where the moisture content was not held constant. For ease of communication and understanding these results have been converted into the ejected bulk density which is more commonly understood. Wherever a density is quoted it will be presented as either “inferred dry” or “bulk” density.

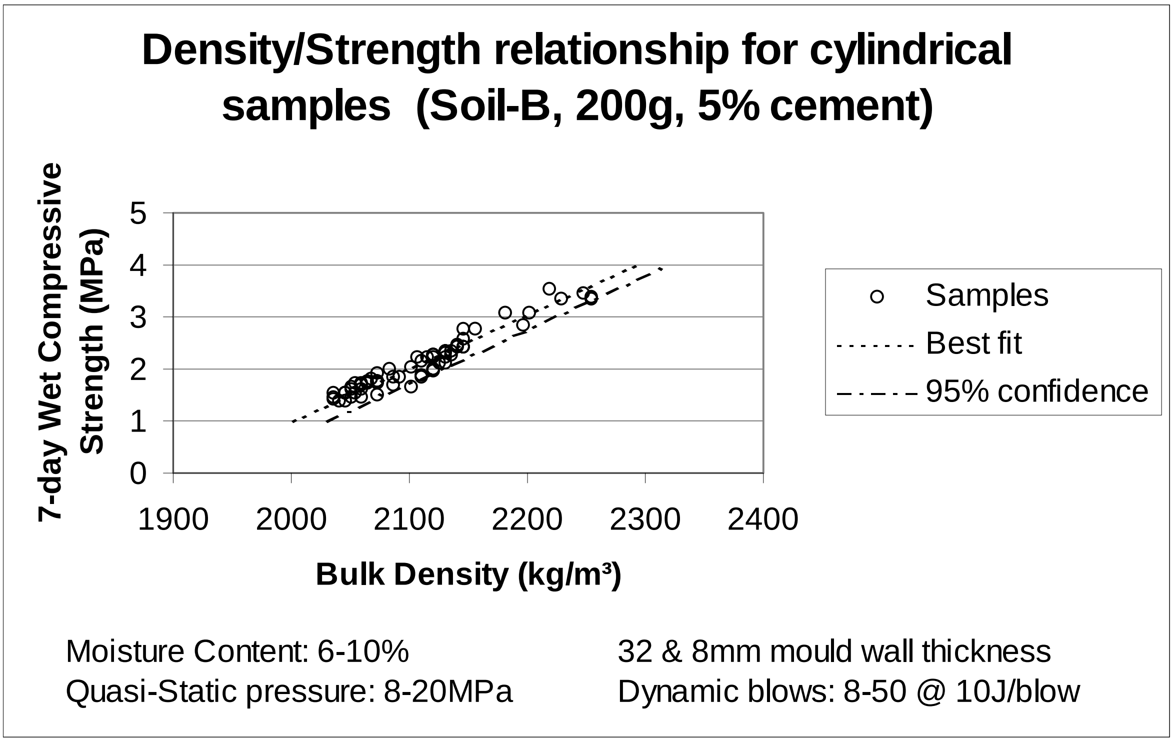
4.1 Summary of Density/Strength data

Before looking at specific variables to see whether or not their effect on the achieved density directly correlates with the effect on strength, a general overview of all the variables would be helpful. This section summarises the production of all of the samples generated and will show the relationship between density and strength even when several entities are varied.

In Section 3.4 above it was shown that at least under some circumstances green bulk density is highly correlated with cured wet strength regardless of the moulding method by which that density was created. That finding, however, does not help determine whether or not the density surrogate can be applied if other variables are changed. Many variables change the density achieved during the production process: these variables may have a greater or lesser effect on the change in strength. A simple method of checking this is to put the data from all experiments carried out in a graph and try to determine the general relationship for strength against density. Some variables (such as cement content) were however held constant because they were already known to have a significant effect on strength for similar densities.

The graph on the next page is a summary of all the tests carried out so far on small cylindrical samples that were stabilised and crushed. The variables include; moisture contents, number of blows, compacting pressure, mould wall thickness. Entities *not* varied were:- soil type, cement content, the size and shape of sample and in the case of impactive moulding, the impactor mass and drop height.

The graph shows a definite trend of strength against density with a reasonably straight-line relationship over the area of interest. The straight-line trend between strength and density is not a surprise because Gooding’s results (displayed in chapter 3) have a similar relationship. What we want to be able to do is to successfully predict with a 95% confidence that a sample compacted to a certain density will have a known strength. In order to do this a best fit line is drawn through the results using the least mean squares method. The results are then normalised to find the standard deviation and a new line is generated two standard deviations away from the best-fit line. This line is shown as the 95% confidence line on the graph and has the equation parameters described below.



For 95% confidence

The equation of this line: $y = mx + c$ is

Bulk Density (ρ in kg m^{-3}) $= 97x10^{-6}$ x Strength (σ in Pa) + 1993

Or more helpfully: $\sigma = 10{,}300\ (\rho - 1933)$

From this we can suggest that over the relevant density range we can use density to predict the 7-day wet compressive strength. This is a very useful property. In research work it allows us to sometimes replace the destructive and cumbersome measurement of strength with a quicker measure that leaves the samples undamaged and hence available for other tests. In block manufacture, green density provides an immediate feedback on block quality that is fairly easy to interpret. Inadequate density points to using a larger charge in a fixed volume mould or more effort in a variable volume mould. Setting density targets is straightforward.

Note incidentally that at mid-range, e.g. σ = 2 MPa, the sensitivity of strength to density is only 0.092, or put another way a 1% increase in density corresponds to an 11% increase in strength.

Whereas the formula above (valid for a particular soil, cement content and thoroughness of curing) is very useful for predicting the strength of these 200g samples, the coefficients may well be different for full-size blocks. The range of values that the above relationship is correct for is only a small variety of possible combinations. The relationship above is only for 200g small cylindrical samples made from Soil-B and stabilised with 5% cement. The moisture can range between 6 and 10% and the mould wall thickness can vary between 32 and 8 mm. Compaction can be either from quasi-static compression between 8 and 20 MPa or from dynamic impact using between 8 to 50 blows at 10J per blow via a 5kg impactor falling through 200mm.

It is hoped that the relationship between these variables at this scale can be extrapolated and adjusted for full scale block manufacture and still exhibit the same trends that have been noted here. This will be examined later on in the project and cannot be reported here.

4.2 Other variables needing consideration

The accuracy and reliability of the results above certainly suggest that the density can be a very good indicator of strength. However, in the normal production of an SSB many different variables would be changing. Some of those would either be out of the range investigated here or be one of the variables that were not investigated. This section looks at some of the possible variables that could either affect the strength without changing the density or variables that will affect the strength that have not been considered earlier in this paper.

Cement content – We have reduced the cement content to the lowest possible value for production and assumed that the manufacturing process would control these quantities very accurately. In reality the cement content will vary and possibly quite significantly depending on the production method and the conscientiousness of the production team. If the cement content varies blocks produced with the same achieved density will have significantly different strengths because of the large effect that cement has on the strength. It is not possible to account for a badly controlled variable, so either a factor of safety must be applied or the cement content vigorously controlled for each block.

Curing regime – Similarly, the curing regime will not be constant in a real production situation. Inadequate curing of the cement is probably one of the most common mistakes in the production of cement SSBs. The difference in strength between a well and a poorly cured block will be highly significant and will not be obvious from the density alone. The achieved density will only successfully indicate the strength if the curing regime is consistent with the reference set and the produced blocks.

Soil characteristics – The soil type used in the manufacture of SSBs may also change during production. The samples produced for this paper were made from a stable and consistent material carefully measured and mixed with cement. A different soil type will have a direct effect on the density that can be easily noted, but it will also have an effect on the ability of cement to add strength to the block. Moreover, due to the expansive nature of certain clays, the soil type may affect the durability of the block even more than its strength. Only long term tests would be able to confirm this proposition and that is currently outside the scope of this project. It would be very useful to show that the particular soil used has only a small effect on block strength or at least that any *change* in density results in a similar *change* in strength regardless of soil type. This analysis has not been carried out and consequently a safety factor would need to be applied to accommodate the possible variation in the soil composition.

Size and shape – The dimensions of the sample produced will have a direct effect on the measurable strength achieved for the same density. Larger samples usually have a lower compressive strength and consequently the short small cylinders used in this research will show a higher strength than would a full-size block of the same density.

Correction factors for compressive strength of concrete samples with a cylinder length to diameter ratio other than 2 can be found in (Orchard, 1979) (p. 79). The 200g cylinders have a diameter of 54.4mm and a height between 41 and 45 mm. Therefore the ratio of length to diameter is between 0.75 and 0.83 giving a strength of between 136% to 125% that of a reference cylinder (with L/D = 2). So normalising to such a reference cylinder for compression testing requires the data in this paper to be multiplied by about 0.77. The small stabilised cylindrical samples that Gooding produced had approximately L/D = 2 and were the minimum size suggested for compression testing of concrete samples, (i.e.: 50mm diameter and 100mm length). Note: The sample size selected for this project is smaller than the recommended minimum, but was so chosen for two reasons. Firstly we wished to keep the ratio of side wall area to compaction surface area the same as for full size blocks. And secondly, the particle size distribution of the soil used contained much smaller particles than the normal aggregate mix used in concrete.

Type of strength test - The usual method of production-testing an SSB is to carry out a rupture test on it. This is done by supporting a block only at both ends whilst loading its centre (by stacking other blocks on top until it fails). This type of test is not as accurate as laboratory compression testing and indeed measures a *tensile* strength that is likely to be not more than 25% of compressive strength.

The principal finding above (that for a given soil, cement content, block shape and curing regime, green density is a good surrogate for strength) could be extrapolated onto full size blocks with a reasonable degree of confidence. Ideally a reference set of compacted blocks would need to be made on start-up of manufacture, the densities and strengths measured for each one and a target density thereby set. In practice cement content, block shape and curing regime may be standardised. This leaves the variation in soil type to be accommodated and hopefully future work will show this not to be a high sensitivity variable.

5. ENERGY INPUT AND CURED BLOCK STRENGTH

5.1 Energy Productivity

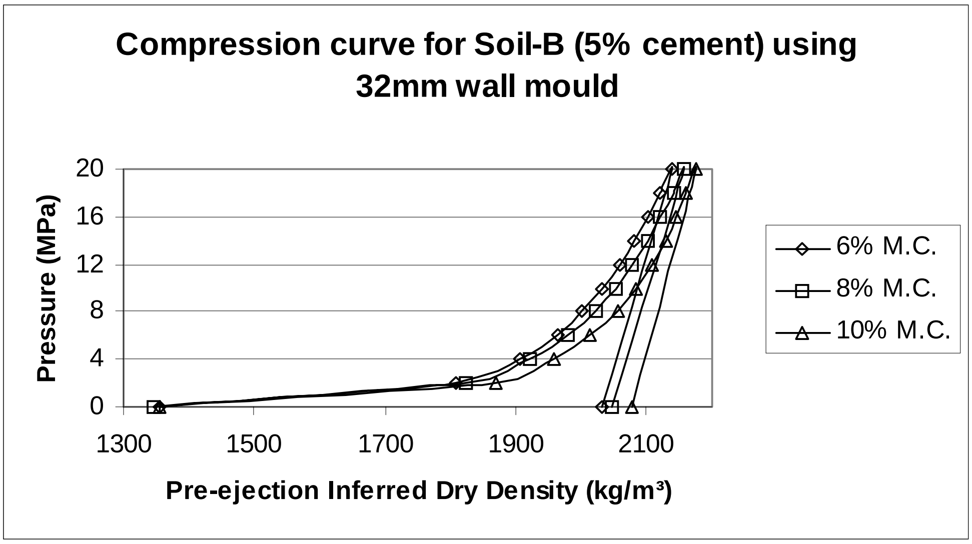
Establishing the factors that affect the final strength of a sample and the possibility of using density as a surrogate for strength were just some of the useful discoveries described in earlier chapters of this paper. To compliment these findings other aspects of the SSB production and performance were noted during these experiments. This chapter will give a brief description of the different observations that were made during the course of the project so far.

One of the variables little studied by previous researchers was 'energy productivity', namely the block strength achieved (in Pa) per unit of energy cost (in J/kg). For manual production, energy is of considerable interest, because labour time is a significant part of production cost. Labour time in turn s closely, although not solely, related to energy input needed per block.

During previous research Gooding discovered that the energy transferred into a full-size block quasi-statically compacted to 10MPa was 279J/kg and this achieved a density of 2038 kg/m³. The soil ('Soil A') he used to make this 8kg block was different from that employed in the current research, so his findings cannot be directly compared with newer data. However, Montgomery later used Gooding's Soil A to make a 10kg block *dynamically* compacted 2040 kg/m³ using only 192J/kg of energy. This indicated a 30% energy reduction for full-size block compaction and is a trend that we would wish to confirm in these results here.

Calculating the energy transfer via dynamic compaction is a trivial calculation using the drop height, the mass of impactor, the number of blows and the gravitational constant. (However if the impactor is released from a constant height, suitable adjustment must be made for the fact that the block's top surface drops, blow by blow, causing the drop distance for the later blows to be higher than for the earlier ones.) By contrast measuring the quasi-static energy transfer is far from straightforward. A force displacement graph needs to be generated during the compression process so that the area under the curve (i.e. energy applied) can be calculated. Doing this has proved quite difficult to achieve for full-size blocks and where necessary previous results have been used for reference.

Three different moisture contents were used in investigating the pressure-density relationship for quasi-statically compressed Soil-B reported above. We can employ the same data to investigate energy productivity. The samples were compressed up to a maximum of 20 MPa and 9 in total were produced. The results of the compaction can be seen in the graph below. Results from other dynamic compaction tests (mentioned earlier in this paper) are used in this comparison.



E_D_E_QS_press'den2

It is immediately clear that there is significant "spring-back" in the compressed material when the load is removed. It has already been established that the difference in achieved density from the different moisture contents is reflected in their respective strengths. We want to use this data to discover what is the approximate energy transfer for different compaction pressures. The cumulative energy transferred for each moisture content and at each pressure can be summarised in the following table.

Table 5a - Q-S compression of 200g cylinders

Pressure MPa	Force N	Average energy transfer (J) 6% M.C.	8% M.C.	10% M.C.
0	0	0	0	0
2	4649	37	39	41
4	9297	54	55	55
6	13946	70	71	70
8	18594	83	86	84
10	23243	97	99	96
12	27891	111	112	108
14	32540	125	126	119
16	37188	139	140	131
18	41837	154	154	142
20	46486	168	168	153

E_D_E_QS_press'den2

From the table it appears that moisture content does not have a great effect on the energy necessary to achieve a certain pressure. A pressure of 10MPa requires approximately 97J of energy to be applied to the sample (i.e. 500 J/kg). This would be equivalent to 10 blows of a 5kg impactor falling through 200mm. Actually the earlier impact blows fell less than 200mm; although the exact distance was not recorded, the energy applied during the first 10 blows was estimated at 95J and we may therefore treat 10MPa Q-S compression and 10-blow impact compression as requiring almost identical energy inputs.

In order to compare the efficiencies of the two methods of compaction the achieved densities of each process needs to be examined. Back in section 3.3.1 the results of several quasi-static compression tests showed an average bulk density of 2067kg/m³ could be achieved with a pressure of 10MPa. Then in section 3.3.2 the results of dynamic compaction tests indicated that 8 blows and 12 blows achieved a bulk density of 2053 and 2097kg/m³ respectively. Taking as a tolerable approximation the average of the 8 blow and 12 blow densities, we obtain a 10 blow density of 2075kg/m³. Thus there is an almost negligible density increase of 8kg/m³ when the same 97J of energy was applied dynamically rather than quasi-statically. The inferred strength improvement is less than 4% and lies within the variability of the strength measurements of the two processes. Consequently it can be stated that for this scale of production there is no significant difference in energy productivity between quasi-static and dynamic compaction.

This finding is a bit of a disappointment, because it was hoped that the higher energy productivity of dynamic compaction detected on a 10kg scale would also hold for smaller blocks. This phenomenon may be a possible result of the very small total energy transfer for these samples, or from probably sub-optimum momentum of the small impactor used in these tests. The better energy productivity of the impactive method may still exist for larger samples and full-size blocks, but this will have to be confirmed later in the research programme.

Combining data from tables 5a and 3.3a indicate that over the range 8 to 12Mpa Q-S compaction pressure, the energy productivity is fairly constant (at about 3500 Pa/J/kg) and hence that for this process the sensitivity of block strength to energy input is about unity. From table 3.3b the energy productivity for impactive formation falls from about 3600 Pa/J/kg at 8 blows to only about 2400 Pa/J/kg at 24 blows - a sensitivity of strength to energy input of only 0.6. Thus beyond a certain point, extra blows give diminishing returns of block strength.

5.2 A good use for excessive strength

The results so far have indicated that a wet compressive strength of around 2.0MPa is possible after 7 days of curing. This would be considered pathetic in the concrete industry, however, as we have already shown much of the concrete literature is not appropriate for the production of SSB’s. The earth building literature (Houben et al., 1994) suggests that a dry compressive strength of 2.0 MPa is adequate for single storey dwellings. This value already has several safety factors to cope with production defects, environmental effects and construction technique. Furthermore the text lists various materials and puts them into classes A, B, C, D; (‘A’ being the best and ‘D’ the worst).

Class ‘A’ building material is considered to have a wet compressive strength of 2.0MPa after 28 days of curing. The graph in section 2.2 shows how the strength increases with time from 3 to 90 days. As 7-day strength is approximately 60% of the 28-day strength for concrete samples, we may assume that blocks shown in the various tables above as having 7-day strengths of 2MPa would be likely to reach 3.3MPa by 28 days. This therefore puts these produced samples well into the ‘A’ class of building materials and a competitor to industrially-fired brick and superior to clamp-fired brick. Indeed they probably are too strong.

It might be said that there is no such thing as too much strength. However, in the efficient use of building materials it is unwise to make a brick several times stronger than necessary. If it turns out that the full-size blocks are much stronger than necessary then it may be beneficial to (i) use less cement for the same amount of material, (ii) use less energy in their production but the same amount of material or (iii) modify the shape of the block to save material. Which of these three options is best will depend on the sensitivity of strength to that input (cement, energy, volume) and the fraction of total cost attributable to that input. In fact the sensitivities of strength to cement, energy and soil volume are approximately 1.1, 0.6 (impactive) to 0.8 (quasi-static) and 1.0 respectively. As all these figures are close to unity, sensitivity alone does not distinguish which option to choose. However, reducing cement usage by 1% will usually save more money than reducing energy usage by 1%, which will in turn save more than reducing soil volume by 1%. Therefore if there is excess strength the most economic course is probably to reduce the cement content. (This conclusion holds less strongly for impactive compaction than for quasi-static because of the former’s somewhat lower strength-energy sensitivity.)

6. BLOCK EJECTION FORCE

As mentioned in section 2.1 the de-moulding force is a dependent variable of interest. The force required to eject a number of fully compacted 200g samples was recorded., and from this data we can make some useful observations. However the factors determining the size of demoulding forces have not been exhaustively investigated and the findings reported here are only provisional. In particular they depend upon data from samples much smaller than a normal building block.

These findings relate to machine design and production technique rather than to block characteristics. However, it could be said that the higher the ejection force the better the surface finish of the final block will be, as significant wiping of particles will occur and a smoother and less penetrable surface results. This characteristic may enhance the durability of the block and perhaps also reduce the rate of moisture loss from the block surface during curing.

We start with the expectation that the greater the achieved density, and hence the higher the moulding forces, the higher the potential force required to eject the block from the mould. Other possible determinants of that force are the compaction method used (quasi-static or impactive), the extent to which the cementitious action has progressed prior to ejection, the ‘stickiness’ of the particular soil used and the mould geometry (e.g. thickness, proportions, taper). We only have data suitable for investigating the first three factors, namely moulding force, moulding method and (indirectly) cement action.

For impactive compression, Table 6a relates ejection force to degree of compaction - as measured by moulding energy or by density achieved. It confirms that the required block ejection force rises with the degree of compaction. The sensitivity of that force to the *energy* input is quite high (over 0.8) so that we might crudely assume that ejection force is proportional to moulding energy. Unfortunately with impactive forming, we cannot easily measure the maximum moulding *force* and hence we cannot explore the interesting ratio of the ejection force to moulding force.

Table 6a Variation of ejection force with degree of compaction

Number of Blows	Energy Transfer J	Av. Bulk Density kg m^{-3}	Ejection Force Average kN	S.D. kN	C.o.V %
8	78	2053	0.77	0.10	13.36
12	118	2097	1.18	0.08	6.94
16	157	2113	1.28	0.08	5.90
20	196	2133	1.50	0.05	3.40
24	235	2162	1.91	0.11	5.98

E_D_E_DS_density2

Tables 6b and 6c allow us to assess the effect of choice of moulding method upon ejection force. We can see that the force required to eject the 200g cylinders formed by the two methods to very similar densities (means of 2054 and 2050 kg m^{-3} respectively) are significantly different. The quasi-statically compressed samples have an average ejection force of 1.07kN, whereas for the dynamically compacted samples it is only 0.77kN - 28% lower. A test on these results confirms that the two ejection forces are significantly different.

Table 6b Ejection force for quasi-static samples

Number of samples	Position in Batch	Av. Bulk Density kg m^{-3}	Ejection Force Average kN	S.D. kN	C.o.V %
6	1st	2067	0.95	0.18	18.92
6	2nd	2054	1.07	0.14	13.40
6	3rd	2050	1.13	0.09	8.03

E_D_E_QS_den-ref

Table 6c Ejection force for dynamic samples

Number of samples	Position in Batch	Number in Batch	Av. Bulk Density kg m^{-3}	Ejection Force Average kN	S.D. kN	C.o.V %
5	1st	1	2140	1.29	0.14	10.61
6	2nd	2	2131	1.35	0.10	7.38
6	3rd	3	2118	1.36	0.12	9.02

E_D_E_DS_den-ref

It can also be noted from Tables 6b and 6c that the 'stiction' to be overcome by the ejector mechanism increases as the position in the batch increases. As successive samples are produced from a particular batch of mixed soil, their density decreases but the force to eject them increases. This increase in 'stiction' cannot be a result of the *fall* in density, but is probably an effect of moisture acting within the soil. As time progresses since mixing a batch, the moisture in the soil become redistributed or even lost, reducing the free moisture available for lubricating the sample against the mould walls. As mentioned in section 3.2, moisture content has a significant effect on the block characteristics, both in terms of achieved density and cement curing. Here we see water also having a significant effect the ejection force required during production. Other earlier experiments had also shown easier ejection with wetter mixes.

Earlier experiments had also shown qualitatively that ejection forces are lower with thick-walled moulds than with thin-walled ones, but that phenomenon needs further study.

7. IMPLICATIONS FOR MACHINE DESIGN

The second objective of this research project is to extrapolate the findings from experimentation with small-scale samples into full-size block manufacture. This requires the design and development of a machine capable of dynamically compacting full-size blocks. Several findings in the previous chapters are significant and should be implemented into a comprehensive machine design and production regime. This chapter summarises these findings and explores how the production of full-size SSB's could be modified to accommodate them.

The basic principle behind quasi-static compaction is an excellent one: the great majority of manual presses in developing countries are based on it. Low-pressure manual presses are readily manufactured and maintained in such countries using local materials and skills. High-pressure machines are more complex and robust, they are more difficult to locally manufacture and maintain and they are significantly more expensive. The higher forces in a high-pressure machine need to be dissipated thought stronger bearings and a thicker steel body. This adds considerably to the weight, production and material costs of the machine, probably putting it out of the reach of the urban poor in developing countries. The high-pressure presses yield a much stronger block and therefore permit production of blocks with only a low cement quantities. But the potential cement savings using the higher-pressure machines do not fully offset the greater machine cost. Gooding conducted a survey for the ODA in 1996 assessing the financial pro's and con's of increasing moulding pressure and reducing cement. He discovered that in every country investigated it was more economic to have a high cement content (8-15%) instead of increasing the compacting pressure.

Gooding's hope was that the high-pressure machines could be replaced with a dynamic compaction machine of comparable cost to the low-pressure manual machines. If this was possible then the reduction of cement content became a viable alternative and the overall cost of SSBs could be reduced. Research since then has shown that excellent stabilised samples can be made via dynamic compaction using only 5% cement. It remains however to show that *cheap* dynamic compaction machines can be devised.

7.1 Machine design specifications

Several dynamic compaction rigs have been manufactured throughout the different periods of research, but dynamic compaction of full-size block was only performed once and using a temporary test rig. A full-size machine should be manufactured both to facilitate research and to show that such a machine can be economically made and operated. The first design will of course not be the final design. There will be inevitable alterations to the design as extrapolation of smaller-scale experimentation to full-size block production takes place. The prototype full-size design therefore needs to incorporate more flexibility than a production model in order to continue effective investigation of the process of dynamic compaction.

Apart from the research requirements of the machine there are several other requirements that can be noted from the research carried out thus far. The safety of the machine is paramount. A falling mass of 50kg is a significant potential hazard and precautions need to be taken to ensure that the impactor cannot fall onto any part of an operators body. If possible the mechanism should be inoperable unless all necessary guards are in place and the operator is well away from the falling impactor. Neither ejection of the block nor routine cleaning of the machine should require operators to place any part of their body underneath the impactor.

Changing to dynamic compaction has shown some reduction in the force required to eject a compressed block. This force is still however substantial - perhaps 10% of the peak moulding force - and will need to be applied manually via a lever by a force not exceeding that which can be repeatedly applied with the hand or foot. Since existing machines require levers over one metre in length to achieve this necessary force *by hand*, it may be possible to use a smaller lever if the force is applied by foot. Either system is acceptable, but a foot-operated lever will be more compact and therefore require less material.

The design of the machine needs to be restricted to a level of complexity that lies within the user’s understanding, and requires only simple and sporadic maintenance. The machine’s construction should also be constrained to use materials and a level of production technology that is readily available in the countries where it is to be made and operated. In spite of the prototype being manufactured in an institution where advanced production facilities are available, the constraints above need to be applied to its design to facilitate its subsequent dissemination and acceptance in the field.

A feature of dynamic compaction is that the peak pressures generated are lower (for a specified final block density) than with quasi-static compaction. This means that the mould walls do not need to be as thick as in traditional presses. An experiment was carried out with dynamic compaction using four different moulds. Each had a different mould wall thickness that followed a geometric progression as follows: 32mm, 8mm, 2mm, 0.5mm. For the same energy transfer it was noted that the 8mm and 2mm moulds generated slightly higher density samples, which was an unexpected yet pleasant finding. Furthermore the samples compacted in the thinnest walled mould achieved a high density yet exerted a stress in the mould walls corresponding to only 30-40 microstrain. The yield strain for steel is around 1200 microstrain, so this shows that the material even when very thin is able to deal with the forces present during dynamic compaction. It should therefore be possible to design a mould for a high-densification impact machine that is comparable in thickness with those in traditional low-pressure quasi-static machines. Such a mould will be much cheaper and lighter than those required by the heavy 10 MPa presses needed to produce comparable densification by the quasi-static method.

7.2 Some production guidelines

This section will attempt to outline some of the key areas of concern in a production regime for manufacturing SSB's. Some of the issues have been discussed above whilst others are a result of past research and experience. As full-size block production has not been carried out as yet it is foolish to categorically state anything as being the most important aspect of production. However, it is possible to suggest some important requirements of the manufacturing process that have been revealed in this research.

Moisture content has proved to be a highly significant variable in the production of SSB's. The available water will have an effect on the workability of the soil/cement mix, the achievable density, the de-moulding force, the ease-of-handling and the curing of the cement. Since these are all important, it is difficult to say which has precedence over the others. Having said that, it is in the handling of green blocks that the greatest production losses can occur and therefore achieving adequate ease of handling might be made a first priority when choosing water content. Many experiments were carried out at around 6% moisture where blocks are both easily handled and readily brought to a high density, so this could be a good starting point for full-size block tests.

Thorough mixing of the materials prior to compaction is very important when the quantity of stabiliser is so small. For these experiments the soil/cement/water mixture was very carefully proportioned and mixed together to give a good consistency between experiments. This thorough mixing is difficult to achieve on full-size block and will be even more difficult to practise in the field. Nevertheless, it is advisable to include a measure of care when mixing the materials together as poor mixing will not bring out the full potential of the SSB. It has been said for concrete that "good concrete and bad concrete are made from the same ingredients, it's the method of production that will determine the finished product". The same could be said for the production of SSB's. It may be that it is one of the tasks of a machine designer to address not just moulding but also ingredient batching.

Handling after moulding - once the finished block is compacted it needs to be ejected and carefully moved to a curing area. Even where moisture content has been chosen to enhance ease of handling, design attention needs to be given to reducing breakage prior to curing. Boards can be used to carry blocks around and special block lifting apparatus can be employed to help transfer the blocks to and from these boards.

Curing - a book could be written about the use and abuse of cement in developing countries. Possibly the greatest and yet commonest mistake in a production regime for SSB's is to leave the freshly formed blocks out in the open to "dry out". This makes the cementitious reaction slow down and stop, as the moisture is lost to the environment. Consequently the crystalline growth does not get very far and very little strength is added to the material. Subsequent wetting of the material may help to further cure the cement, but this will not be as effective as thorough curing of the blocks immediately after moulding.

Batch size: Time delay in the production of the SSB’s from a batch of soil has been shown to be of importance. If the time, between adding moisture to a batch of soil and the production of the final block from that batch, can be minimised then the SSB’s produced will be both stronger and more consistent. The extreme case of having a batch size only large enough to produce one block at a time, is not economically viable and the material for several blocks will need to be made at the same time. However this will introduce unwanted variation in the characteristics of the finished blocks and the blocks produced later in the batch will be inferior to the ones made first. Consequently using a small batch size not only facilitates good manual mixing, but also gives consist block attributes with the batch itself. The ideal of continuous mixing and the design option of adding water only as the charge enters the moulding chamber will be investigated further.

8. CONCLUSIONS AND RECOMMENDATIONS

The first and most important conclusion to make is that the process of dynamic compaction works as effectively as the current method of quasi-static compaction in densifying stabilised soil building blocks. The tests described in this paper have shown that, at least on the small-scale used for tests, the dynamic method performs as well in terms of energy productivity (Pa/J/kg), achieved density and the wet compressive strength of cured blocks. We also have good reason to believe that larger scale dynamic compaction will achieve higher energy productivity than reported here. This finding will need to be confirmed on full-scale tests to be carried out in the future.

The research has also brought to light several factors that affect the stabilisation of soil blocks. Stabilisation is mainly concerned with adding durability and strength to a material that would otherwise be unsuitable for construction. Since the durability of the samples produced could not be checked then compressive strength was used as the best available surrogate. Using the same fraction of cement and the same curing regime, the wet compressive strength of samples was found to depend entirely on the level of compaction that they achieved. Consequently density on demoulding can be used for a satisfactory indication of the subsequent cured strength of a block.

Dynamic compaction brings one significant advantage to the process of heavily compressing soil: it requires much lighter equipment. High-pressure quasi-static compaction is much more complex and expensive than the lower-tech method of dynamic compaction. The experiments reported indicate that a machine for dynamic compaction could be similar in cost yet much superior in performance to the low-pressure quasi-static presses that are popular throughout developing countries. Thin mould walls, short levers and the absence of hydraulics make dynamic compaction available to a wide group of people in need of low-cost housing solutions.

Changing the method of compaction from quasi-static to dynamic is potentially straightforward. However comprehensive machine design is yet to be done and a full-size prototype is yet to be built and tested. This is should be achieved in the next year. The safety of the machine is the only major factor of concern as this needs to be fully addressed before a design can be propagated.

Once a prototype has been produced and laboratory tested then the technique needs to be fully tested in the field using potential users and readily available soils. This process will help to determine the obstacles to successful dissemination of the technology in the areas where it is most applicable. Possibly the largest issue is the public's attitude towards soil itself. Soil, even when stabilised to perform as well as fired brick and concrete, currently has an unfavourable image and other alternatives still exist for the uneducated urban poor. Small brick clamps are currently the most popular method of soil stabilisation but these use increasingly scarce resources such as firewood in a very inefficient way. Substantial improvements in the performance and economics of the cement-stabilisation alternative are needed if it is to make much headway in the short term.

Future research will initially focus on the extrapolation of the findings to date onto full-size blocks. This should include the fabrication of some sample walling for realistic durability testing. The production process for full-size blocks needs to be carefully refined to ensure that the maximum benefit is obtained from the inputs of effort and cement. Once this research has been completed then it will be necessary to disseminate the findings (especially through demonstration) and to assess reactions to the new technology. The level of technology and understanding required for this technique is such that if the reaction to it is favourable its dissemination could occur by normal processes of copying and commercial initiative in urban areas of relevant low-income countries.

DTU Working Paper No. 54 **February 2000**

The Problem of Evaluating the Performance of Landmine Detection Systems

by Russell Gasser and Terry Thomas

Contents

1 Introduction

Even in densely mined areas mines tend to be widely separated, and very few mines will remain undetected by a good mine detector system. Objective analysis of the performance of mine detectors based solely on the percentage of mines not detected is thus difficult at more than an anecdotal level. Field conditions, the types of target and operating procedures vary so widely that testing in a laboratory or test area may not reveal the limits of the performance of a mine detector in a specific mined area with a particular type of mine/UXO contamination. Generalisations about humanitarian demining equipment performance can have only a very limited validity.

Reports of promising technologies of necessity quote results such as a "95% success rate" or "16 out of 16 targets found" [Ano00] but usually do not attempt to present an analysis of the statistical confidence of such data. This working paper examines the difficulties in assessing the performance of mine detecting equipment both quantitatively, by developing a statistical analysis and presenting the results, and qualitatively, by analysing the practical difficulties of evaluating equipment performance specific to demining. Use of the concept of "margin of detection" is proposed as a possible way forward.

2 The three main problems

The three principal difficulties in assessing prototype demining equipment are:

1. Testing equipment that is still under development, and hence not yet capable of finding every mine, in live areas is not possible because of the risk to the operator. Testing under simulated conditions does not yield the same results; the major impediments to finding mines, such as vegetation, have to be removed or altered to place surrogate mines. Deminers, no matter how carefully they seek to re-create their working practices, are likely to act differently in live areas from ones they know to be safe. The ethical justification for asking deminers to perform a trial in a safe area while leading them to think that it is mined in order to simulate live conditions more accurately, is debatable.
2. Finding enough mines or surrogate mines to provide a meaningful statistical analysis of the detection rate at a useful level of confidence is quite impractical as meaningful trials require hundreds of targets.
3. Sensitivity to factors beyond the control of the test protocol may be greater than sensitivity to the parameters being measured. For example, the exact depth of a small buried target may strongly influence the probability of detection. Placing a target and then re-filling above with soil makes precise determination of the depth difficult, moreover it may well not give the same results for some methods of detection as long-buried mines, and the precise depth of soil may vary slightly after heavy rain or vegetation growth.

The rest of this working paper addresses problems two and three above.

3 The statistics of missed mines

The only published paper of note on detection probability in humanitarian demining and associated confidence levels appears to be that of Voles [Vol98] who presented his argument somewhat cryptically. His method permits the calculation of results for only a limited number of levels of confidence, namely the values of the cumulative Poisson function $F(x;\lambda)$ where x= 2, 3, 4 or 5 and $\lambda = 1$. The analysis outlined below is both simpler and more general, and is believed to illuminate an inconsistency in Voles' assumptions.

Mine detection satisfies the conditions for a Bernoulli trial [MF85, page 57]:
(i) there are only two outcomes (mine detected or mine not detected),
(ii) the probability of success is the same for each trial,
(iii) there is a constant number of trials (the total number of mines), and
(iv) the trials are independent (locating a mine does not affect the performance of the mine detector when attempting to locate the next mine).

Thus the use of the Binomial distribution for probability calculations is justified. The conditions for using the Poisson approximation to the Binomial are also satisfied if the number of mines (n) is large and the probability of failing to detect each mine (p_{fail}) is small. In general the Poisson approximation can be considered valid if $n \geq 20$ and $p \leq 0,05$ or if $n \geq 100$ and $n.p \leq 10$ [MF85] [Bar94].

3.1 A conceptual model

A useful conceptual aid to understanding the statistics of mine detection can be to consider the model of a population of mines of which a fraction u are undetectable, and a detector capable of always finding all the rest. This gives the same results as a population entirely made up of theoretically detectable mines and a detection system with a probability of only $(1 - u)$ of locating each mine. A practical example of this conceptual model is the type of minimum-metal mines that are supplied with steel discs which can be optionally fitted as the mines are emplaced in order to make them easy to locate later with a standard metal detector (e.g. the TMA-4 anti-tank mine formerly made in Yugoslavia). If the detection performance required is the commonly accepted 99,6% success rate then it can be assumed that on average four mines per thousand have not been fitted with discs, and the metal detector will find all of the mines with discs and none that lack discs. This is a reasonable assumption in practice if the mines have been laid at the correct depth. Defining the exact reason for indetectability makes no difference to the statistical analysis provided that it is a random process. In practice this condition may not be completely satisfied as failure to detect a mine may be due, for example, to specific soil conditions that prevail over some mines and not others in a non-random manner, but the consequences of this are considered to be negligible.

3.2 Definition of the problem of sampling

The problems of obtaining meaningful results from limited-size trials can be expressed thus:

Test results show that in a sample of n mines (the trial size) x (= 0, 1, 2, 3,..., n) mines were ***not*** detected. What is the probability that an arbitrary proportion π of similar mines from the same population would also escape detection? What is the limit of confidence in this result?

Clearly if the number of mines used in the test (n) is very large there is a high degree of confidence that $\pi = \frac{x}{n}$. If the sample size is small it will less accurately represent the stock of mines as a whole and there is a certain likelihood that the value of π is larger than $\frac{x}{n}$ (or smaller than $\frac{x}{n}$ if $x > 0$). The trial result therefore depends on (i) the probability that any individual mine is detectable and (ii) the confidence that the sample accurately reflects the stock as a whole.

Taking the standard promoted by the United Nations of 99,6% mine clearance, an example of the conceptual model outlined above might be a crate of 1 000 mines of which 996 are detectable (they have steel discs that

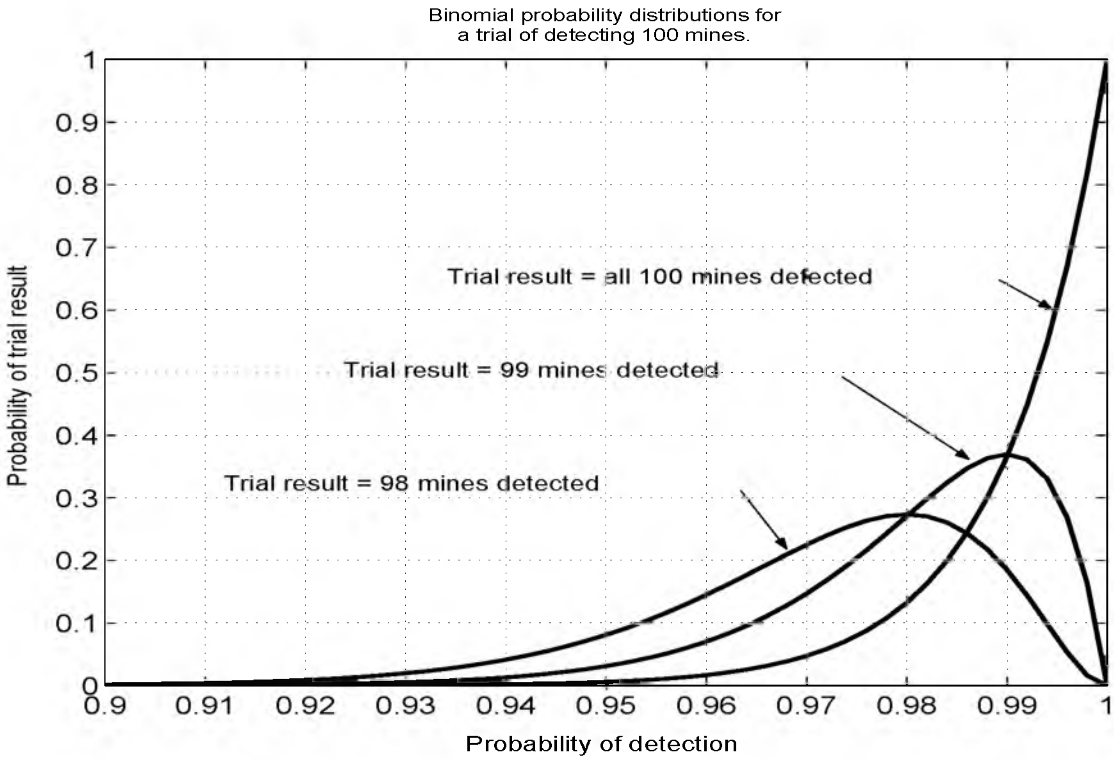

Figure 1: **Probability of result versus assumed probability of detection (fraction of mines that are detectable) for trials of 100 mines.**

make detection possible correctly installed) and four are undetectable (without the discs). It is obvious that a small sample, such as 20 mines, taken at random from the crate might well not include any undetectable mines. Clearly, it is not correct to conclude that because a small sample contains no undetectable mines that there are no undetectable mines in the crate. The question is, how many mines must be detected in a test to be sure that there are indeed very few undetectable mines in the crate, and what are the precise percentage probabilities?

3.3 Analysis using the Binomial probability distribution

The likelihood that a sample of size n, taken at random from a stock of mines having a proportion π of undetectable mines, will contain exactly x undetectable mines is given by the Binomial probability distribution

$$f(x; n, \pi) = {}_nC_x \pi^x (1-\pi)^{n-x}$$

where ${}_nC_x$ is the number of combinations of x events in n events.

Thus the likelihood that the sample will contain from zero to k (inclusive) undetectable mines is given by the cumulative Binomial function

$$F(k; n, \pi) = \sum_{x=0}^{x=k} {}_nC_x \pi^x (1-\pi)^{n-x}$$

Figure 1 shows the results of calculating the probability of the outcome of trials of attempting to find 100 mines, plotted against the probability of detection; the Binomial distribution relates the two probabilities as

$p_{result} = binomial(x, n, \pi)$ where x mines escape detection in a trial of n mines by a detector with a p_D of $(1 - \pi)$. Clearly if the detector is perfect (p_D=100%) the probability of finding all the mines is one, and the probability of failing to detect any number of mines is zero. When the p_D is 98% the most likely outcomes are one or two mines not detected.

In practice it is usual to discuss the case of a *lower limit of probability of detection* on the basis that any improvement in performance is welcome. When a detector is referred to as "having a p_D of 99%" the more complete statement is that the p_D is 99% *or greater* under certain conditions.

3.4 Using trial outcome to predict p_D

Predicting the outcome of a trial from a knowledge of the detector is less useful than using the results of a trial to find values for the probability of detection and the confidence in that probability. This is a standard problem in statistical quality control and is covered in text-books, for example Yamane [Yam73] who bases his text on the earlier work in the 1930s of Clopper and Pearson [CP34] and Barnes [Bar94] who presents a nomogram adapted from Johnson and Kotz [JK69].

Two hypotheses are tested. These are:
H_0 : The mine detector performs to the required standard.
H_A : The mine detector is defective.

The associated errors are $\alpha = P(H_0$ rejected when true) and $\beta = P(H_0$ accepted when false). In quality assurance α is known as the producer's risk and β as the consumer's risk.

In testing mine detectors (1-α) is the confidence that the detector is accepted correctly from the test results (confidence in the result), and (1-β), known as the power of the test, is the confidence that an unsatisfactory detector will be rejected. In the case of a trial where all the mines are detected β is clearly meaningless as the detector has been shown to function with a theoretical maximum p_D of 100%. In trials where one or more mines are missed β can be used to define the confidence with which an unsatisfactory detector would be rejected, though this is likely to be so low that it is not useful.

In any distribution the parameter α can be visualised as the fraction of the area under the tail of the probability curve lying below the value p_{limit}. This is illustrated in figure 2.

In most statistical quality assurance the areas under both "tails" of the distribution curve contribute to the probability α; manufactured items that are oversize as well as those that are undersize should be rejected. In mine detection there is no meaningful interpretation of a detector that is "too good" so α is exclusively the probability that the detector is not good enough, the area under the curve below the required minimum value of the probability of detection. This is the lower limit of the possible range of values of p_D for that value of α.

An arbitrary decision has to be made as to the relative magnitude of the p_D and confidence (1-α) in order to analyse test results. This decision can also be visualised as moving the vertical "decision" line to the left or to the right on the graph of the probability function. As the line moves leftwards the area under the curve to the right of the line increases illustrating that as the minimum probability of detection required is reduced the confidence that this can be achieved increases.

Direct calculation of the Binomial distribution is straightforward and can be performed rapidly using a digital computer. There is no longer any need to employ analytical methods including further assumptions to reduce the problem to a form that is more readily calculable; this was necessary until computer power

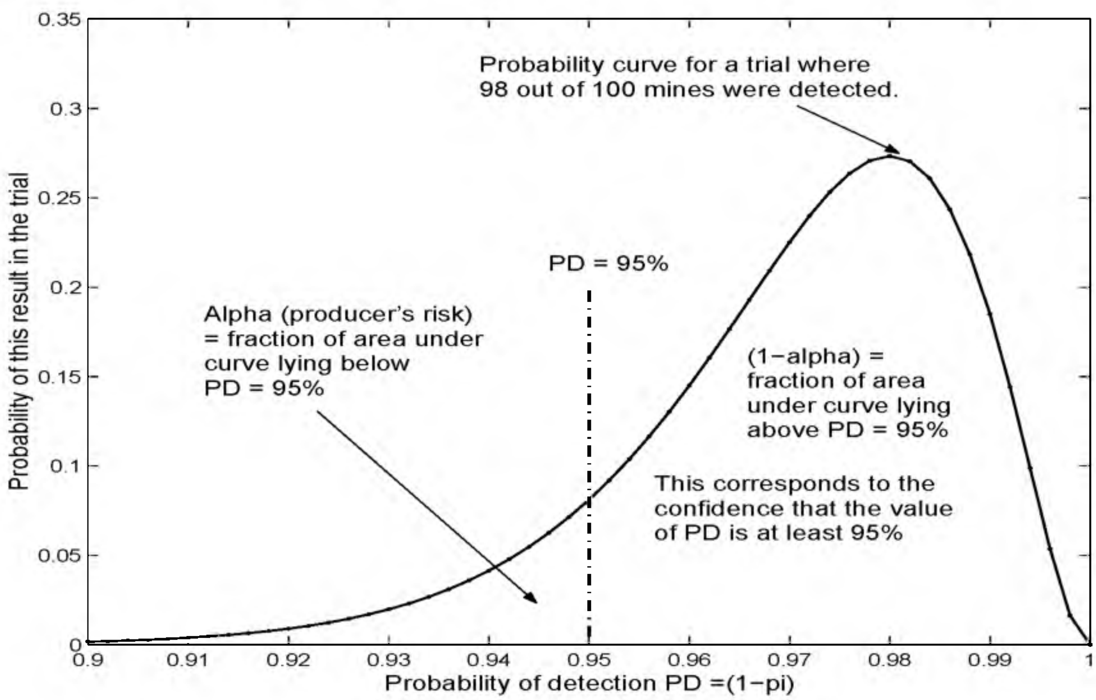

Figure 2: **Probability of result versus probability of detection for a trial of 100 mines, to illustrate α for a p_D of 95% .**

became cheaply available in recent years and was therefore widely covered in textbooks. The solution to the calculation for evaluating p_D from the results of a trial of a detector can be performed by a direct numerical approach of seeking solutions that fit. Although this may appear clumsy and inelegant it produces unequivocal results without the need to make further assumptions about the data, and once the computer programming has been done it is a very quick method. To avoid computational difficulties that arise when the sample size is large, the result can be calculated using the identity $b(x; n, \pi) = b(n - x; n, 1 - \pi)$.

Numerical solution of the Binomial approximation leads to the conclusion that Voles [Vol98] may have misinterpreted one of his own assumptions. Not only is a numerical solution to the case of no undetected mines possible (which is not the case for his method) but the results obtained for the case of zero undetected mines are the same as for the results he offers for the case of zero or one undetected mines. It appears that his assumption that the number of mines undetected is *less than or equal to one* should in fact be that the number undetected is *strictly less than one.* The interpretation of the limiting case is that the mine detector just managed to find all the mines and with any reduction in p_D would have missed a mine, instead of the case that the detector just failed to find one mine and any increase in p_D would have led to finding all the mines.

3.5 Selection of p_D and confidence

The selection from the results of an appropriate p_D and its associated confidence depends on the circumstances of the testing. The result of a trial is the set of points that form the curve of p_D versus (1-α) for the number of mines detected and undetected, as shown in figure 3. While investigating a new detection

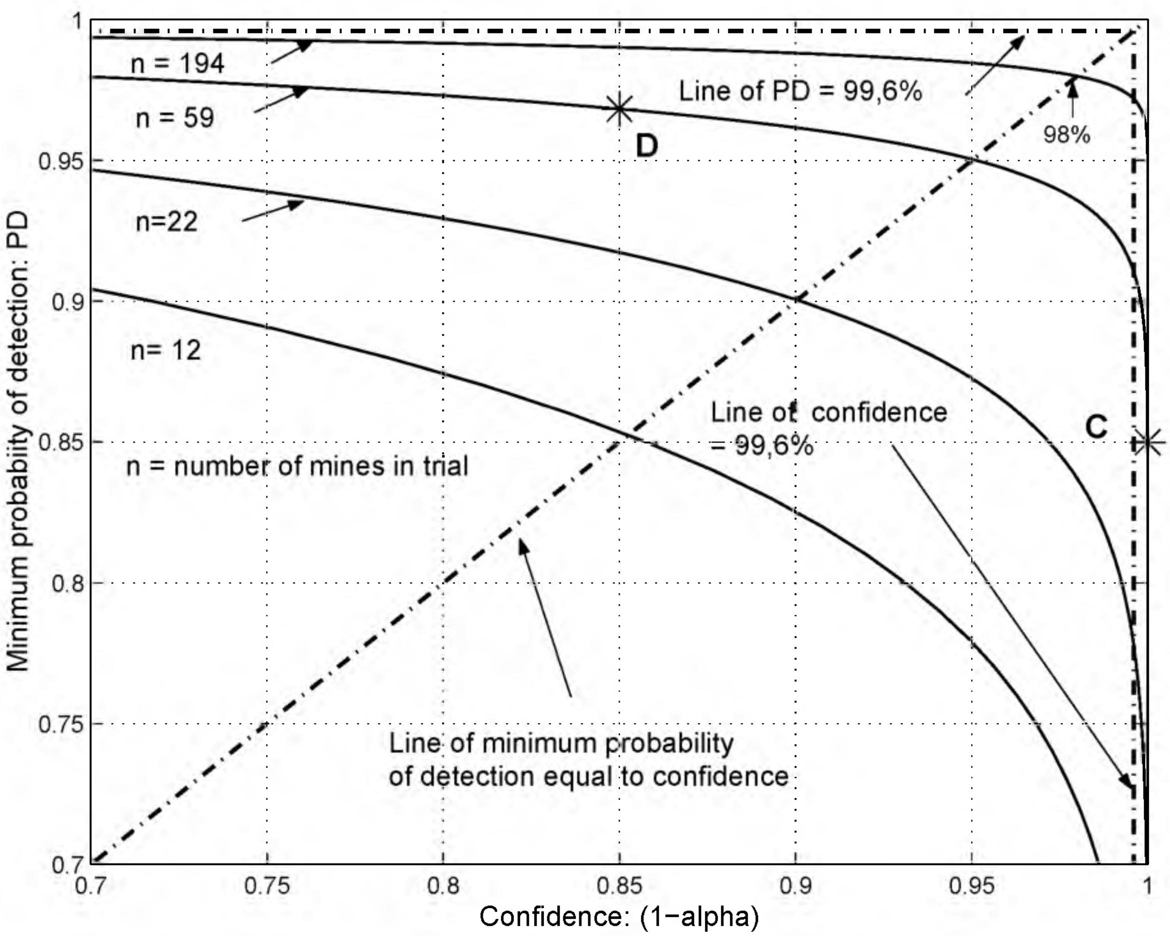

Figure 3: **Minimum probability of detection vs confidence in the result, for trials in which 100% of the mines are detected.**

Confidence (1-α) = Minimum probability of detection, %	**Number of mines in trial**		
	All mines detected	1 mine not detected	2 mines not detected
50	1	3	7
75	5	10	18
80	8	14	18
85	12	22	35
90	22	38	59
95	59	94	139
98	194	290	411
99,0	459	662	913
99,2	602	861	1177
99,4	851	1204	
99,6	1378		

Table 1: **Number of mines required in trial for a given minimum probability of detection, when minimum probability of detection is numerically equal to confidence in the result.**

method it may be initially useful to build prototype equipment that is known to have an unacceptably low p_D in order to investigate how, under field conditions, this p_D varies with soil type, temperature, moisture or other factors. In this case a higher confidence and lower p_D would be appropriate. On the other hand, during detailed testing of a detector that is known to perform extremely well setting the p_D to the desired performance level and calculating the resultant confidence level might appear a better strategy.

Figure 3 shows that the curve is not symmetrical about the line of equality (p_D = (1-α)) and whereas in a 100% successful trial of 59 mines a probability of detection of 85% can be stated with practically 100% confidence — point C on graph, a confidence level of 85% corresponds to a p_D of only 97% — point D. This serves to re-emphasise the difficulty of obtaining any meaningful results from measurement of the rate of detection in reasonably sized trials. The artificial separation of the two parameters of a test result, and the difficulty of the concept of confidence compared to the relative simplicity of probability of detection, lead to correct, but misleading, claims of such figures as 95% or even 100% success in trials. A p_D of 100% can only occur when the confidence is zero but the asymmetry allows confidence levels of 100% to be closely approached at values of p_D of well over 50%.

A useful approach to reduce the difficulty of presenting the results of testing mine detection equipment is to calculate a single value for both p_D and confidence by using the point where the two are numerically equal. The locus of these points is shown on figure 3 as a diagonal line. Solving numerically for the limiting case of $(1-\alpha) \geq \pi$ (i.e. confidence equal to or very slightly greater than probability of detection) gives the results shown in figure 4. Table 1 cites examples from the data. A trial of reasonable size can be seen to have p_D well below 100% by this method, finding 22 mines and missing none in a trial has a p_D (= confidence) value of just over 90%. In practice this is probably a more useful measure than expressing the same result as, for example, "99,6% p_D at a confidence of just over 8%." A small improvement to the equipment is unlikely to change the 99,6% p_D figure by a significant amount but will be clearly indicated by an increase in the value of joint value for p_D = confidence.

Table 1 shows the size of a trial needed to demonstrate a probability of detection and confidence level both equal to 99,6% to be 1 378 mines successfully detected and none missed. This is completely unrealistic.

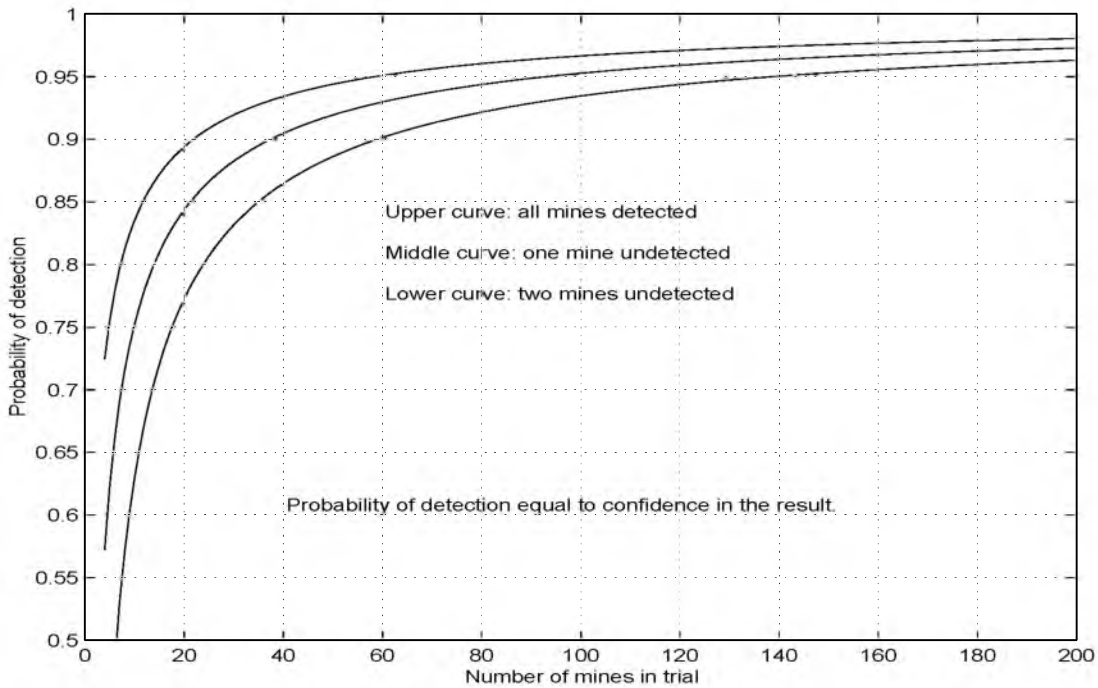

Figure 4: **Probability of detection vs size of trial when the minimum probability of detection is numerically equal to the confidence in the result.**

4 Qualitative factors

Testing mine detectors "in the field" under realistic circumstances introduces so many variables that trials of a size that are feasible cannot be expected to yield results within an order of magnitude of the desired failure-to-detect rate. More information than just the crude detection rate must be included, either in a comparative manner or analytically, if the results are to be useful.

4.1 Limitations of "crude detection rate" data

The approach of defining a single overall detection figure determined by limited testing is not only unworkable in practice but conceptually flawed. Manufacturers of safety-critical systems such as passenger aircraft or nuclear power plants do not define the probability of failure of their products by waiting for occasional failures and then projecting a probability of failure rate from the results. Whilst the development of an exact method for testing humanitarian demining equipment is beyond the scope of this working paper, it is clear that mine detectors are not the only safety-critical equipment that requires testing, and that sophisticated methods have been developed to deal with this situation in other industries. The most distinctive characteristic of humanitarian demining is the wide variability of the environment. This requires focusing on the development of test methods and procedures that are as insensitive to the environment as possible. In this regard a crude detection rate of 99,6% is a very poor measure as it depends heavily on the environment, and on the training, skills and supervision of the operator and not just on the performance of the mine detector.

4.2 Human factors

The limiting sensitivity of a mine detector can depend in part on the skills and hereditary characteristics of the operator. The ability of different people to detect a small change in the pitch of a tone is known to vary by more than an order of magnitude [VLFM99], yet many metal detectors use a change of pitch to indicate a target.

The operator interface of mine detecting equipment has a large impact on how the equipment is used and ultimately the probability of detection. There are many non-technical aspects to designing equipment with an intuitive feel; this topic is beyond the scope of this working paper.

4.3 False alarms and unwanted alarms

Analysing the results of testing humanitarian demining equipment requires a workable method for dealing with false alarms. Taking once again the example of metal detectors, increasing the sensitivity increases the probability of detecting a minimum metal mine, but also increases the number of small pieces of scrap metal detected. In areas where it is considered that there are no minimum metal mines, deminers are known to reduce the sensitivity of the metal detectors to decrease the false alarm rate. Yet in doing so they are making a decision to reduce p_D.

At present no distinction is made in defining the false alarm rate between mine-like objects that are identified by the detector as possible mines, and false alarms due to interference or sensitivity to non-mine-like objects. The statistical analysis presented above does not include any analysis of false alarm data.

For example, a small piece of scrap metal found by a metal detector is considered a false alarm just as an area of highly mineralised soil that triggers the detector is considered a false alarm. For the purpose of analysing the detector's performance these are two separate cases. The small piece of metal might be the firing pin of a minimum metal mine that had already detonated; clearly it falls within the range of items that should be detected by this method and as such is an unwanted alarm but not a false alarm. To distinguish an unwanted alarm from a mine, a separate detection method must be used which seeks to identify a different characteristic of the mine such as its dielectric constant in the case of radar systems, the presence of explosive in the case of olefactory and quadrupole resonance systems, or the physical presence of a mine case by prodding and excavation.

To a deminer both types of alarm are a nuisance. However, for the purposes of analysis one is an unwanted but correctly identified alarm and the other is truly a false alarm. If false alarms can be clearly distinguished from unwanted alarms then the high unwanted alarm rate of metal detecting can be used to provide an improvement in the statistical basis of quality assurance. By considering all unwanted alarms as valid targets in a statistical analysis, the number of targets is increased to a level at which a measure of the crude rate of detection can begin to offer some meaningful results. However, this is not enough of a benefit to outweigh the nuisance of large numbers of unwanted alarms.

Currently, it is common to have a detector with the highest possible probability of detecting both mines and unwanted alarms in order to reduce the number of mines not found (i.e. p_D is at a maximum). A subsequent discrimination method is then used to distinguish between mines and unwanted alarms. The common secondary method in humanitarian demining is to excavate manually and look for a mine, which is costly and tedious. The maximum usable p_D may in practice depend not only on the equipment under test but also on the associated secondary discrimination method and the operating procedures used. This makes a meaningful statistical measure of p_D more difficult to define.

Area cleared, m^2	Mines found	UXO found	Metal fragments found
19 489	5	7	20 015
76 264	6	9	35 931
35 290	6	93 (in 20 groups)	72 220

Table 2: **Number of mines/UXO and scrap metal items found in three cleared areas in Cambodia.**

5 Quality Assurance

Sampling methods of quality assurance (QA) are not appropriate to demining, yet they have been used. Some humanitarian demining organisations have, for example, carefully rechecked a part of a cleared area to be sure that they are confident that the demining has been done thoroughly. The commonly adopted current practice of removing all metal fragments from an area and then performing a check that it is entirely free from metal is a non-analytical form of QA.

The scarcity of mines in a mined area can be seen from the data from three mined areas visited in Cambodia in 1999, presented in table 2. It is clear that with any reasonable probability of detection there will be few, if any, mines/UXO overlooked. If one mine has been overlooked then the chance of it being found in a sampled QA test area is minimal — if 1% of the entire site is re-sampled then the chance of finding the missed mine is 1 in 100. If there were five mines found in the entire area and one not detected this amounts to a probability of detection, p_D, of only 83%. QA methods must demonstrate a high probability of being able to detect such a low p_D, certainly far more than just 1%.

Statements about the required clearance rate of 99,6% lack value if only five mines have been found; the confidence level with p_D equal to 99,6% in a trial of five mines, even when they are all found, is tiny — less than 2%.

There are also important issues concerning the need for an independent mine locating technology to be used for QA (i.e. one that is unrelated to the primary detection method) to avoid missing the same mine for the same reason. One of the more promising methods is the use of dogs or artificial noses which can tell if explosive vapours are present in an area without necessarily being able to locate any individual mine. Any suspect area can be rechecked by hand.

In practice, the only way to guarantee mine clearance to a very high standard is to introduce not post-clearance sampling methods but methods that evaluate the performance of the demining operation as it is taking place. One way of doing this by using the concept of the "margin of detection" is proposed in section 6 below.

The strict operating procedures and supervision of manual demining are a method for maintaining an adequate quality of clearance. It is generally not the quality of current clearance methods that is a problem, but the time and cost of achieving the required standard and the lack of a way to guarantee that it has been achieved.

6 "Margin of detection"

In a typical trial two metal detectors may both find a set of targets without failure. However, connecting suitable measuring equipment, such as an oscilloscope, may show that one is at the limit of its ability to distinguish the targets but the other has a substantial reserve of performance and could still detect the targets under substantially more demanding conditions. Clearly their performance is not identical but the crude detection rate does not distinguish between them. To do so requires the introduction of a measure of how close the "signal" from each mine is to the limit of detection of the equipment being used. An estimate of how easily the detector identified all the targets, or almost all the targets, adds considerable useful information to its evaluation.

Similarly, in an area being cleared of mines/UXO, if all the mines already located have been found easily, and the geographical conditions are similar throughout the area to be cleared, then it is possible to be confident that further mines of a similar type and depth could be found readily. However, if the mine detector had been functioning at the limit of its performance while one or more mines were detected then it is possible that a mine buried slightly deeper, or one encountered by a tired deminer at the end of a working shift, might be missed.

Thus the concept of the ease of detecting of a target, or the "margin of detection" is one way to resolve the problems of statistically meaningful testing of mine detectors as well as QA.

A further weakness of testing methods that rely solely on the crude maximum detection rate is that a crucial evaluation is made when the desired signal from the mine/UXO is only just distinguishable from the "background" which is noise, clutter, interference and other undesired signals, depending on the detector type, soil, vegetation and other factors. The measurement of a signal barely different from the background is unlikely to give reliable or repeatable results. To avoid this it is common throughout engineering to use methods of extrapolation; the signal is measured under less critical conditions and a curve fitted to the results which is then extrapolated to define a point at which detection is just possible. The goodness of fit of the curve can be analysed statistically to provide measures of confidence and probable error limits. Individual manufacturers of mine detectors may well be using this method to enhance their products, what is required is a more general technique which can be used to compare different detectors.

A suitable measure of the margin of detection might be the ratio of signal to background noise at some point in the detector circuit. For complex detection methods a measure of the effective "signal to noise ratio" can be made from probabilistic considerations. However, in defining the conditions of the measurement of the margin of detection the number of variables is large. The sensitivity of the detection process to some of these variables is also large; in the case of the limiting distance to a small metal target in air, the metal detector's received signal depends on the inverse fourth power of the distance from the detection coil to the metal fragment. Moving from 100 mm to 110 mm causes a reduction in the received signal of 32%. A small pebble on the surface of a test area can clearly cause significant variation in the results depending on whether operators touch the pebble and push it aside or raise the detector over it.

The margin-of-detection parameter attempts to give a readily understandable result for a wide variety of targets. It can be evaluated by presenting a range of known targets to the detector under controlled conditions. Extrapolation of these results should give an acceptable estimate of the limits of the performance of the detector under ideal conditions. The performance of a known detector in the field can then be used to define the effect of the field conditions using the ratio of margin of detection. For example, a soil with a high metal ore content (e.g. laterite) might be considered three times more difficult for detection using a metal detector than a sandy soil, or dry sand might be considered three times more difficult for a radar

Ratio of the power of the signal to the power of the background noise	Ratio expressed as decibels (dB)
100 000	+50
10 000	+40
1 000	+30
100	+20
50	+17
20	+13
10	+10
2	+3
1	0
0,5	-3
0,1	-10
0,01	-20

Table 3: **Power ratios expressed as decibels (dB).**

system than moist soil.

These ratios may be conveniently expressed in decibels (dB) which are defined as $10 \times log_{10}(ratio)$. Table 3 gives decibel values for some ratios of the strength of the signal to that of the background, measured from the power of each.

In practice, an easy-to-detect target might be defined as 45 dB above background, and a difficult to detect target perhaps 5 dB above background using a standard mine detection system. A different detector that is being evaluated could then be measured and might perhaps give figures of 40 dB for the first and 6 dB for the second; this detector is more capable of finding the smaller target. Such ratiometric measurements allow direct comparison with existing “reference” equipment with which deminers are familiar, thus producing numbers with an immediate practical application.

Similarly, by inserting a standard target to a known depth, field conditions can be measured. A standard target might be described as producing, for example, a level 3dB above background in a particular area, whereas it is known to produce 5 dB above background under “standard conditions”. This area thus has a background level 2 dB worse than standard conditions; the impact of this on the maximum depth of detection of small targets can be directly calculated. As most demining organisations check the operation of equipment at regular intervals against known targets this operation adds little extra effort to the work of demining.

6.1 Application of “margin of detection” to QA

When applied to quality assurance the concept of margin of detection has considerable appeal as it provides a working check on both the equipment and its operation.

If the depth of a target, either a mine/UXO or an unwanted alarm is known then the margin of detection can be used to provide a measure of the level of confidence of finding another similar target at the required depth of clearance in the same soil. If, in the case of a metal detector, the target is a small piece of scrap metal that is excavated, it can be compared to an objective detection performance in air by measuring the margin of detection for the object at a known distance. This can be readily measured by dropping the scrap metal into a plastic container of known depth and placing the metal detector on top of the container. For example, if a particular target gives a margin of detection of 10 dB under the test conditions and was found at a particular depth then predicting the probability of detection of known minimum metal mines at a similar depth should be possible. Many of the factors that affect detector performance at the particular site can be combined into a single measure by following such a procedure.

By maintaining a record of all items found and the corresponding margin of detection, the performance of the equipment and operator can be continuously evaluated and a statistically meaningful quality assurance may be possible.

6.2 Use of unwanted alarms and margin of detection to enhance QA

Quality assurance could be immediately enhanced by introducing a simplified form of measurement of the margin of detection. This can be directly implemented with existing detectors. In terms of metal detection, small metal fragments can be characterised after excavation by the distance at which they can be detected in air; this gives a simple measure of their "detectability," and depends on their size, shape and composition. If the depth at which they were detected in the soil is noted, the limits of detection for the particular combination of soil, mine detector and operator can be approximately categorised. From this simple analysis it is possible to verify that a target similar to a minimum-metal mine would be found at a depth that would give adequate safe clearance of all mines. Research into this method should be able to determine if a rule of thumb that is easily memorised can be deduced, or a simple tool based on a nomogram developed. Simple categories that can be readily coded as "acceptable'," "marginal," and "unacceptable" could be used, with appropriate colours or symbols.

Overall, measurement of the margin of detection is a simple and powerful tool that could be applied to both detector evaluation and quality assurance methods in demining.

7 Summary and conclusions

Producing useful results from the evaluation of mine detection systems is surprisingly difficult; testing prototype equipment of unproven reliability in live areas may be hazardous, and testing in safe areas offers limited realism.

The provision of tests of sufficient size to give a statistically meaningful outcome is difficult and the impact of the test conditions and operator training may dominate the results.

Measurement of the crude detection rate of mine detectors in realistically sized trials fails to offer meaningful information on their performance. This paper presents a rigorous statistical analysis that demonstrates this, using a clear conceptual model.

An alternative to quoting *probability of detection*, p_D, and *confidence in the result*, (1-α), data separately is suggested and examined. Combining these two aspects of the result by using the value of p_D that is numerically equal to (1-α) provides a simple way of expressing the two crucial measures of a test result in a single figure, and permits a simple and direct comparison between different tests.

The large impact of qualitative factors such as the effects of the environment and the operator are discussed, and the need for test methods that are not highly dependent on these factors is explained. This is particularly important when using crude detection rate data.

The problem of achieving a statistically significant method of quality assurance after demining is examined and found to be so severe that such post-clearance QA is infeasible.

The concept of "margin of detection" is offered as a potential way to resolve some of these problems. Its advantages and implementation are discussed in relation to both testing mine detectors, and QA during clearance. Simple ways of implementing a crude form of margin of detection that are compatible with existing equipment and operating procedures are outlined, and the need for further research into possible ways of implementing the concept identified.

School of Engineering, University of Warwick

CONTENTS

Appendices

DEFINITIONS, ABBREVIATIONS & COSTING UNITS

A = area of roof (in m^2)

C = cost per litre

D = daily demand (not necessarily constant through the year)

DRWH = domestic roofwater harvesting

Dry season = all days when total runoff in the preceding 14 days < 7 R

E = W / (P x A x F) = efficiency of rainfall capture

F = 'Run-off fraction' = Water volume reaching the downpipe ÷ volume falling on roof (e.g. .85)

K = ratio of dry season water value per litre to wet season value

lpcd = litres per capita per day

P = annual precipitation (in mm)

Q = rainwater harvested (in litres per day per household)

R = P x A x F / 365 = mean daily runoff

RWH = Rainwater Harvesting or Roofwater Harvesting

S = 'security' of supply = fraction of days demand is satisfied

Sf = W ÷ ΣD = fraction of demand volume that is satisfied

T = V ÷ R = tank volume expressed in 'days mean supply'

Target Area = S Uganda, NW Tanzania & Rwanda

U = W ÷ V = utilisation factor for storage (in number per year)

V = volume of tank (in litres)

VLC = very-low-cost (say <$50 per system)

W = annual water supply volume obtained from RWH system (in litres per year)

Wet season = all days when total runoff in the preceding 14 days exceeded 7 R

Costing has been expressed in £ sterling (or in pence sterling 1p = £0.01). At the time of the study the approximate conversion rates into the three local currencies were:

£1.00 ≡ USh.2250/- ≡ TSh.1190/- ≡ RWF540 ≡ $US1.50

1. INTRODUCTION

Although numerous new water supplies have been constructed in rural Africa in the last decade, population growth has resulted in only a small projected increase in the fraction (32% to ca 36%) (WHO/UNICEF,1996/2000) of households having ‘access to adequate quantities of safe water’. Moreover official statistics are based on understandings of the words ‘access’, ‘adequate’ and ‘safe’ that seem inappropriate to rural Africa. ‘Adequate’ is taken to mean over 20 litres per person per day (lcd) and ‘access’ is taken to mean a water source within 1 kilometre of the home. Actually 20 lcd is well above current usage and immediate aspirations; it is quite incompatible with a carrying distance as long as 1 km. Collecting even only 10 lcd for a household with 6 members requires 3 round trips per day. If the source were 1 km away, this would take at least 2 woman-hours per day (collection is predominantly by women and children). “Water equals walking” has long been an accurate adage in rural Africa. It will be decades before point sources like wells or standpipes are sufficiently numerous, and hence close-spaced, that walking for water is no longer a major household burden. Yet most water programmes are still solely concerned with providing new point sources, often using techniques that have proven operationally unsustainable.

In recent years rainwater harvesting, for long an informal water technology (Agarwal, 1999) has been acquiring a higher official status world-wide. Its main domestic form, *roof*water harvesting (DRWH), has been aided by the rapid growth in the use of hard roofing (usually corrugated iron sheeting) in areas formerly dependent on grass roofing. DRWH has thereby become feasible in most of Sub-Saharan Africa. It is a technique with the great attraction of delivering water to the very door of the user’s house. Its main perceived disadvantages are its high cost and its individual nature. The former however only applies to some forms of DRWH, not all, and the latter’s unattractiveness to promotional agencies like NGOs is diminishing as they lessen their former overwhelming emphasis on *group* enterprise.

The Target Area (see map in Appendix III) of this Feasibility Study is technically favourable for very low cost DRWH, by reason of its good rainfall and convenient rainfall distribution. Even so, DRWH is likely to be affordable only when it is combined with some other ‘back-up’ source. Fortunately multiple sourcing can be shown to be already a common rural water practice across much of the tropics. The Target Area has characteristics that make existing water sources rather unsatisfactory. Its poverty means that clean sources are few in number. Its topology results in a paucity of perennial streams and springs and arduous carrying conditions in most places. The water table is commonly deep except near swamps (where dwellings are understandably sparse) and in some areas the ground water is so mineralised that it is dangerous to ingest or objectionable in taste.

In association with local organisations in Africa and tropical Asia, the Development Technology Unit at the University of Warwick has been researching DRWH systems for some years, looking for better understanding, lower costs and higher performance. It has found that DRWH development has reached a point where ‘partial’ DRWH systems could be affordable by the bulk of rural households in the Target Area. Such systems would typically increase a household’s annual water consumption by 50% while reducing its water-fetching time by 70% - at a cost as low as $\$40_{US}$ which equals about half the cost of roofing a small house. We may call this form of RWH ‘very-low-cost’ roofwater harvesting (VLC DRWH).

A Study – financed jointly by the Laing Trust and by the University of Warwick – was therefore initiated in May 2000 to evaluate its apparent promise, in an area where rainwater currently providing under 2% of household water because it is largely restricted to expensive forms. The purpose of the study was to confirm or rebut the apparent promise of VLC DRWH, examining both its performance and its unsubsidised affordability by the bulk of rural households.

The form of the three-month study, whose headquarters were an organic farming training centre, Kyera Farm, near Mbarara in southern Uganda, was;

(a) to field-test and refine candidate VLC DRWH technologies, and

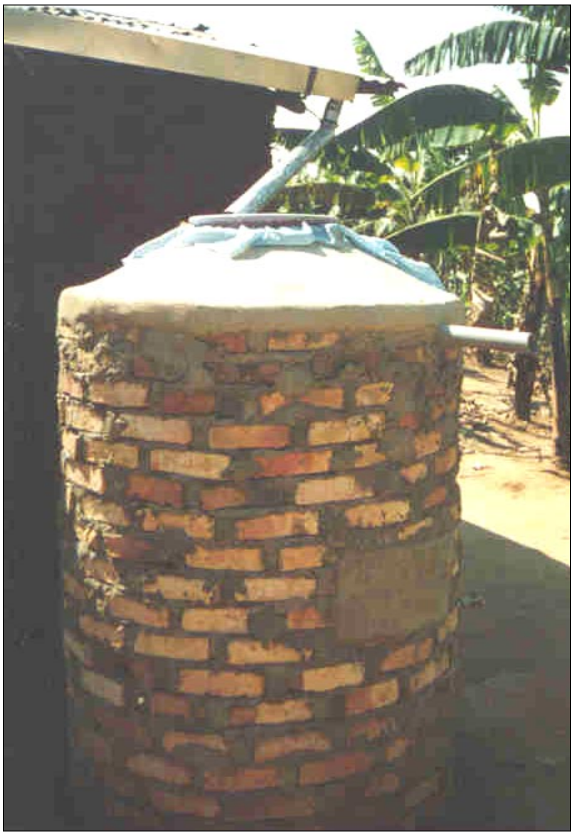
(b) to interact with 9 agencies already involved or interested in RWH in the target area.

At a concluding seminar in July 2000, the findings were presented to all these parties for their information and comment. The Study was intended not only to assess the desirability of switching to much smaller DRWH designs than used hitherto, but also to prepare for a major programme with such agencies to kick-start the adoption of VLC DRWH in the region.

In the ensuing sections technical, economic and social analyses are presented, backed by appendices containing more detailed data such as design drawings of novel system components.

The DTU team of three are very appreciative of the financial support of the two Study funders (Laing Trust and The University of Warwick), the energetic input from local staff in Uganda and the unstinting collaboration of the partner agencies in Southern Uganda, Rwanda and NW Tanzania.

2. THE CANDIDATE TECHNOLOGY (VLC-DRWH)



A roofwater harvesting system comprises a roof, a storage tank and a means such as guttering of connecting the one to the other. Other possible components are filters or ‘first-flush’ diverters to reduce the quantity of dust or debris entering the tank, access points for cleaning, a means of extracting water from the tank and in-tank devices to aid water management or to maximise water quality.

The most costly system element is usually the store (tank), which in a ‘stand-alone’ system may be designed to hold all the water required throughout the longest expected dry season. Middle class households in the *humid* tropics might have upwards of 10000 litres of storage, while in a Monsoon (summer rains) climate storage may be two times larger. Such large structures are expensive unless use can be made of some natural rock foundation. Underground stores are less space-consuming and are generally cheaper, volume for volume, than surface mounted stores; however the former need a pump and are prone to failure modes that are difficult either to calculate or monitor.

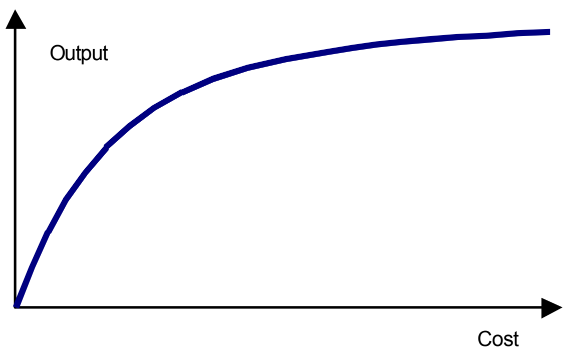
The quality of the collected water is usually quite high although it drops following the arrival of the first rains after a dry season due to dust on roofs. Bird droppings and other contamination may cause a sharp temporary rise in such pollution measures as counts of faecal coliforms. In rural areas it is thought that contamination by human pathogens is uncommon - 30% of farmers have long drunk roofwater in Australia, a country with high environmental health standards - but untreated roofwater does not reach the strict standards used for urban supplies in industrialised countries. Besides bacterial quality, there are other health and taste factors affecting DRWH and these are discussed in Section 6.

A striking feature of DRWH systems is the strong law of diminishing returns that operates for tank sizing. As the graph below shows, a system containing a very small tank (holding only 7 day’s household consumption) might yield 75% of the water per year of a system with a very large tank (capable of holding 100 days’ consumption). This suggests a route to cost minimisation, provided that an alternative, albeit more costly per litre, alternative back-up water source is available. In rural areas such a back-up supply is likely to be the distant spring, well or pond formerly used.

Besides keeping tanks very small, economy measures in LDCs include constructing tanks more efficiently, using cheaper materials, devising slimmer gutters and downpipes, substituting low-cost local labour for more capital-intensive production and devising management strategies that minimise the cost:benefit ratio. These matters are discussed in Section 4.

Currently DRWH systems in developing countries commonly use, for their storage element, mortar jars, ferrocement jars, cylinders and cuboid shapes of plastered brick, oil drums and corrugated iron cylinders, reinforced concrete tanks or (for richer households) plastic drums. Usually these are not tightly designed and have failure safety factors that are uneconomically high. (Very large tanks however need and get engineering design, as their failure can be dramatic and dangerous.) There is therefore considerable scope for material savings. Little-used materials of promise are stabilised earth, plastic sheets and the ground itself, especially if designs separate the functions of strength and water-tightness. Prior to this Study the DTU had identified three promising designs for small stores (500-800 litres) as well as a large (8000 litre), but relatively low-cost, 'partly-underground' tank, with associated village-manufacturable pumps. It was estimated prior to the Study that complete systems containing 750 litres (ca '7 days') of storage might be producible in the Target Area for $\$40_{US}$ and 2000 litre systems could cost under $\$80_{US}$. These estimates took into account the high prices of items like cement in the Area. Field-testing and construction were needed to confirm these estimates and affordability studies focussed on identifying what figure to design to.

Figure 2.1: 'Diminishing returns' Output v Cost curve



Fortunately DRWH is amenable to 'staged' construction, with guttering and storage being increased in steps over several years. In Thailand and Cambodia it is common to see a house surrounded by several large, mortar, rainwater jars - presumably not all installed at the same time.

Development agencies are understandably nervous of involvement with technologies having a bias to the rich, and DRWH has been accused of that tendency. Concentrating on small systems is one way of counteracting that danger. Developing the ability to service the grass roofs of the poorest would be another. Water can be collected from crude thatch, but it is coloured and turbid and its capture requires wide gutters. There are some directions for possible progress, including clarifying the stored water and employing sheet-plastic gutters. For the Study reported here, ability to work with grass roofs was decided to be desirable but not essential if the fraction of homesteads with hard roofs were found to exceed 70% and to be still rising. In fact the fraction of homesteads in the Target Area with at least one hard roof does generally satisfy this test: the prevalence of iron roofs in particular has risen dramatically in the last decade.

3. WATER NEEDS IN THE REGION AND THE POSSIBLE CONTRIBUTION OF VLC DRWH

3.1. Existing water sources and collection times

Data on water sources in the Target Area is not very readily available. In Rwanda there is a national register of springs. In Uganda the 1991 census recorded some relevant data from which the following tables for (old) Mbarara District, whose population was then 0.9 million people, were constructed.

Table 3.1: Use of different water sources in Mbarara District

Source type	Percentage of households using
Piped water	3.3
Boreholes	5.5
Protected well/spring	8.6
Open well/spring	45.2
Stream/river	19.6
Lake/pond/dam	17.4
Total 'clean'	**17.5**

Source: Uganda Nat Census (1991)

Table 3.2: Distribution of roofing types in Mbarara District

Roofing type	Percentage of households using
Iron	37.2
Tile/asbestos/concrete	0.7
Total 'hard' roofs	**37.9**
Grass/papyrus	39.2
Banana	22.9
Total 'soft' roofs	**62.1**

Source: Uganda Nat Census (1991)

Since 1991 however, Uganda has undergone significant economic and demographic growth and there has been some improvement in the fraction of households using such 'clean' sources as protected springs, protected shallow wells and boreholes. Piped water supplies in the few serviced urban areas have also improved. Nationally the fraction of the population having 'access' to clean water in 1994 was deemed to be 47% for urban areas and 32% for rural areas. Figures for Tanzania and Rwanda have not been obtained, neither country is listed in the source below. However the source suggests that for Africa as a whole clean water coverage has changed little from 54% over the last decade.

(Source: WHO/WSSCC/UNICEF http://www.thewaterpage.com/coverage_figures.htm)

Locally in the Study Area there are areas like Rakai District where highly mineralised groundwater forces reliance on surface sources such as swamps.

The Ugandan building data above is seriously 'out of date'. It indicates that only 38% of roofs as being suitable for RWH whereas the proportion of dwellings for which at least one building has a hard roof is now probably over 65%. None of the 12 NGOs contacted, all working in DRWH, felt that absence of hard roofs was a serious restriction in the uptake of the technology. Corrugated iron roofs, that cost about £1 per m^2 of building plan area, have become the norm for both housing and institutional buildings.

Rwanda is characterised by very steep but not mountainous terrain. In much of the country hillside springs have been the traditional water sources, augmented in the 1970s and 1980s by gravity-fed distribution piping. However since 1990 a growing fraction of the population may be found living considerably *above* the spring line and are carrying their water up through considerable heights. In the drier and flatter parts of the country to the East where springs are few, former National Park land has been recently settled by returned refugees. Rwanda was well-known for its attractive fired-tile roofing, today however cheaper corrugated iron has gained in popularity there.

In Tanzania the Target Area comprises Kagera Region, which is much wetter than the national average and thus more prone to have hard roofing. The terrain is less steep than in neighbouring Rwanda and good springs are far less common. Piped water is rarely encountered and shallow wells (some protected, some not) are widely used. The area is very 'peripheral', being 3 days journey from the capital, so material prices are relatively high.

Figure 3.1: A typical traditional water source in NW Tanzania

In all three countries, water collection distances are significant and the terrain is rarely flat. A survey of (only) 120 households in parts of the area is summarised in Table 3.3. From the table it can be seen that it took about 3 hours per household per day to collect water. These figures were based on a mean round trip speed *on the flat* of 65 meters/minute and lower speeds on slopes. This norm may be rather high although it is compatible with the few direct speed measurements made. Queuing time is not included and if it were collection times might be about 25% higher.

In some well-populated plateau locations, water collection in the dry months is especially onerous because convenient sources dry up. Water then has to be hauled up from valley sources as much as 5 km from (and 200 m lower than) the homestead.

3.2. A survey of small-scale RWH systems in Kabarole District, Western Uganda

A survey being carried out in Kabarole district, Western Uganda, gives some idea of the benefits that can be obtained using a small tank. The survey covers 6 households distributed around the district. To date the data for the months of May, June and July 2000 has been collected and analysed. The survey will continue for a further 3 months into the wet season. The survey analysis to date can be considered as a dry season analysis. The jars had been built as part of a study into water quality from cement jars and were 400 – 500 litres in size (the variation due to manufacturing variability).

Table 3.4 shows the initial analysis of the survey data. It is also worth pointing out that the survey form was designed to measure water carried from the traditional water source. The survey therefore measures the minimum benefit, as water consumption is likely to be higher when water is taken from the jar during the wet season.

Table 3.3: Analysis of water-collection distances/times

	Mbarara, Uganda	Biharum'lo Tanzania	Mbarara, Uganda	Karagwe*	Mbarara*	ALL
Agency	IVA	BRATIS	DTU	KARAD'A	MUST	
People (no)	210	385	175	381	359	1,510
Water (litres)	3,400	5,260	1,560	3,440	2,360	16,020
Households	40	60	20	60	60	240
Sources	2	3	3	3	3	12
Time (mins)	4,030	12,639	7,209	12,929	11,250	53,464
Distance (m)	207,300	725,894	640,364	789,739	415,580	2,586,768
Notes				*December	*November	

Averages for all households/people

people per H/H	number	6.3
water per H/H	litres/day	66.8
time per H/H	hour/day	3.7
distance per H/H	km/day	10.8
water per person	lcd	10.6
time per person	hour/day	0.6
distance per person	km/day	1.7

It can be seen that the percentage coverage for the period looks quite low, only 35% to 57.5%. It should be noted, however, that the percentage of rainy days during the period (19% - dry season) is low compared with the annual average (35%) and so the annual coverage figures will be higher. Also it can be noted that where the number of persons in the household is low, the savings are greater (with the exception of Kaahwa).

An indication of the walking time and walking distance shows that particularly high savings can be made when the distance to the traditional source is high (Katenta and Kayula), or where lpcd consumption is high (Mugisa) which is obvious. The actual daily time and walking saving are very significant – 55 minutes and 125 minutes being the outstanding examples.

It is interesting to note that there is no strong correlation between distance walked and lpcd consumed, which is generally believed to be the case. The lpcd figures do correlate well with estimated consumption figures for the region and with observations made by the authors

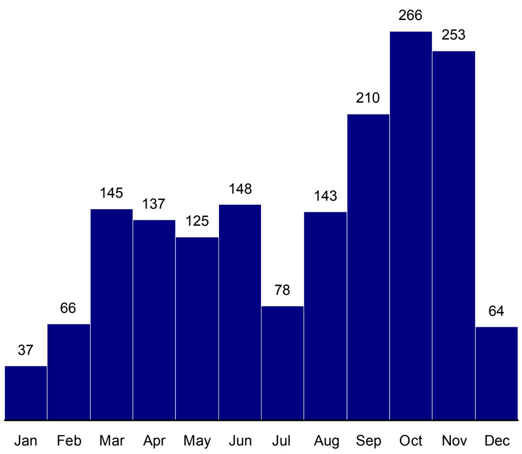


Figure 3.2: Average monthly rainfall for Kyenjojo, Kabarole, Uganda

Table 3.4: Analysis of survey data

		Kandole	Katenta	Mugisa	Kaahwa	Karamagi	Kayula
General data	Distance to source (m)	200	500	400	400	300	1500
	Number of occupants	6	5	4.5	4	9	8
	Roof area (m sq)	20	27	24	22	24	30
	Total days considered	106	106	92	85	92	106
	Rainy days during period	15	28	20	11	21	18
Calculated data	Jerry cans carried from source (daily average)	3.4	1.3	2.5	2.2	3.2	3.3
	Jerry cans consumed (daily average)	5.4	3.0	5.3	3.0	4.9	5.0
	Average lpcd consumed	18.0	12.0	23.5	14.8	11.0	12.4
Estimated savings	Litres (daily average)	40.7	34.5	57.5	18.1	35.5	34.8
	kilometres walking (daily average)	0.81	1.73	2.30	0.73	1.07	5.21
	Minutes walking (daily average)*	19.5	41.4	55.2	17.4	25.6	125.1
	%age total water consumed	37.7	57.5	54.3	30.6	35.9	34.9

*assuming a walking speed of 2.5kms per hour – in the majority of cases the terrain is steep

4. ECONOMICS OF DRWH

4.1. Economic overview

All households already have some access to water from point sources. For some days per year, many also employ 'informal' rainwater harvesting, placing bowls and jugs under eaves or even trees during rainfall.

The introduction of more formal (and productive) RWH will normally be accompanied by three benefits. The most obvious is a reduction in the time spent carrying water from point sources – a reduction more or less proportional to the volume of water no longer carried. The second is an increase in household water consumption wherever it was previously constrained by the effort of collection. The third is a common, although not invariable, increase in water quality. All these benefits rise with DRWH storage capacity, albeit in a way showing diminishing returns.

Figure 4.1: Typical informal RWH using an old 200 litre oil drum at a household in SW Uganda

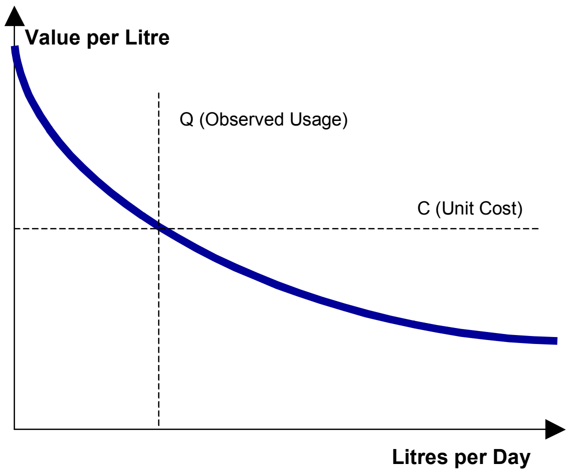
The increase in water consumption with VLC RWH has not been widely measured. Generally any increase is restricted to the wet seasons. DRWH (and VLC DRWH in particular) is not generally capable in the dry seasons of supplying quantities larger than already obtained from point sources: this means that it will be used to supplement, but not to substitute point-source water.

The costs of DRWH are overwhelmingly capital costs, as neither operation nor maintenance usually involves significant expenditure. Storage-tank cost is usually the dominant item, by contrast guttering accounts for only about 25% of the total system cost. These capital costs are subject to economies of scale. The sensitivity (elasticity) of tank cost to storage capacity is about 0.8. The sensitivity of gutter cost to gutter capacity is even lower, so that it is usual to install gutters that are so large (e.g. designed for rainfall intensities up to 2mm per minute) that they can catch all but 1 or 2% of the annual run-off reaching them.

4.2. Value of water

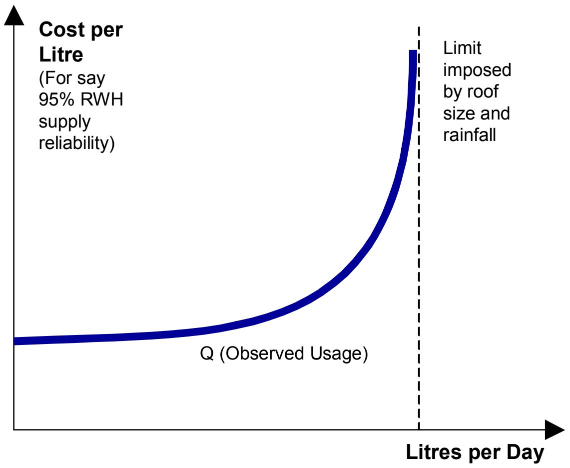
As with many other goods, water has a declining value with quantity. The first litre per day is worth more than the tenth. By examining the limited data available that relates household consumption per day to the effective unit cost of water (i.e. cost per litre), we might construct a curve such as shown in Figure 4.2. Each socio-economic group would have its own curve.

Figure 4.2: value v quantity



The cost line on Figure 4.2 is horizontal, which reasonably represents the situation where water is fetched, each successive litre requiring the same input of labour. Such a line does not fairly represent harvested roofwater, where the effective cost general rises with daily consumption despite the economies of scale in tank construction. A typical cost v volume characteristic for RWH supply is shown in Figure 4.3.

Figure 4.3: cost v volume



Sometimes we can find examples of water purchase and use them to infer the value of water. Richer households, or those experiencing illness, may pay for water to be brought to the house. More usually we have to infer costs indirectly through conversion of fetching distance/height into time and then time into money. Such costs, like the value of water discussed above, will be lower for poorer households than for richer ones.

4.3. Time cost of water carriage

This is a function of a household's distance to, and height above, a water source, of the means of transport used, and of the persons involved in carriage and their respective unit time costs (actual or opportunity). So we will examine each of these factors in turn.

(a) Haulage distance

Table 3.3 shows the results of a small survey of walking distances (users of 6 sources). Although there are some homesteads in the Study Area that haul water from distances greater than 5 km away in very dry months, the dry season average for 120 users of 6 point sources in the Target Area was 1.5 km to the source.

A much larger survey is required to give reliable averages for the whole Area and to measure the seasonal variation of haulage distance, walk time and water consumption.

(b) Height

Point water sources are generally *lower* than homes, so that the laden return journey is usually uphill. A round trip that comprises walking downhill with an empty water container and returning laden uphill is always slower than one of the same distance on the flat. For calculation purposes it would be convenient either to replace any climb height by an extra horizontal distance of equivalent carriage time, e.g. "add 1 km for every 100 m climb". Alternatively we might assign a different round-trip mean speed for each gradient. It is likely that a very steep (return) uphill slope of say 1-in-5 will halve the round-trip mean speed, especially for climbs exceeding 100m. A gentle gradient of say 1-in-30 will have little effect on round trip time. Experiments were undertaken to measure the effect of gradient on walking speed, but they gave rather inconclusive data because the samples were small and it proved impractical to control other variables such as youths' desire to impress, sense of urgency or tiredness etc.

(c) Walking speed

The speed of movement of a person collecting water depends upon many factors and varies between about 1.5 and 5 km/hour.

For short haulage distances some people use a strategy of hurrying to minimise time or arm strain; this strategy cannot be maintained for more than about 200m. Running down a gentle slope with an empty jerrycan, some young people exceed even 5km/hour. Conversely, long uphill hauls require a slow steady pace with regular rests. Young children tire more quickly with distance than adults, even though they usually carry only 3 or 5 litre loads.

For distances over 1.5 km but only where slopes are gentle, pushed or pedalled bicycles are sometimes used to carry 1 or 2 x 20 litre jerrycans (especially by 'commercial' water fetchers) at speeds of about 3.5 km/hour. There is virtually no evidence of water carriage by pack animal in the target area – neither mules nor donkeys are commonly available. Such animals have to be driven slowly (3 km hour) but carry up to 80 litres at a time (recent Mexican experience).

Table 4.1: Survey of variation of walking speed with path steepness

Route No		1	1	2	2	3	3	3	4	5	6
Slope when carrying water		flat	flat	easy down	easy up	med up	med up	med up	steep up	med up	med up
Date	d/m/2000	16-7	16-7	16-7	16-7	16-7	16-7	16-7	8-8	8-8	8-8
Slope angle (up) source-to-house	Degrees	0	0	-5	5	11.5	11.5	11.5	14.2	7.6	9.5

Notes:

a. 'easy' slope = 3% to 10%, 'medium' slope = 10% to 20%, 'steep' slope = >20%

b. NK = not known

c. Men walked faster than the females during some of the early trials but were slower on the later trials. The "macho" image may be the reason for the early trials being at faster rate. The slower rates on the later trials may be due to the fact that the men did not pace themselves, having less experience than the females in carrying water.

d. The considerably slower rates on route No4 of 29.7 may be partly explained by the fact that the actual route was longer than 740m as the path meandered its way through the plantations. Also negotiating the rough ground on the way down tended to impede ones progress.

e. There are many factors which could give rise to data varying, some of which may be:
   - Whether the person is aware of being timed or not a (10% increase in the walking speed maybe a reasonable value when the person is aware of being observed)
   - The number of people queuing at the water source
   - The number and length of rests a person takes
   - The flow rate of water at the source (this decreases during drought periods)
   - Who is performing the task, i.e. children are prone to the least distraction whereas a women may walk quickly to get back to other household chores
   - Tiredness of the person

(d) The carrier's age, gender and urgency

Water is most commonly carried by women and therefore by (in Africa) busy people. Babies may be left behind (a reason to increase speed) or may be carried (which reduces speed). Women often carry together, waiting at the source until a friend has filled her container. School children regularly carry water (more often girls than boys) especially at weekends. They are usually in less hurry than adults and more prone to combine water collecting with 'social' activities. There has been some recent discussion of the (moral/AIDS) danger to teenage girls of going alone to fetch water at dawn or dusk, which might lead to parental pressure on them not to loiter en route. In dry periods when distances are greater, men play a larger role in water fetching and probably travel a little faster than women. However, even strong men do not carry two jerrycans over any significant distance – the adult unit of water carriage is largely standardised at 20 litres (= 20kg).

(e) Total time and time cost

The table above indicates a mean time for water collection of 3 hours per household per day. Insofar as the survey was small and the month was dry, this can only be taken as a crude estimate. It is perhaps an over-estimate in that none of the households surveyed were in trading posts or other population concentrations. However the figure is only an inferred walking time and does not include waiting time. In the drier months it is not uncommon to see a queue of 20 jerrycans at a source yielding under 5 litres per minute, implying a waiting time there of 80 minutes. The queue rarely includes adults; women try to avoid such queues by fetching water before dawn, an expedient not without physical dangers (falls in the dark, snakebites etc.).

The opportunity cost of 3 hours per household is, in rural East Africa today, between $\$_{US}0.2$ and $\$_{US}0.6$. The payment to a youth in a trading post to carry four jerrycans (a typical quantity - see Table 3.3) from a source 1.5kms away is currently about $0.5.

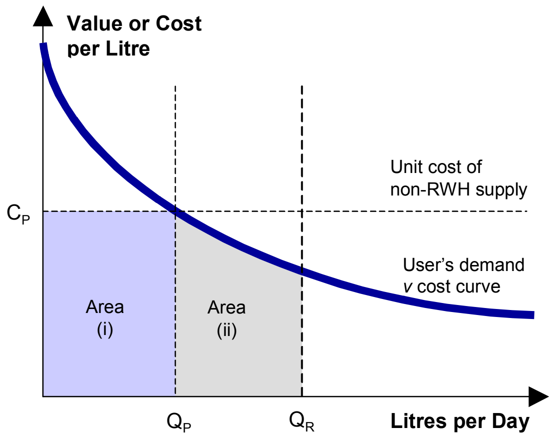
4.4. Combining RWH with other water sources

The following two Sections (4.4 & 4.5) are an in depth study of the economics of combining water sources (multi-sourcing) and the effect of using differing water management strategies on seasonal water security. Those who are looking for a brief overview can skip these sections.

For a given size and location of RWH system and for a given operating strategy, there will be a limit on the water it can supply per day, per week or per year. The maximum per year, corresponding to zero tank overflow, in litres will be the product of roof area (m^2), the annual rainfall (mm) and a run-off capture factor (typically 0.85).

Consider first the situation where we can disregard seasonal factors, and assume that before RWH arrived, daily consumption from a point source was Q_P (litres/day). Q_P is determined by the interaction of the user's demand (cost v volume) curve and the unit cost C_P of supply from the point source. The daily cost to the user was therefore Q_P x C_P.

Figure 4.4: Value of rainwater



If the water Q_R available per day from RWH is *less* than Q_P, then the users will draw Q_R from the RW system and the remainder Q_P-Q_R from the point source. The total consumption will not increase and the effective value of the harvested rainwater will be the saving Q_R x C_P .

If the water Q_R available per day from RWH is *more* than Q_P, then the users will increase their consumption from Q_P to Q_R and the rainwater will be worth more than the former total cost Q_P x C_P. Exactly how much more will depend on the user's demand curve. The situation is represented in the diagram below, where Area (i) is the saving (Q_P x C_P) while Area (ii) is the value of the extra water.

Note that Q_R is the daily amount *available* from RWH, whereas Q_P is determined by the price of supply (from non-RWH sources). The total value Area(i) + Area(ii)) is less than (Q_R x C_P) because the extra water is per litre less valuable to the user than the water 'replaced'.

4.5. Seasonal effects and water management strategies

In the last section we ignored seasonal effects, although one can identify the condition $Q_R<Q_P$ as representing a dry season and $Q_R>Q_P$ as representing a wet one. However seasonality is central to the operation and performance of a RWH system. A user can choose to emphasise dry season security or alternatively to emphasise roofwater capture. To some extent the dry and wet season water needs are in competition with each other. Consider the following four water management strategies for an already built RWH system.

To make the strategies easier to visualise, assume a scenario typical of a homestead in the Great Lakes region where mean daily roofwater runoff is R = 100 litres). Assume that 'dry' weeks (runoff less than 350 litres per week) comprise 1/3 of each year and that the RW storage capacity is 700 litres (7 x R or '1 week'). This storage is only modest, but corresponds to perhaps 50 days drinking water or 14 days total water under very careful management.

Strategy 1 – *High Water Capture* – Water is withdrawn at a high rate, Q = 1.5 R, (e.g. 150 litres/day under our scenario) whenever it is available. This will result in fairly low occurrence of tank overflow, but leave little reserve for dry weeks.

Strategy 2 – *High Security* – Water is withdrawn at a low rate, Q = 0.5 R, (e.g. 50 litre/day) whenever it is available. Much water will overflow the tank, so annual capture will be low.

Strategy 3 – *Adaptive* – Water is withdrawn at a rate Q determined by how much is in the tank, thus:

Q = 1.5 R (e.g. at 150 lpd) if tank > 2/3 full;

Q = R if tank < 2/3 but >1/3 full;

Q = 0.5 R, if tank < 1/3 full.

Strategy 4 – *Maximum Security* – Water is saved for the dry seasons and drawn frugally (e.g. 50 litres/day) *only* after nearby point sources have run dry or after 2 weeks without rain.

The trade-offs involved between these alternatives are summarised in the following table, in which the word 'security' is taken to mean the fraction of days the demand is met by RW (the tank does not run dry). The factor K is the dry-season value of water (valued at its cost from the nearest point source) divided by its wet season value. Thus K=1 represents places where point-source water is unvarying through the year, whereas the extreme value K=10 represents places where in the dry months all local sources dry up, so water must be queued for, then carried from, very far away. A typical value of K in the Target Area might be 2.

Table 4.2 suggests how we might account for seasonal differences in our economic evaluation, namely by assigning different wet and dry season values for water and operating the system to maximise their sum.

Table 4.3 represent the simulation of the four strategies applied to respectively a small DRWH system (storage volume V = 7 x mean daily run-off, R), a medium size system (V/R = 21) and a large system (V/R = 63). Data from Mbarara (daily rainfall for 10 years) has been used and a roof area of 45 m^2 has been selected to give the assumed mean run-off R = 100 litres/day. For Mbarara the dry season (defined by rain in the last fortnight being under 50% of mean fortnightly rainfall) is 36% of the year.

As well as water supplied (column 5), a 'weighted' water supplied column is shown alongside in which effectively K = 5. This yields the weighting (a 'wet season litre' is a cost-equivalent volume): 1.0 dry season litre is deemed to be worth 5.0 'wet season litres'

The **bold** columns in the table contain the performance measures of most interest.

Column 3 shows 'Capture efficiency', (*E*) – a high value indicates that most of the roof run-off is being consumed.

Column 8 shows 'Dry season water security', (S_d) – the fraction of dry season that tank does not run dry and so demand has been satisfied; note however that under Strategy 1 the dry season demand is maintained very high at 1.5 *R*, whereas the other strategies are using demand of only 0.5 *R* for the dry season.

Column 6 shows weighted annual water consumption, Q_5, which is a measure that attempts

Table 4.2 System Performance under Different Operating Strategies

Strategy No	Annual consumption	Relative value of annual water harvested		Wet season security	Dry season security
		if K=1	if K=10		
1	high	high	med	high	v. low
2	low	med	med	high	low
3	medium	low	v. low	high	low
4	very low	med	med	nil	med

to combine quantity, and security measures, by valuing wet season water much more highly than dry season water.

Examination of the top part of the table – which is for a VLC system with V/R only equal to 7 days – indicates that Strategy 1 (in which water is drawn generously whenever available) gives the highest annual water yield E, the lowest level of dry season security S_d, yet a high value for the seasonally-weighted yield W_e.

By contrast Strategy 4 (water is drawn sparingly and only in the dry season) gives the highest dry season security at the cost of the lowest annual yield. The seasonally-weighted yield is however also low. In fact we can dismiss Strategy 4 because even here, where per litre we have valued dry season water at *five times* wet season water, it still gives the lowest output valuation.

Table 4.3: Relating RWH system performance to operating strategy and storage volume

Strategy number / type	V/R	Capture Efficiency	Tank Utilisation	Mean daily consumption Q in litres		'Security' (*S*) = fraction of days demand is satisfied by roofwater		
	tank size days	*E*	*U*	*Q_1 K=1*	*Q_5 K=5*	*S_w* Wet	*S_d* Dry	All year
Small tank, VLC system								
1 High demand High capture	7	**0.70**[1]	36.5	70	**95**	0.75	**0.22**	0.56
2 Low demand High security	7	**0.41**[3]	21.4	41	**80**	na	**na**	na
3 Adaptive	7	**0.66**[2]	34.4	66	**93**	0.94	**0.38**	0.74
4 Max security in dry seas	7	**0.17**[4]	8.9	17	**84**	na	**0.52**	na
Medium size tank								
1	21	**0.91**	15.8	91	**125**	0.90	**0.25**	0.67
2	21	**0.47**	8.2	47	**107**	na	**na**	na
3	21	**0.86**	14.9	86	**138**	1.00	**0.66**	0.88
4	21	**0.26**	4.5	26	**128**	na	**0.73**	na
Large tank								
1	63	**1.00**[1=]	5.8	100	**165**	0.92	**0.38**	0.72
2	63	**0.51**[3]	3.0	51	**123**	na	**na**	na
3	63	**0.99**[1=]	5.7	99	**203**	1.00	**0.98**	0.99
4	63	**0.37**[4]	2.1	37	**182**	na	**1.00**	na

Notes:
1. Data is for Mbarara, Uganda
2. Annual run-off = annual demand
3. na indicates strategy does not allow demand to be met.
4. Highlighted cells indicate best strategy or within 3% of best
5. Strategy 1 gives best **Q_1** (highest water capture)
6. Strategy 3 gives best **Q_5** (highest benefit if K = 5)
7. Strategy 4 gives best **S_d** (highest dry season security)
8. Strategy 3 is always best or second best by all measures.

'Value' is calculated assuming first litre per day is worth 1.5 falling via 0.5 at the 100th litre to zero at the 150th litre

Strategy 1 is to withdraw 1.5 times base demand when available (and otherwise what is available)

Strategy 2 is to withdraw 0.5 times base demand when available (and otherwise what is available)

Strategy 3 is to withdraw 1.5, 1 or 0.5 times base demand, according to amount in tank

Strategy 4 is to withdraw nothing in wet season and in dry season base demand when available (and otherwise what is available).

Strategies 2 and 3 are intermediate in performance, with Strategy 3 (adaptable) generally outperforming Strategy 2 (fixed low-demand).

From this table we can conclude that unless dry season water has exceptional value – e.g. it is per litre worth more than the 5 times wet season water assumed in the table – Strategies 1 (high usage) and 3 (adaptive) are superior to the other strategies.

The bottom band of the table is for a much more expensive system with 9 times larger storage. With such a large tank, the relative superiority of Strategy 3 is increased. We also see the benefit of the larger store. Comparing say Strategy 3 for the very large tank with that for the small one, we find a 50% increase in water harvested (E), a nearly 4-fold increase in dry season security (S_d) and under the assumed value ratio (K=5) a 120% increase in water value. The graph below shows the variation in value of water harvested for varying values of K and for various sizes of tank. It confirms that VLC systems (V/R < 10 days) give a generally acceptable performance unless dry season water is deemed very much more valuable (e.g. K=5) than dry season water. Note the clear 'diminishing returns' with increase in tank size. If water value had been plotted against tank *cost* rather than tank *size*, the same pattern of diminishing returns would appear but with a slightly reduced strength.

A VLC system in the Target Area, attached to a $50m^2$ roof, might be expected to harvest around 25,000 litres of water per year (say 75% of run-off), averaging about 90 litres per day in the wettest 8 months and 30 litres per day in the driest 4 months.

Table 4.4**:** Performance under Strategy 3 – Table showing variation of value ratio, capture efficiency and security with tank size

	dry:wet value per litre	**Normalised tank size – V/R in days**								
		1	**3**	**5**	**7**	**14**	**21**	**30**	**60**	**90**
Benefit ratio = value of water harvested ÷ value water demanded	if K=1	0.29	0.49	0.60	**0.66**	0.79	0.86	0.91	0.98	1.00
	if K=2	0.24	0.40	0.49	**0.53**	0.65	0.72	0.79	0.90	0.94
	if K=5	0.18	0.30	0.35	**0.38**	0.48	0.56	0.65	0.82	0.88
Capture efficiency		0.39	0.66	0.76	**0.82**	0.90	0.93	0.95	0.99	1.00
Security		0.15	0.41	0.57	**0.67**	0.81	0.86	0.90	0.98	1.00

Notes:

1. Under this strategy the demand is varied from 0.5 to 1.5 times the mean daily runoff according to how much water remains in the tank
2. V/R is tank size (normalised to mean daily run-off); K is dry-to-wet season water value ratio; the bold column shows the performance of a typical very-low-cost RWH system

5. THE MANAGEMENT AND SOCIAL IMPACT OF DRWH – QUOTATIONS AND EXAMPLES

During the recent study in Uganda, information was gathered from communities regarding the social aspects of water collection and the impact of the RWH systems. The information is given in anecdotal form in the following examples. The experience with small scale RWH in Thailand is shared in Section 5.6

1.1. Children and water collection

Children collect water in containers of varying sizes. The containers used by the children vary from 3litres to 10litres for children below 8 years of age. Children above 8 - 10 years of age use larger containers and take on a more responsible role.

Where water is close to the house, say within one kilometre, children may be the sole collectors of water. When water sources are more distant, women will help the children. During the dry spells, the men may also help as the nearest water source may be 4kms or 5kms distant. Men tend to use bicycles, carts or donkeys for water collection.

Some children do not find water collection such a burden, as we see in the example below:

Moreen. Birere, a young girl from Rukungiri was asked how she spends her time.

> *"Our parents are very strict, the only time to let us out from home is, when going to school, church or collecting water. It's harder in the holidays. The only chance to meet friends is at the spring (water collection)"*

1.2. Sickness and water collection

The elderly and the sick tend to suffer disproportionately. This is due to the fact that the sick find it difficult to collect water and usually carry smaller quantities of water.

Timanya: An elderly women of (65yrs) in Kabale, Uganda.

> *"Water collection has become more of a problem than before in my life, I suffer from backache, all my grand children stay with their parents in turn, every day I collect 5 litres. At times children from the neighbours help me".*

1.3. Ranking of water sources

A ranking system is used by beneficiaries of RWH to determine the value of the captured rainwater. There are three main categories used for ranking water:

Ranking of sources by quality

Communities consider rainwater to be of high quality, hence other water sources are used where high quality is not an issue e.g. making mud for houses, mixing building mortar.

Ranking source by effort cost

For certain activities requiring large quantities of water, e.g. washing clothes or watering the animals, rainwater is not used. Usually people will take their clothes or animals to a water point for cleaning and watering as the effort involved in carrying the water is reduced greatly this way.

Ranking of sources by seasonal reliability

Communities vary their source of water depending on season. The closest available source is preferred, but sources that are used for cattle watering in the wet season may get priority for human consumption during the dry season.

1.4. Rainwater and water security

Householders consider RWH to be a water source that is supplemented by other sources. This has been an advantage in the dissemination of small rainwater tanks, as the beneficiaries see the tanks as a partial supply and their expectations are not too high.

Member of Rakai women's group:

> *"We know our jars are small, they cannot meet all our water demands, but we use the water sparingly, to prepare tea, drinking only after boiling".*

1.5. Rainwater management

Rainwater is managed in a number of ways. The main management strategies are listed here:

Maximum security

The water from the tank is not utilised not until all the possible water sources are completely depleted. In this case, in the rainy season, after the tank has been filled it is locked up. This has a disadvantage of not maximally using the water from the roofs; the tank is left to over flow.

Maximum capture

The tank is used as a water source throughout the rainy season. It keeps filling as the stored water is being utilised. However, there is a tendency of reducing the daily consumption as the dry season sets in.

1.6. Comparative experiences with small-scale RWH in Thailand

Rainwater harvesting is more widespread in Thailand than any other country in the world. More than 10 million 1000 to 2000 litre rainwater jars and hundreds of thousands of 6 – 12m^3 rainwater tanks were constructed between 1985 and 1992. Most of the households in north-eastern Thailand have at least one, and some have many, rainwater jars. The Thai RWH programme is considered to be one of the most successful examples of how potable water supplies can be increased on a national scale.

The rapid growth and success of the Thai programme was made possible by a combination of factors that may be relevant to other countries interested in developing broad, as well as limited scale, RWH programmes. Government commitment was very strong ad national objectives and targets were clearly defined, and there was popular support at all levels including NGO's, community based initiatives and the private sector. RWH is a long-standing tradition in Thailand and the annual rainfall is high relative to many other regions of the world, with a rainfall pattern favourable to RWH. The demand for improved water supplies in rural areas was tremendous, and this demand led to the emergence and growth of many independent jar making micro-enterprises. Thailand also experienced a period of national economic growth and an increase in private affluence during the life of the programme which made it easier for families to invest in RWH technologies. Funding came from a number of sources, including the well-established Rural Job Creation Project, the Provincial Development Fund, the Provincial Administrative Organisation, as well as the private sector and non-profit organisations.

Originally, the jar construction programme was to be financed by a revolving fund, using start-up money from the government. However, the programme expanded so rapidly that the administration of the funds could not keep up with demand and these funds were generally not used. Many districts provided construction materials, tools and training and people contributed labour to construct their own jars under the guidance of experienced technicians.

It was initially envisaged that villagers would construct their own jars, but as the programme evolved the private sector became very much involved in rain jar construction. Small jar making factories sprang up and developed into successful micro-enterprises in many provinces. The price of a 2m^3 jar in 1992 was US$40 and many of the village based companies were manufacturing up to 30 jars per day. Subsidised and affordable cement added to the favourable conditions.

Some of the early tank designs suffered form major problems. More than 50,000 bamboo reinforced tanks were constructed and these suffered from attacks by fungus, termites and bacteria. An interlocking block tank design was abandoned because the skill levels required were not suited to local conditions. The eventual design that was adopted by the Ministry of Health is a cement mortar jar that has a lid on the top to prevent contamination; a tap for easy access to water; and a drainage plug for easy cleaning. Commercially made jars often did not have these essential features. Numerous moulds have been used, including jute bags filled with rice husks, a 54 piece cement mould, and the star fruit (segmental) steel or cement mould. Larger jars of up to 3 – 5m^3 were also constructed for individual households with iron reinforcement. Thousands of larger tanks have also been constructed at schools, clinics, temples and private homes.

A major rainwater quality study, published in 1989, showed that only 40% of samples met the WHO guidelines for total bacterial count for drinking water. It was convincingly shown that much of the contamination came from secondary causes, such as poor water handling. Despite the problems found with the water quality, the study concluded that rainwater is still the safest and most economical source of drinking water available in most rural areas.

6. HEALTH ASPECTS

6.1. Health

Water relates to health in complex ways. It is conventional (Cairncross & Feacham 1993) to identify five types of water-related illness

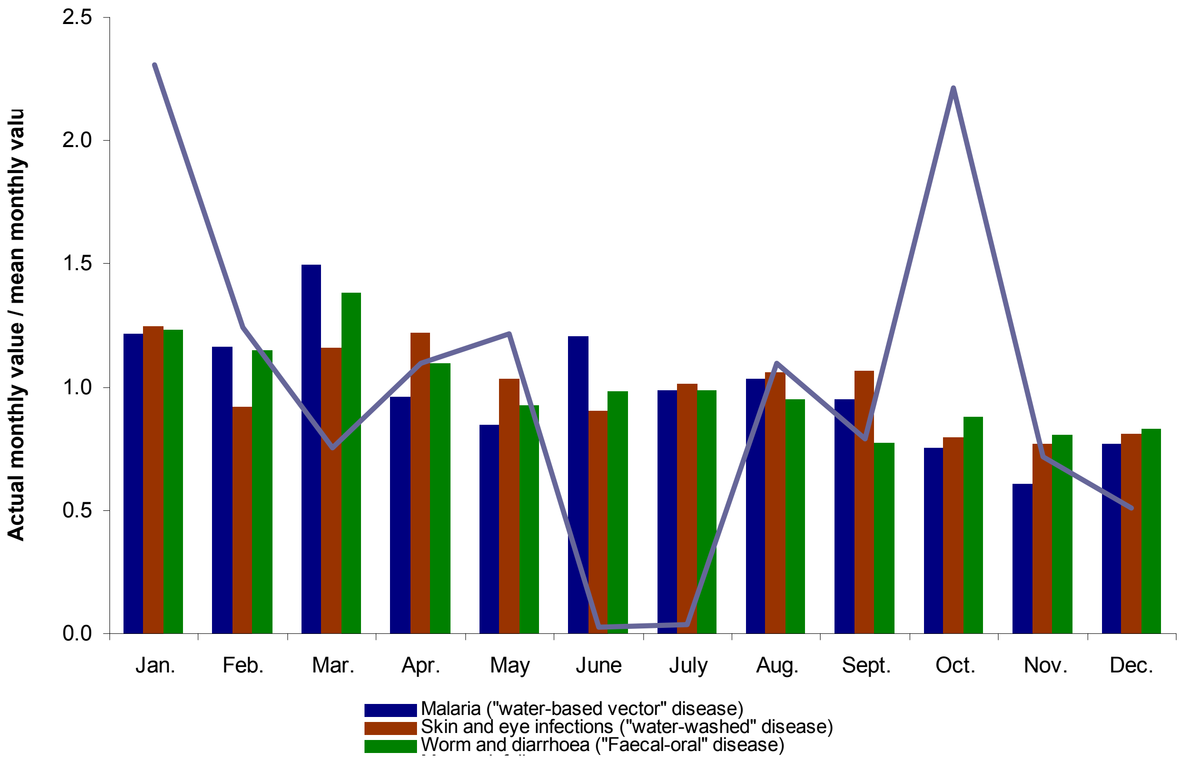
1. Water-born or faecal oral diseases caused by biologically contaminated water
2. Water-scarce or water-washed diseases, mainly skin and eye infections – however as water scarcity lowers hygiene standards, some diseases are both water-borne and water-washed.
3. Water-based diseases involving agents like bilharzia parasites that have an aquatic stage in their life cycle
4. Water-related (insect) vector diseases like all those carried by mosquitoes
5. Poisoning by substances dissolved in water.

Practically the introduction of DRWH might be expected to definitely reduce categories 3 and 5 diseases. Only where it increases water consumption might it reduce category 2 disease.

The impact of DRWH on category 1 disease depends on whether it is a bacterially cleaner or dirtier source than was used hitherto. The debate on RW quality is a complex one (Gould & Nissen Petersen Chap 6). Generally, RW stored in well-covered tanks is as clean as water carried to a house from even a very clean source and is certainly cleaner than water from swamps or streams. Conversely water from a RW tank containing drowned rats is unhealthy.

The impact of DRWH uptake on mosquito breeding has also been much, but not very conclusively, discussed. It is not easy to maintain effective anti-mosquito screening throughout the life of a water tank. So RWH might be expected to increase malaria, particularly during the dry seasons when other mosquito breeding sites are scarce. Conversely

Figure 6.1: Fluctuations of normalised malaria cases, skin+eye cases, worm+diarrhoea cases and rainfall for 1998



present water sources are often valley-bottom wells close to swamps. Queuing at these at dawn or dusk carries a high risk of being bitten by mosquitoes, a risk that DRWH should reduce.

In the absence of DRWH one might expect a fall in malarial cases and a rise in water-washed diseases during the drier months. Medical data was collected from Mbarara hospital and grouped to emphasise any such seasonal variations. Many thousands of cases were summarised. Skin+eye infections were taken to represent water-washed disease, worm+diarrhoea cases to represent water-borne disease and malaria to represent water-related insect vector disease. Figure AA below plots the normalised incidence of each disease group alongside rainfall for each month of 1998. Inspection of the bar chart does not confirm the seasonal relations forecast above. Indeed formal statistical analysis shows insignificant correlation between monthly variations in rainfall and any disease group ($R^2<0.5$). Against this background it is very hard to predict the health implications of any large increase in DRWH use.

Insofar as DRWH replaces water haulage by women and children, there are safety benefits associated with mothers not having to leave young children attended only by older ones (babies burnt in fires) and children not having to venture in lonely places before dawn or after dusk (an oft-expressed concern). A reduction of jar-carrying probably also reduces the incidence of arthritis and back injury. Falls are a danger during water carriage on steep slippery slopes during or soon after rains, so that being able to avoid trips at this time is particularly valued. East Africa does not generally have the sort of society where water-collecting gives women their only legitimate reason for leaving the home; even so a reduction in walking might slightly reduce social interactions.

Table 3.3 indicates a mean daily water consumption of about 10 litres per capita. This figure was confirmed by a small survey in Kabarole District and thought to be representative by officers of local water NGOs. The WHO recommended minimum is 20 lcd but this figure is rarely reached where water has to be hauled for significant distances. A generation ago Bradley and White (1972) explored in *Drawers of Water* the influence of haulage distance and family size on per-capita consumption of water drawn from point sources in East Africa. Their study is reportedly being currently updated under a project named *Drawers of Water II,* but no data could be obtained from that source for this study.

Lastly come the issues of reduced exhaustion, better nutrition and the use of released time, all of which have a difficult-to-quantify health impact.

Qualitative evidence from Rwanda indicates no change in malaria morbidity with DRWH introduction.

Other 1991 census evidence from Uganda, shown here, suggests that Districts within the Target Area having better access to safe water do broadly have a lower infant mortality rate. However the definition of access is a very broad one. Kabale and Rukungiri Districts are very hilly so water carriage there is especially onerous.

6.2. Findings from a recent study into water quality in DRWH systems

A study was carried out recently at the Indian Institute of Technology in Delhi, India, to determine the quality of rainwater from domestic rainwater harvesting systems. The major conclusions reached

Table 6.1: Health data from the Target Area

District	Infant mortality	Access to clean water	Population in 1991	Population density
Units	per live birth	%	1000	Persons/km^2

Source: 1991 Uganda Census

are as follows:

1. Generally, the physico-chemical quality of water in terms of colour, odour and taste, pH, total dissolved solids (TDS) and total hardness (TH), meet the prescribed standards. Occasionally pH has been reported to be low (acidic) or high (alkaline).

2. Toxic metal ions and toxic chemicals are reported only in rare cases and may arise from material used for the roof or atmospheric pollutants adsorbed on dust.

3. Most of the material used for storage tanks e.g. cement, iron, wood and plastics do not negatively affect the physico-chemical quality, with a few exceptions.

4. The physico-chemical parameters can be tested easily by using available field kits.

5. The main problem with the quality of stored water in DRWH lies with its bacteriological quality. The following are the main issues:

    - Dust from the soil, and droppings of birds and animals can also be the source of contamination by the above bacteria.

    - In any case where first flush eliminating devices are absent, all the indicator bacteria are generally present in water samples in numbers beyond what is acceptable by any standards. Higher temperature reached by a metallic roof due to solar heating may lead to reduction in bacteria.

    - From the health point of view it is important to clean the gutter from time to time and ensure that water does not stagnate. This leads mosquito breeding.

    - Tree hanging in the vicinity, definitely enhances the possibility of contamination due to increased access of the roof to birds and animals.

    - On storage, generally due to limitation of nutrients, bacterial count falls. Different indicator bacteria under study decay over 7-20 days depending on the initial amount of bacteria, nutrient availability and other storage conditions.

    - Increase of temperature due to sun's heat or exposure to UV radiation of sun, reduces and ultimately eliminates bacteria. However, exposure to sunlight in the presence of nutrients can lead to algal growth, especially when the storage is open.

    - Mosquito breeding generally occurs if mosquitoes are already available in the vicinity of storage. Water quality deteriorates with the breeding of mosquito. The only way to prevent mosquito in the tank is by covering the openings by appropriate screens.

Thus the basic conclusion from the study, substantiated by actual experimentation under the project are that DRWH must be designed, taking the following into consideration:

1. Convenient first flush device must be integrated. Roughly the first flush to be may be taken to be 2 mm rainfall and the volume is obtained by multiplying this by the area of the roof.

2. Storage must be tightly lidded and all entry points must be closed by a mesh to prevent entry of mosquitoes and eggs.

3. It is preferable to allow the water to stand for some time before drawing. The bacterial count is more at the bottom. Hence the water may be drawn from a higher level, e.g. withdrawing water from an over flow system may be useful. Thus, instead of one tank of large capacity, more tanks in a series may be used, but increase in total cost has to be considered.

4. Some rapid testing methods like H_2S test methods are useful in the field for indicating presence of biological contamination. The safest methods of treatment are exposure to UV & boiling.

7. TECHNOLOGY – DOMESTIC WATER STORAGE

It is difficult to understand why certain technologies prosper over others. There are many examples of situations where inferior technologies thrive whilst the ideal (in the eyes of the technologist) is shelved or dropped in the dust bin. The reasons are often political or market driven, rather than technology driven and a good salesman can be a wonderful asset. In the case of developing countries, technologies which are well-suited to improving the lives of rural poor are also overlooked on occasions. Again, there are a variety of reasons, the main reasons usually being a poor access to knowledge and information, traditional cultural practises and a lack of political will. Small-scale RWH is one such technology that has been largely overlooked by the majority of poor rural households in LDC's. In countries where the technology has been embraced (Thailand being the most prominent example), great benefits have been seen and large steps taken in alleviating the daily drudgery faced by householders in the task of meeting their water needs.

7.1. Requirements of a domestic water storage tank

Any vessel used for storage of potable water in a domestic context should have certain attributes. These are investigated below in some detail:

Strength.

Any tank that is to store water must have sufficient strength. Water pressure inside the tank creates stresses, which, if not dealt with properly, can cause the tank to fail, which could in turn lead to serious damage of the tank and injury to persons and /or damage to surrounding buildings. Ideally a full engineering analysis should be carried out for any new tank design and tests carried out to confirm the findings. In practise, tanks are usually designed and built, based on previous experience with the material being used and/or previous experience with similar vessels. A good safety factor is usually incorporated in such cases. In Section 2 the shape of tanks was discussed. Existing tanks come in a number of common shapes. The relative merits of these shapes are discussed in Table 7.1

Impermeability.

A water vessel should obviously be impermeable. This is achieved in one of a number of ways, depending on the material from which the tank is made. Some materials are inherently water proof e.g. corrugated steel sheets or fibre glass, and require no (or little) treatment to provide an impermeable barrier. Traditional materials, such as masonry and brick, are usually dealt with by applying an internal render of sand and cement, which can be treated with a water proofing agent or given a final coat of 'nil' (cement slurry). Ferrocement technology uses this concept by applying a cement slurry onto the wall of the tank when complete. Modern plastics may allow low-cost linings to be produced although little has been done in developing countries to

Table 7.1: Relative merits of some common tank shapes

Tank shape or type	Stresses	Material usage and construction
Cuboid	Stresses are unevenly distributed and difficult to calculate	The ratio between material usage and storage capacity is lower than for a cylindrical and doubly curved tank. Construction is quite simple
Cylindrical	Stresses are more evenly distributed and are easier (though trivial) to calculate	There is an improvement in the material use to storage capacity ratio (a saving of 7.5% given a good height to diameter ratio) Construction becomes more difficult with traditional materials e.g. bricks
Thai Jar Style (doubly curved tanks)	Stresses are ideally distributed if the proportions of the jar are correct	Material usage to capacity ratio is very good (savings of up to 20% over a cuboid) but construction can be very difficult, often relying on specialised moulds.

develop a suitably sized off-the-shelf solution. Other modern materials, such as bituminous paints, suitable for use with potable water supplies, are slowly becoming available on the market in LDC's.

Durability

of storage tanks is a critical question. Engineering techniques for determining the durability (through accelerated ageing) are expensive and so the only way to properly 'test' a new technology is usually to apply the test of time. This is problematic when we are looking for a useful life of 20 – 30 years. Little information seems to be available on existing tanks and their useful life spans. The experience in Thailand (documented in Section ??) shows how some unsuitable technologies can be widely disseminated before major flaws appear. In the Thai case more than 50,000 bamboo reinforced mortar jars were manufactured, many of which failed due to termite and fungal attack on the bamboo.

Sufficient storage capacity.

This topic is discussed in far more detail in other sections of this report. Many techniques are available in the RWH literature for determining the ideal size of a tank for full water coverage throughout the year, but none exists for determining the size with modified consumption (during the wet season for example), or for partial coverage.

Maintenance of water quality.

A good storage vessel should maintain and improve the water quality. This is achieved in a number of ways:

- a good fitting, light-proof cover will prevent debris, animals or humans from entering the tank and prevent light from causing algae growth
- water quality can enhanced by putting water into the tank and taking it out of the tank at the correct location – low-level tank entry and floating off-takes are devices designed to aid this approach
- good sanitary conditions around a tank will prevent disease being spread
- water extraction should be such that the water is not contaminated while being drawn
- filters improve water quality are discussed in a following section

No increase in health risk.

Sometimes, with all good intentions, a water tank can become a serious health hazard. This is particularly the case when mosquitoes are allowed to breed in the tank. This can be avoided by sealing the tank well and preventing the mosquitoes entering and breeding by covering any openings with mosquito gauze.

7.2. Tank size – ideal tank size vs. affordability

Tank sizing techniques usually only consider the optimum size for a tank based on the rainfall available, the size of the catchment area, and the demand on the system. Little consideration is usually given to the affordability of the tank. It is assumed that the customer will be looking at capturing all the water from the roof or enough to meet all their demand. But in some cases, people will be happy with *some* water from their roof. In many cases, the customer may not be able to afford a tank suitable for catching the optimum amount of water. In such cases the tank size is determined by the tank cost and so, in this case, we need to maximise capacity for a given (low) cost.

Below, in Table 7.2 we have classified *domestic* tank sizes into three distinct groups – small, medium and large scale.

Affordability is a strong function of tank size and tank design. The smaller the tank the cheaper it will be and the cheaper the construction materials and labour costs, the cheaper the tank will be. For increased affordability we are therefore looking at small-scale, locally produced RWH systems that use local materials. Local manufacture and use of local

Table 7.2: Tank scale classification

Scale of domestic tanks	Description
Small-scale	Any tank or jar up to seven days storage or up to 1000 litres
Medium-scale	A tank up to several weeks storage or between 1000 and 20,000 litres storage
Large-scale	Any tank with several months of storage or above 20,000 litres storage capacity

skills are design issues, and have been given great consideration during the design process described in Sections 7.4 and 7.8. Affordability is a function of a number of socio-economic factors and is decided at the household level.

As an indication of actual costs for a number of different tank types, a cost analysis of commonly available small and medium scale factory made tanks has been made, and compared with locally manufactured tanks. This is shown in Table 7.3 and shows the actual costs while Table 7.4 shows the cost per litre storage.

As expected, economies of scale show the cost per litre dropping as tank size increases. Also, as expected, factory made tanks are generally more expensive than locally manufactured tanks. The general advantage of off-the-shelf, factory-made, plastic tanks is convenience, a good range of sizes and usually a guarantee of quality. The disadvantage is the high cost. The advantage of the GI sheet tanks is again off the shelf availability, but the quality is dubious with the manufacturer claiming a 15 year life and local contacts stating a more realistic figure to be 2 – 3 years. The usual mode of failure is that the base of the tank rots out and the usual method of repair is to surround the base with concrete. The cost is much lower than that of the plastic tanks. They are manufactured primarily on the outskirts of Kampala and some of the major Ugandan towns by micro-

Table 7.3: Cost comparison between 'imported' and locally made tanks in East Africa (all cost figures in £ Sterling)

Tank size (litres)	Plastic Tanks [2]	GI Tanks [3]	PBG Tanks [4]	F/C jars and tanks	Brick jar 5	Plastic tube jar [6]	Tarpaulin tank [7]
100	20						
250	36						
500 – 600	62			28[5]		21	
750	88				33		
1000	115						
1500	158						
2300 – 2500	219	72					
3000	289			79[1]			
4000	379	88					
5000	463	100					
6000	590	132					40
8000	747	147					
10000 – 11000	976	159	155	264[1]			
12000		207					

Notes:

1. Costs take from 'Rainwater Catchment Systems for Domestic Supply' Gould and Peterson (1999). Costs are from 1998 and converted from Kenyan Shillings at a rate of 113.7 (15/8/2000)
2. Costs from price list, Poly Fibre (U) Ltd, P O Box 3626, Kampala, Uganda - cost of filter and tap not included. Factory made, spin moulded, plastic tanks.
3. Costs from price list, Tank and tanks, PO Box 1219, Kampala, Uganda. Cost of filter and tap not included. These tanks are made from curved galvanised iron sheets which are riveted together and soldered to make them waterproof. Estimated useful life 15 years (by manufacturer) or 2 to 3 years (by local contact). These tanks are also available in Kampala or Masaka (2 hrs drive from Mbarara).
4. Partially below ground tank. Design by DTU. Approximately 10 have been built in SW Uganda of between 5,000 to 20,000 litres. Cost is for 10,800 litre tank not including handpump (approx. £10 extra), based on costing exercise carried out June 2000.
5. Cost based on actual construction cost during study, July 2000. Cost includes tap and filter. See Section 7.8 for design detail and full cost breakdown.
6. Cost based on actual construction cost during study, July 2000. Cost includes handpump and filter. See Section 7.8 for design detail and full cost breakdown.
7. For detail see http://www.eng.warwick.ac.uk/DTU/cs/cs20.html. Costs based on actual construction costs, July 2000.
8. All costs (other than Note 1) were converted from Uganda Shilling prices converted at a rate of 2509 Shillings to the pound (15/8/200)

Table 7.4: Cost comparison – pence per litre storage capacity of tanks in East Africa

entrepreneurs, who sell small numbers of tanks. They also make gutters and downpipes from flat GI sheet. These tanks are found throughout Uganda, but not in very great numbers.

The figures given for the locally made tanks and jars are taken from the work carried out during the study (and documented in Section 7.5), as well as from the RWH literature for the region. It can be noted that the costs are generally lower than for the plastic tanks but in line with the GI tank costs. The expected useful life for the majority of the locally-made tanks is much higher than that of the GI tank. It is also noted that only one size is quoted for each of the small jars – this is because the costing exercise was only done for the work carried out under the study. Similar economies of scale would be expected for larger jar sizes using similar materials, but the design would need to be reconsidered. The aim of the small jars is to provide systems for poor rural households who don't have sufficient money to purchase the larger tanks.

The tarpaulin tank, developed by the Rwandan refugees in Uganda uses a 5m x 4m polypropylene tarpaulin, which is fitted inside a lined pit with walls of poles and mud built up to about 1m around the pit. The outhouse-like building is roofed with corrugated iron sheet (see Figure 7.1). The simple design and use of predominantly local materials make this tank extremely cheap for the given, maximum 6000 litre, storage capacity. The cost per litre storage is only 7% that of the plastic tank of the equivalent size. Tarpaulins and corrugated iron sheet are available locally

Figure 7.1: A Figure 7.1 – The tarpaulin tank. Note the inlet into the side of the tank and the door at the front for scooping water

7.3. Choice of tank type

The type of tank that may be chosen will be dependent upon a number of factors:

- space availability will determine the maximum dimensions and whether the tank will be above or below ground
- soil conditions determine whether a tank can be built below ground – rock causing excavation difficulties and sand being liable to subsidence during excavation

- the choice between factory made or locally made tanks is usually a function of wealth
- for low cost tanks (as defined above) the material and construction technique is usually dominated by what is available locally and what is affordable.
- subsidies, often give as part of tank building programmes, can influence the type of tank that will be bought or built
- there are many other factors that influence the choice of tank

7.4. Materials for tank construction

The fundamentals of design for sustainability suggest that where possible, local skills and materials are used for manufacture. This should be carefully considered when designing RWH systems, particularly in rural areas of developing countries. A

Table 7.5: Advantages and disadvantages of a variety of tank types

Tank type	Advantages	Disadvantages	Comments
Plastic tanks	Off the shelf convenience Quality assured Wide range of sizes	High cost Central manufacture High tooling costs Local skills ignored Transport costs extra	Factory made in large numbers
GI tanks	Off the shelf convenience Reasonable initial cost Moderate range of sizes Low tooling costs for the manufacturer Open to local manufacture	Doubtful quality Transport costs extra	Made by micro-entrepreneurs in the major towns
PBG tank	Reasonable cost Good range of sizes available Low tooling costs Suitable for local manufacture Local skills enhanced Use of many local materials Transport costs embodied in material cost	Quality only assured through good workmanship Water extraction device required to prevent contamination of water	DTU design. To date approximately 30 or 40 tanks have been built in SW Uganda by local artisans.
Locally manufactured small jars	Use of many local materials Use of local skills Low tooling costs – suitable to local artisans Transport costs embodied in material cost Suitable for poor rural households Suitable for incremental adoption	Limited range of sizes for given design Quality only assured through good workmanship	DTU designs dealt with in Section 7.8 These are new designs that have been prototyped and are currently under survey.
Tarpaulin tank	Very low cost Uses skills available to most rural farmers Uses only local resources (except tarpaulin and GI sheet) Very few tools required Significant storage capacity for small farms for irrigation or livestock Suitable for poor rural households Quality assured if new tarpaulin is used	Maximum size dependant on tarpaulin size Some problems at present with termites eating poles and tarpaulin Water extraction device required to prevent contamination of water	Tank developed by refugees in East Africa using UNHCR tarpaulin and now built in some number by ACORD and IVA / UNIFA in SW Uganda.

careful study of locally available skills and materials should be carried out before the design process begins. This can vary from dramatically from place to place, depending on natural resources, the range imported goods and tools and local building techniques (which are usually closely linked to availability of natural resources). Local knowledge is invaluable during such a survey. For the work described in Section 7.5, such a study was conducted and the findings are listed below in Table 7.6 and 7.7

Table 7.6: Resources available close to the site at Mbarara town

Local resources		
Item	**Availability**	**Comments**
Sand	Good quality sand is difficult to find in the area. The sand used was transported 30kms from the Oruchinga Valley. Sand of poor quality is available within one km.	Transport is needed and this costs up to *six* times the sand cost for the 30 km trip. Loading and offloading costs need to be considered – can be as much as the cost of the sand. Bulk purchase (4 tonne loads) is cheaper than buying small loads.
Aggregate	Available locally – about 5 kms from site	Again transport is needed and is costly. Loading and offloading to be considered. The stone is quarried and broken locally by hand.
Stone	Available locally at site.	Stones suitable for foundations and masonry work were available from previous work at the site.
Bricks	Good quality bricks manufactured about 40kms from the site. Poor quality bricks are manufactured locally.	There are the same concerns with transport and loading. The bricks are of reasonable quality but dimensionally irregular. Special (angle ended) bricks were needed and this had to be arranged in advance – a mould was supplied and the special bricks were made and burnt in the next available batch.
Wood / timber	Poles for building and for making ladders and scaffolding are available locally	We could harvest these from the site, as they were growing on the land. Sawn timber is available in town or sometimes locally if trees are being felled and sawn by local farmers.
Materials available in the local market place (a selection)		
Item	**Unit**	**Comment**
Cement	Bag 50kg	Used for most of our construction work
Chicken wire 1/2"	Roll (30 x 0.9m)	Used for ferrocement work
4mm mesh	Roll (30 x 0.9m)	Useful for sieves and for ferrocement work
Rebar 8mm	13m length	Reinforcing and cover manufacture
Rebar 6mm	13m length	Reinforcing and cover manufacture
Welded mesh	2 x 1 m sheet	For concrete reinforcement
Binding wire	kg	For tying rebar and other uses
Barbed wire (double strand)	Roll (600m)	Used for our rammed earth work
GI and plastic pipes and fittings	Wide variety of sizes and components available	Water extraction
Sisal rope	Roll	General purpose
Nails	kg	General purpose
Water proof cement	kg	For tank linings
Fencing staples	kg	General purpose
Plastic sheet (250 micron)	87cm wide roll – bought by the metre	For plastic tube tank – quality in local market is dubious as ends get easily scuffed
Tarpaulins	5m x 4m	For tarpaulin tank – available in some hardware shops or possibly from lcoal agencies dealing with refugees
Timber	Any size to requirements	General purpose (not accurately cut)

Table 7.7: Skills available close to the site at Mbarara town

Skill	Comments
Local pole and mud construction	Known to, and practised by, most rural farmers
Brick laying and rendering	Widely used and known to most masons
Stabilised earth technology	Not known locally
Stone masonry	Known to some masons but not widely practised
Ferrocement tank construction	There had been some previous training in the area, so a number of masons had been exposed to the technology. One local mason was very experienced and did good quality work.
Carpentry	Several carpentry workshops in town with a limited range of power tools available (thicknesser, planer, power saw, pillar drill, etc). Most carpentry shops specialise in furniture making. The quality of the work varied enormously. Local village carpenters have no power tools and have limited skills. Accuracy of work is generally low. Lathe work can be done but not very accurately.
Metal work	Welding equipment is available in town, but quality of work is not high at most workshops. No turning or toolmaking equipment available. Angle iron and flat bar available locally but few other profiled sections.
Other	A wide range of services are available in Kampala, 4 hrs drive from Mbarara

7.5. Tank trials at Kyera Farm, Mbarara, as part of this Study

A technical study was undertaken as part of the Feasibility Study to allow the study team to build and assess a number of small-scale RWH systems suitable for local manufacture in the region. The study was carried out at Kyera Farm, a training centre in organic farming techniques and rainwater harvesting techniques, based 8kms south of Mbarara, in SW Uganda. During the study 3 types of small storage vessels were investigated, namely:

- a cylindrical brick jar of 750 litres
- a ferrocement jar of 500 litres
- a partially below ground plastic-lined tank of 600 litres

(Technical drawings of each of the designs is given in the Appendix II. Sizes given are approximate)

Figure 7.2 The plastic tube tank

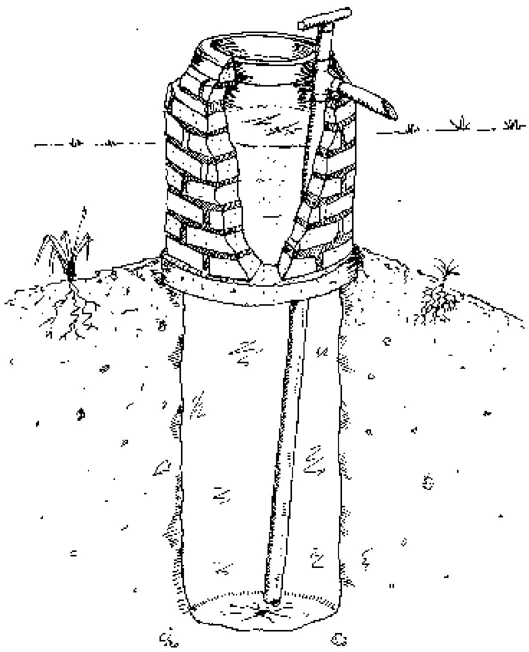

Figure 7.3: The brick jar

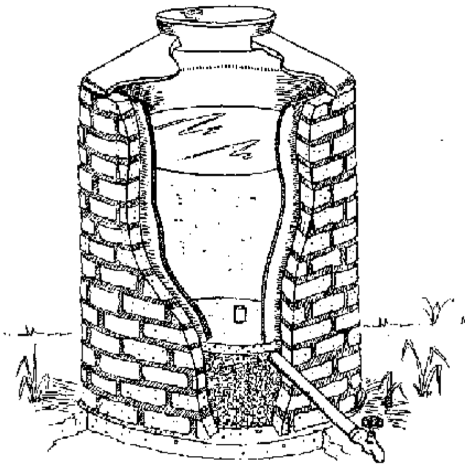

Figure 7.4 The ferrocement jar

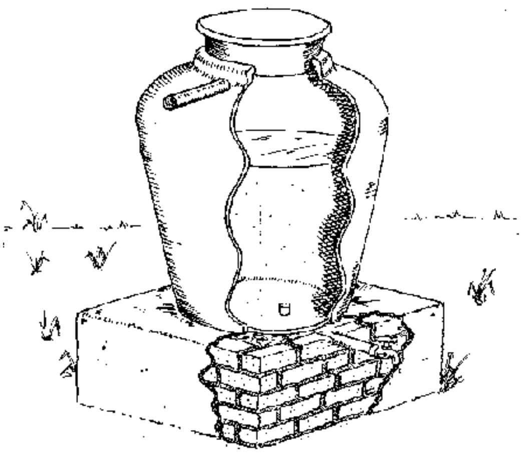


The aim of this study was:

- to test three designs of small storage vessel (one well established and two new designs)
- to build prototype / demonstration RWH systems at Kyera Farm to assess the skills and materials required for each of the designs, and their suitability for local manufacture
- to make improvements to the design based on early experiences with the prototypes
- to investigate the use of RWH on grass roofs
- to build a number of systems in the local community to allow a survey to be conducted – the survey will look at the technical suitability of the systems, as well as the use of the jars by householders and the benefits and savings brought about by the RWH system
- to carry out a full costing for each of the RWH systems

7.6. The designs

The design of the jars was undertaken using the principles set out earlier in this chapter.

In the case of the ferrocement jar, the design was taken from the RWH literature (Watt, 1978) and adapted slightly to suit local conditions. The size of the jar was increased from 250 litres, as suggested by Watt, to 500 litres. A tap was incorporated, and the jar set on a plinth, to allow water to be extracted without contamination. Chicken wire was added to the cement jar described by Watt, to give added strength and a combined cover and filter was incorporated to help improve and maintain water quality.

The cylindrical brick tank was developed as it was seen to be a tank, which very closely matches local skills, materials and known building techniques. Brick manufacture is common in the area and brick building techniques well known. The jar is cylindrical, which, as described earlier in this section, reduces stresses and gives a good material:capacity ratio.

The plastic lined tank was developed as a new innovation, specifically aimed at reducing costs. It is an adaptation of a larger partially below ground tank developed by the DTU in Uganda. The tank was designed in such a way that plastic tubular sheet, available in the local market, could be used to line a hole dug to a suitable diameter. The above ground section of the tank is made of brick. The handpump used with this tank was designed during the project and generated considerable interest, enough to warrant a short training course for local NGO technical staff.

It was decided that three designs should be developed, in order that a choice would be available to local artisans and to their 'customers'.

Further information and design drawings are given in Appendix II

7.7. Small tank costs

A detailed costing of the small RWH storage vessels was undertaken and a breakdown of the costs are given in Appendix III. A brief summary of the costs is given in Table 7.8 to allow for easy comparison

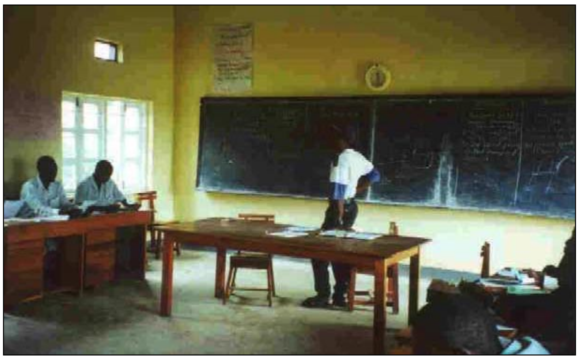
It is worth making a few general comments on the data presented in Table 7.8 and in the tables in Appendix III.

1. Cement is a major expense. A bag of cement costs 3 times the daily wage of a mason. For the jars constructed the cost of cement is dominant – 42% of the material cost for the f/c jar, 45% for the brick jar and 24% for the plastic tube jar. Reducing cement content can significantly reduce cost.
2. Irregular brick size increase cement content as extra mortar is used to fill the gaps. It is worth carrying out a quality control exercise at the brick manufacturing plant.
3. Water extraction can be made cheaper in most cases, but then there is the increased risk of contamination.
4. Further cost reduction exercises should be carried out e.g. reducing f/c wall thickness through proper experimentation, possibly omitting chicken wire from f/c tank, using more locally available materials such as wood poles and mud. It is worth bearing in mind that the jars constructed at Kyera were demonstration/ prototype jars and were constructed to a high standard.

7.8. Training

As part of the study, training was given to eight masons, 4 taken from the local community and 4 taken from a pool of masons who work closely with a local farmers organisation (IVA, Mbarara) who are already building RWH systems. The training was for a period of 6 weeks and was primarily 'on-the-job' training, with instruction being given by the project technician and with a classroom component included at the end of the period to re-cap on the work undertaken during the training. Feedback from the masons on the practical implications of the designs was absorbed and often changes implemented directly as a result of suggestions.

Figure 7.5: Classroom sessions for the masons gave opportunity to reinforce the techniques being taught as well as allowing the masons to discuss concerns and make suggestions



A series of Photo Manuals for the construction of these small RWH systems have been developed based on the work carried out at Kyera Farm. They can be found on the DTU Web Site at http://www.eng.warwick.ac.uk/DTU/rainwaterharvesting/workingpapers.htm or obtained directly in hard copy from the DTU.

A pump training course was arranged as a result of high levels of interest shown by people attending the programme seminar. This course in Low-cost Handpump Manufacture was run over a two-day period on the 22nd and 23rd August 2000 by Vince Whitehead, a Warwick mature student (and experienced machinist) who is working at Kyera Farm voluntarily during his summer break.

Table 7.8 Cost comparison between the jars constructed at Kyera

Type of jar	Size (litres)	Cost (USh)	Cost per litre storage capacity (USh)
Brick jar	750	83,000	110
Ferro-cement jar	500	70,000	140
Plastic tube jar	600	51,500	86

8. TECHNOLOGY – OTHER DRWH SYSTEM COMPONENTS

8.1. Roofs

For domestic rainwater harvesting the most common surface for collection of water is the roof of the dwelling. Many other surfaces can be, and are, used: courtyards, threshing areas, paved walking areas, plastic sheeting, trees, etc. In some cases, as in Gibraltar and Zimbabwe for example, large rock surfaces are used to collect water which is then stored in large tanks at the base of the rock slopes.

Most dwellings, however, have a roof. The style, construction and material of the roof affect its suitability as a collection surface for water. Typical materials for roofing include corrugated, galvanised, iron sheet (GI Sheet), asbestos sheet; tiles (a wide variety is found), slate, and thatch (from a variety of organic materials). Most are suitable for collection of roofwater, but only certain types of grasses e.g. coconut and anahaw palm (Gould And Nissen Peterson, 1999), thatched tightly, provide a surface adequate for high quality water collection. The rapid move towards the use of GI sheets in many developing countries favours the promotion of RWH (despite the other negative attributes of this material).

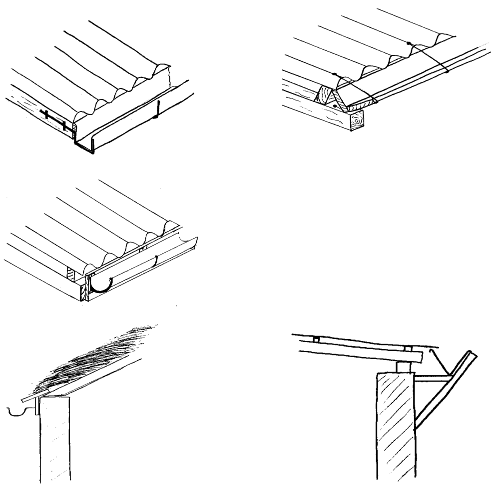
Some work was carried out during the study to investigate the possibilities of using grass roofing for DRWH. Guttering was installed on one grass roof that had been constructed with a plastic membrane beneath it – this helps to prevent UV degradation of the plastic. The grass was loosely thatched and found locally. The plastic sheet guttering that was installed is shown in Figure 8.1. It is designed to capture all the water falling on the thatch and passing through to the plastic sheet. It is fixed using two long poles, one suspended below the eaves and one on top of the thatch. It can also be designed to be demountable from the upper surface, such that it can be 'put away' under the eaves when there is no rain. Again this helps prevent degradation due to sunlight. A follow up survey will look at the longevity of the plastic guttering and the taste, odour, colour and palatability of the water captured. The survey will run until February 2001.

Figure 8.1: Plastic sheet guttering

8.2. Gutters and downpipes

Guttering is used to transport rainwater from the roof to the storage vessel. Guttering comes in a wide variety of shapes and forms, ranging from the factory made PVC type to home made guttering using bamboo or folded metal sheet. In fact, the lack of standards in guttering shape and size makes it difficult for designers to develop standard solutions to, say, filtration and first flush devices. Guttering is usually fixed to the building just below the roof and catches the water as it falls from the roof. Some common gutter shapes and fixing methods are shown in Figure 8.2.

Figure 8.2: Gutters and fixings



8.3. Water filtration

Again, there are a wide variety of systems available for treating water before, during and after storage. The level of sophistication also varies, from extremely high-tech to very rudimentary. The simple trash rack has been used but this type of filter has a number of associated problems: firstly it only removes large debris; and secondly the rack can become clogged easily and requires regular cleaning.

The sand-charcoal-stone filter is often used for filtering rainwater entering a tank. This type of filter is only suitable, however, where the inflow is low to moderate, and will soon overflow if the inflow exceeds the rate at which the water can percolate through the sand. Settling tanks and partitions can be used to remove silt and other suspended solids from the water. These are usually effective where used, but add significant additional cost if elaborate techniques are used. Many systems found in the field rely simply on a piece of cloth or fine mosquito mesh to act as the filter (and to prevent mosquitoes entering the tank).

Post storage filtration include such systems as the upflow sand filter or the twin compartment candle filters commonly found in LDC's. Many other systems exist and can be found in the appropriate water literature.

8.4. First/ foul flush systems

Debris, dirt, dust and droppings will collect on the roof of a building or other collection area. When the first rains arrive, this unwanted matter will be washed into the tank. This will cause contamination of the water and the quality will be reduced. Many RWH systems therefore incorporate a system for diverting this 'first flush' water so that it does not enter the tank.

There are a number of simple systems that are commonly used and also a number of other, slightly more complex, arrangements. The simpler ideas are based on a manually operated arrangement whereby the inlet pipe is moved away from the tank inlet and then replaced again once the initial first flush has been diverted. This method has obvious drawbacks in that there has to be a person present who will remember to move the pipe.

Other systems use tipping gutters to achieve the same purpose. The most common system uses a bucket that accepts the first flush and the weight of this water off-balances a tipping gutter which then diverts the water back into the tank. The bucket then empties slowly through a small-bore pipe and automatically resets. The quantity of water that is flushed is dependent on the force required to lift the guttering. This can be adjusted to suit the needs of the user.

Another system that is used relies on a floating ball that forms a seal once sufficient water has been diverted. The seal is usually made as the ball rises into the apex of an inverted cone. The ball seals the top of the 'waste' water chamber and the diverted water is slowly released, as with the bucket system above, through a small bore pipe.

Although the more sophisticated methods provide a much more elegant means of rejecting the first flush water, practitioners often recommend that very simple, easily maintained systems be used, as these are more likely to be repaired if failure occurs.

8.5. Water extraction devices (handpumps for sub surface tanks)

There are a number of designs of handpumps currently being investigated at Warwick and in Uganda for the extraction of water from below ground tanks. The findings are published as a DTU Technical Release (TR-RWH09 The Manufacture of Direct Action Handpumps for use with Domestic Rainwater Harvest Tanks)

8.6. Treatment of rainwater for potable supply

A number of post storage treatment techniques are recommended. Boiling water is the most commonly recommended, but it is seldom practised. Ceramic candle filters are easily purchased in most major towns in Africa, but their cost is often prohibitive. A technique that is being widely recommended currently is solar disinfection or SODIS. This technique requires only clear glass or plastic bottles that are filled and then placed in the sun for one day. More detail is given in Appendix VII. It is also worth remembering that in many cases contamination takes place during secondary storage or during water handling, due to unsanitary conditions.

9. MECHANISMS OF DISSEMINATION

9.1. Candidate mechanisms for dissemination

Any programme of disseminating a new developmental technique should be built upon evidence that the technique

- has a reasonable chance of meeting important and basic needs in a sustainable way, *and*
- requires an input of 'outside' effort to overcome specific obstacles to its adoption, *or*
- deserves to have its adoption accelerated.

Many useful innovations in the Target Area in recent years have occurred without any non-commercial promotion – the widespread uptake of burnt bricks and iron roofing sheets for housing, bicycles for transport, and plastic jerrycans for water are good examples.

Domestic roofwater harvesting is increasingly practised in the Target area by a minority of better-off householders, and during the last 5 years metal gutters have appeared for sale in many hardware shops. However it has been perceived as too expensive for poor rural households. Recent research has however demonstrated that, properly installed, DRWH *can* be economically viable for all but the very poorest households – in part because of the increasing commonness of hard roofing mentioned above. The payback time of a VLC system is around 1 year. Because RWH is relatively 'capital-intensive', it may need linking to micro-credit programmes or other means of spreading its cost over between 6 and 24 months.

Large (institutional) RWH systems require considerable care in construction and have been the subject of governmental or NGO training programmes for some years [FAKT & KRA, 1997]. Smaller domestic RWH systems have also been promoted, on the basis of their potential to reduce water-collection drudgery, their prospect of providing a focus for women's groups and the absence of familiarity and relevant skills.

Any promotional programme, once it has established that there are benefits in a technology being taken up more widely, can select its activities from the following list:

1. provide a continuing subsidy to make the technology affordable to the target group;
2. provide a temporary subsidy to accelerate take up and cover learning risks;
3. supply micro-credit to facilitate adoption of viable but capital-intensive techniques;
4. improve, adapt and test the technology;
5. train suppliers (especially where these are local artisans);
6. organise the provision of key tools or materials not yet available locally;
7. inform potential users (and producers) of the existence of the technology;
8. provide an independent source of quality control;
9. influence governmental or aid policies to facilitate take-up.

Moreover the promotion may be a primary objective or a secondary one – many technologies are disseminated as part of developmental programmes whose primary purpose is to generate employment, redress gender discrimination, empower citizens, improve health, protect the environment and so on. This can lead to considerable conflict in priorities.

Finally the promotion may be intensive or extensive. *Intensive* programmes have a high level of interaction with a small group, usually defined by socio-economic and geographical criteria, and a low 'multiplication factor'. *Extensive* programmes aim to reach a large group by means that have a large multiplication factor. They are necessarily more narrowly focussed and may employ such techniques as politics and advertising to benefit or reach its large and widely-located target group.

9.2. Regional experience of promoting DRWH

There is a surprisingly large number of organisations active in promoting *domestic* RWH in the Target Area, some of whom have been active for over a decade. Moreover other sources indicate a steady growth in 'commercial' DRWH – e.g. the attaching of tanks to middle-class houses by their owners. The formation of the Uganda Rain Water Association in 1998 and the recognition of the technology by Government are further pointers to its growing popularity. It would seem that the proportion of households operating DRWH systems is rising steadily, perhaps by as much as 1% per annum.

However the Study Area as shown on the map in the Introduction of this report, namely S Uganda, NW Tanzania and E Rwanda has a total population of over 6 million and therefore contains about 1 million homes. Against this figure, the perhaps 2000 DRWH systems installed by the combined efforts of the organisations in table 15 above represents but a tiny impact – say 0.2% penetration. Even if the seeds planted by training were to multiply vigorously, it seems unlikely that the number of DRWH systems disseminated by NGOs etc will catch up those in the private sector. In those same households the (purely commercial) penetration of ($100) iron roofing probably exceeds 60% and of ($50) bicycles perhaps 25%.

It is clear from the reports from active RW organisations in Appendix VI, and from the discussions at the Mbarara Seminar which concluded the Study, that non-commercial propagation of DRWH is extremely constrained. Not only is RWH generally treated as part of intensive rather than extensive interventions, but it also reported to be highly and permanently dependent upon availability of external subsidy. Repeatedly it was reported that it is too expensive for most of the population to purchase. The fraction of system hardware costs (i.e. *excluding* training and promotional costs) provided by beneficiaries in the interventions reported varied from about 10% to 70%. Thus there appears to be no sense that these interventions are for 'kick starting' a technology that is ready to run on its own.

One conclusion could be that DRWH, even in its very-low-cost (say $40) form is not affordably by the great bulk of its potential recipients. It is only a technique in a long-term programme of government-funded or Agency-funded provision of better water supplies for those too poor to do other than collect from 'free' natural sources. It may often cost less per household than such alternatives as protecting more springs and wells, or extending gravity-flow schemes, but it is not sustainably affordable. Thus either (a) DRWH should continue to be extended under substantial subsidy – perhaps over 50% of the organisational and material costs of each installation – at the rate that the availability of such subsidy affords or (b) it should be deemed to have failed to affordably meet water needs and aid should be devoted to other more deserving ends.

An alternative view – hardly a conclusion – is that DRWH should be just left to commercially trickle down from higher-income to middle-income households in locations where other water sources are inadequate.

A further option is to strive to reduce both the cost of individual systems and the cost of promoting/supporting them, so hat far more poor households can be reached with a given financial resource. Moreover the threshold of affordability could also thereby be changed so that all but the poorest say 30% of households could access water in this way without outside subsidy.

This Feasibility Study indicated that VLC systems are often financially justified where the 'opportunity cost' of householder time is over say $1 per day.

10. CONCLUSIONS: PROSPECTS FOR EXTENSIVE TAKE-UP OF DRWH IN THE GREAT LAKES AREA

This Feasibility Study was undertaken to assess whether 'very-low-cost' domestic roofwater harvesting has the potential for extensive take up in the Study Area. It found that 'informal' DRWH, using bowls or sometimes 200 litre drums, is already widely practised and that rainwater collection goods like gutters and GI tanks are on sale in many trading centres. Moreover a large (>65%) and growing fraction of households have at least one roof of GI sheets suitable for RWH.

A number of NGOs have been active in promoting DRWH amongst the rural poor in the Area.

However it seems unlikely that their efforts have yet affected more than about 0.2% of the region's households, far fewer than the number practising DRWH because they can afford its full cost. These NGOs generally hold that for poorer households DRWH can only be accessible if it is strongly subsidised. The activities of NGOs and local government have made the DRWH option far better known and acceptable than a few years ago. Moreover DRWH has been used in a few cases to carry interventions aimed at enabling women to achieve greater status, skills and confidence.

Modelling using rainfall data from various locations in the area indicated that a water store of capacity about 600 litres would enable most households to draw 65-75% of their annual water from such stores, but would still need to collect the remainder from point sources like wells. This relief from water-carrying would be almost total in the wet seasons (about 2/3 of each year) but rather slight in the driest months when carrying distances and queuing times are at their longest. The average annual saving in distance walked corresponds (in this hilly terrain) to a mean time saving of about 700 hours per household per year, worth perhaps $70 at a realistic 'opportunity cost' for time. For households having to pay cash for their water carriage – at typically $0.1 per 20 litres – the benefits would be somewhat greater but at the expense of the income of professional carriers.

At present water consumption per capita is about 13 litres per day. With DRWH this is likely to rise significantly, but only in the wet seasons.

Six hundred litres of storage, including a domestic handpump in the case of underground storage, was shown to be achievable at a cost of around $50 to which might be added $10 for guttering and a downpipe. Three designs of small tank and four designs of simple handpump were developed, tested, demonstrated and used for training. However the cheapest of the stores (a partly underground polythene-lined store) has yet to satisfactorily pass endurance trials.

From this data, and from the various assumptions made, it appears that counting reduced walking time as the sole benefit, the 'payback time' for investment in VLC DRWH is about 1 year. This is an acceptable but not outstanding figure, indicating broad economic viability provided that promotion costs do not exceed say $10 per household. The availability of suitable credit would make take-up much easier for the poorest households. For households that are particularly poorly located with respect to point sources the payback period may be as low as 6 months. The benefits accrue more to women and school age children than to men.

No conclusive data was collected in this Study concerning the health or safety impacts of greater DRWH usage, although studies elsewhere indicate that they should broadly be more positive than negative.

Overall it was found that DRWH could bring considerable benefits to the majority of households in the Study Area, is likely to continue to expand into higher-income households and has considerable potential for adoption by low-income households if artisan training and either credit or modest subsidy can be provided.

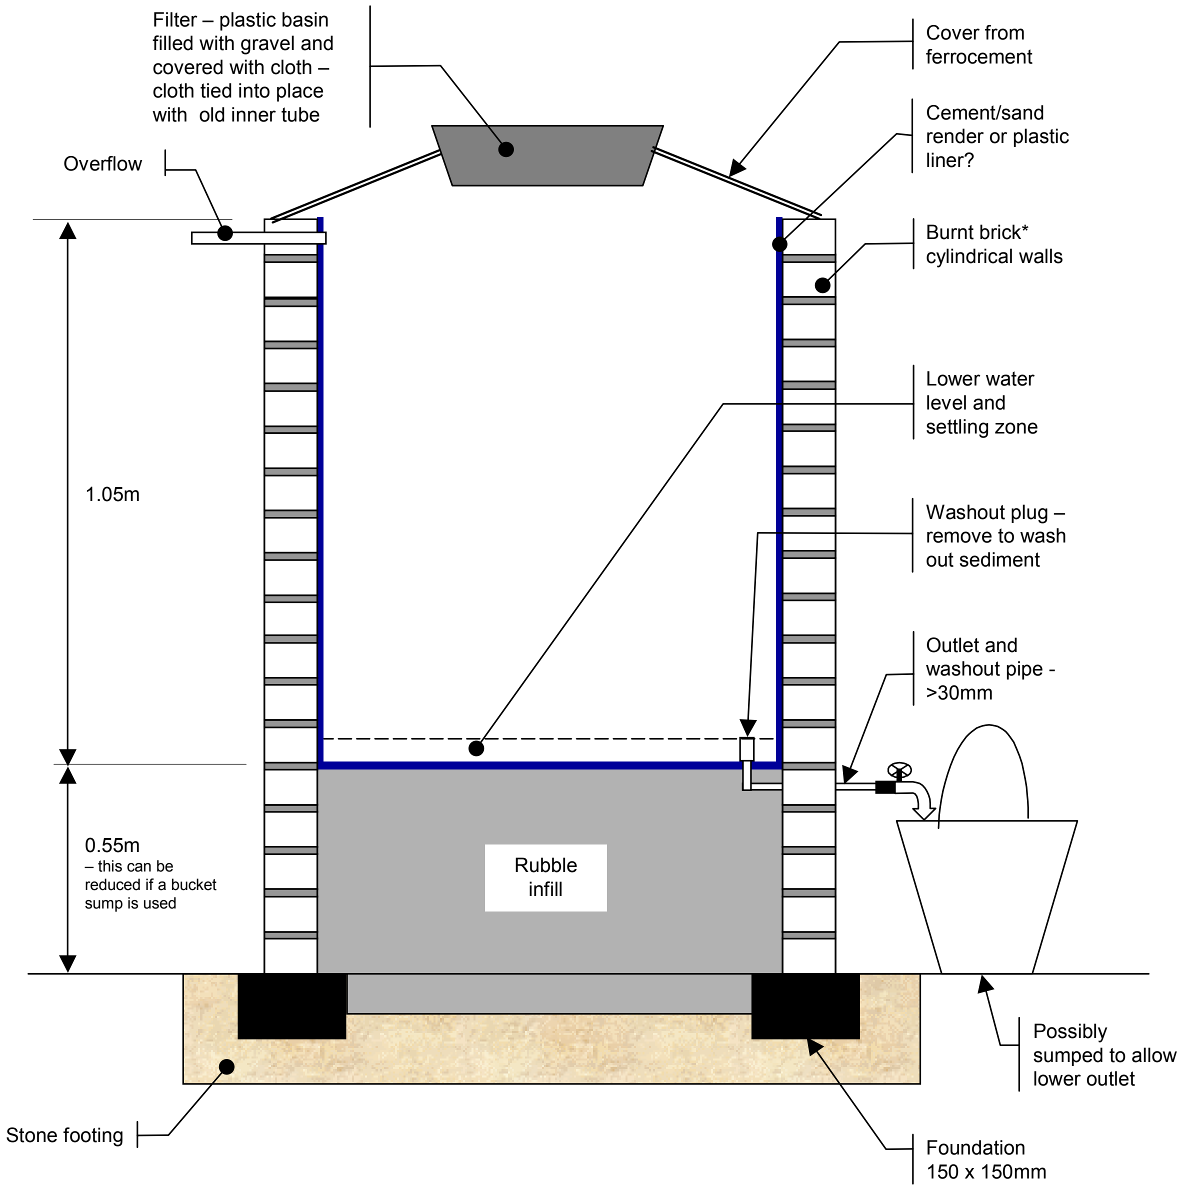
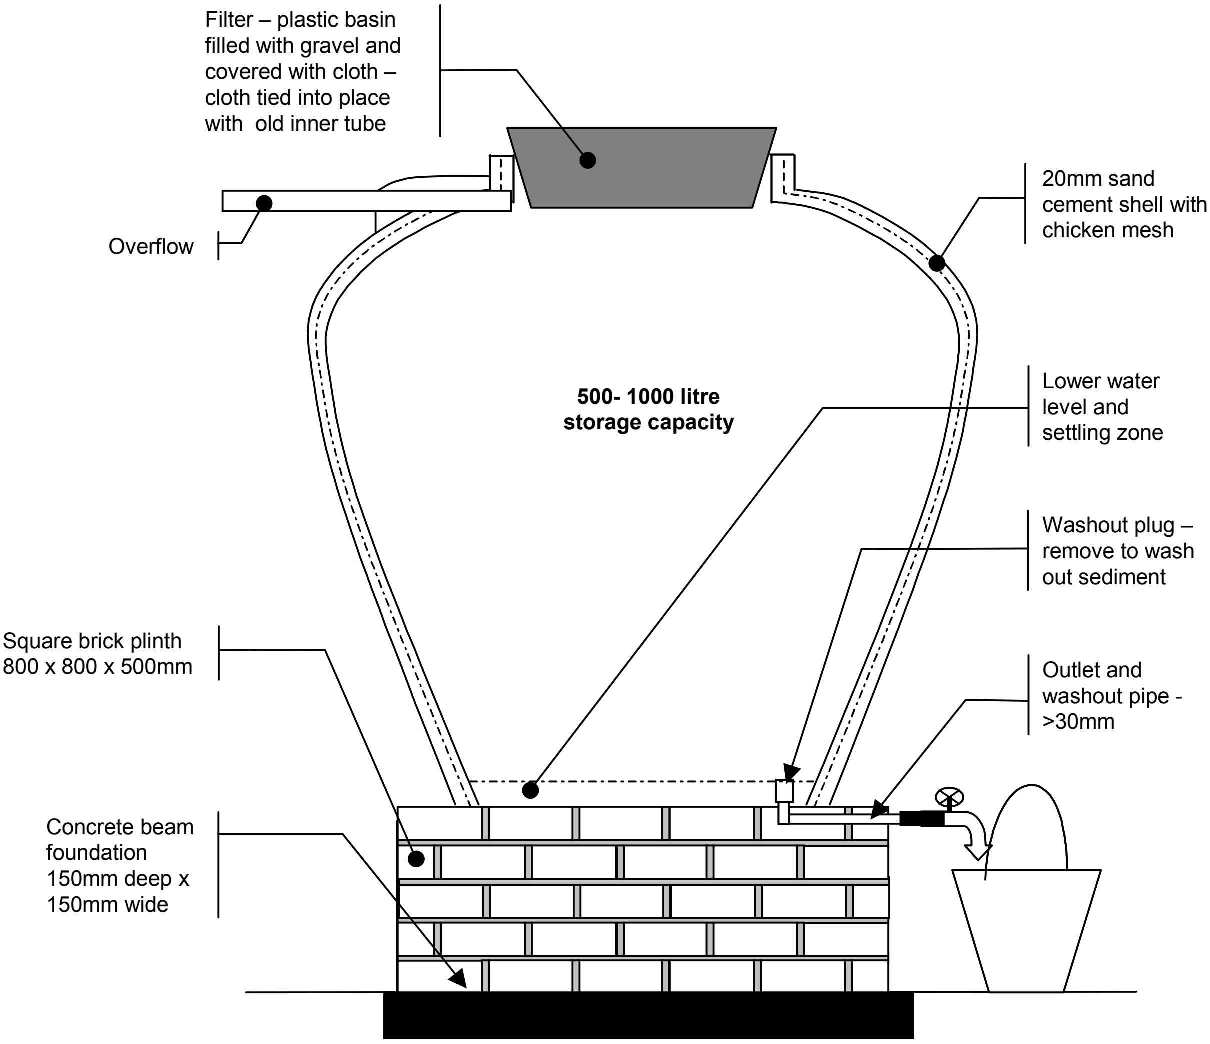
APPENDIX II: DESIGN DRAWINGS (VLC RWH SYSTEMS)

Brick jar – 750ltr



Notes:
- Number of courses – 21* * Burnt brick size – 225 x 100 x 75mm
- Number of bricks per course - 14
- Total number of bricks - 294
- Shaping of bricks or using half bricks
- Cover - conical from ferrocement
- Good stone footing under foundations – 100mm deep
- Size of tank will be about 750 litres useful storage capacity
- If drainable bucket sump is possible then infill section can be reduced, reducing number of bricks for construction

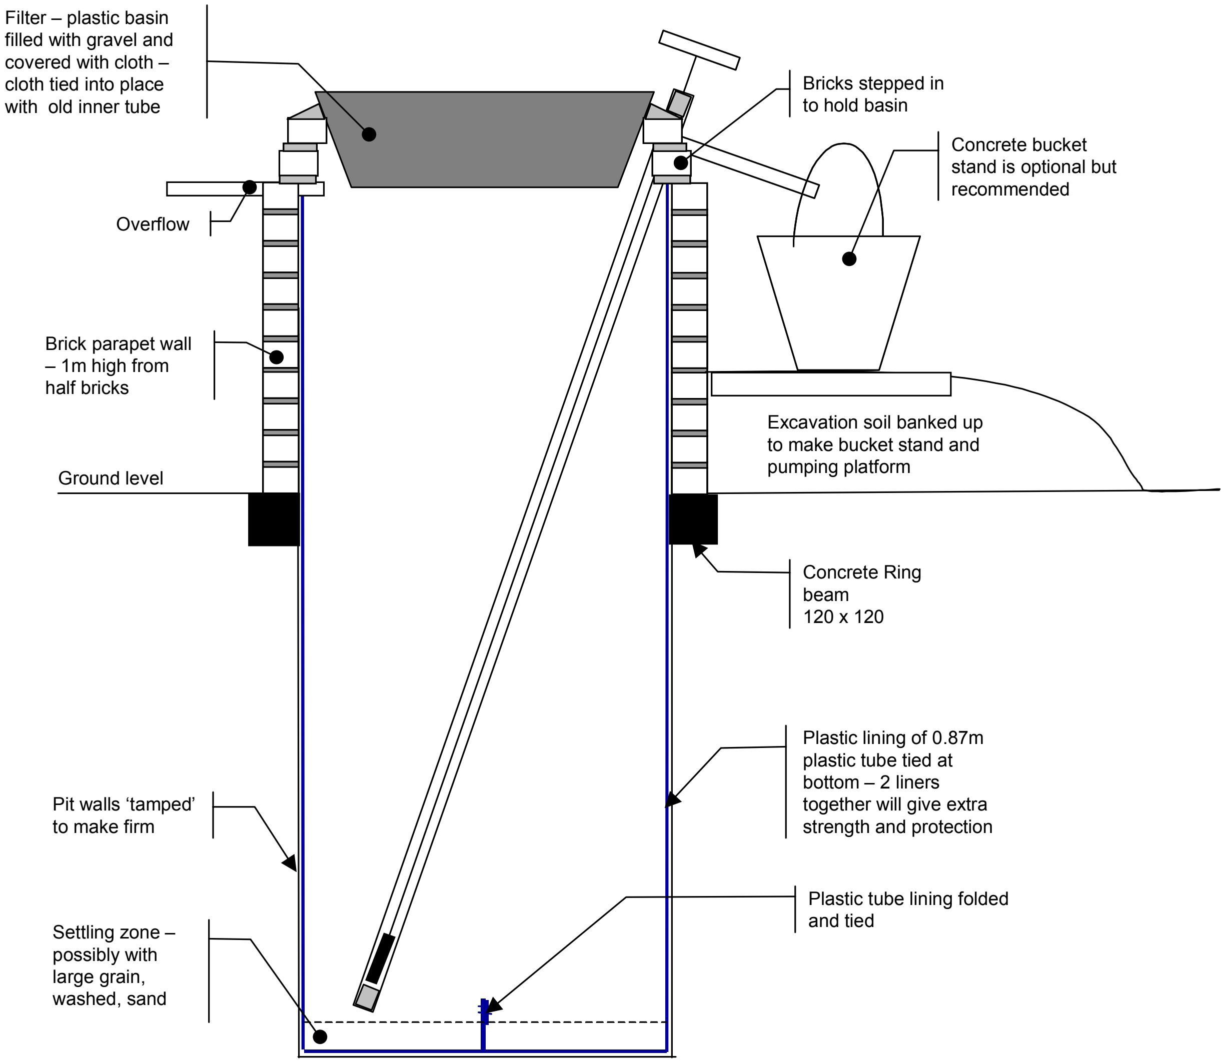
Ferro-cement jar – 500ltr



Notes:

- This version of the ferrocement jar uses a polypropylene sack mould that is filled with sawdust / rice or coffee husks and is then rendered. It uses an optional single layer of chicken wire. The level of skill required (based on recent experience in Kyenjojo) is quite high. Size is about 500 – 1000 litres depending on size of mould (dimensions below for 500 litre mould).
- There are a number of alternatives: using block moulds, wooden moulds, making cylindrical tanks using a number of different mould types,
- We could possibly simplify the design by using a collapsible cylindrical or octagonal mould. This would be easier to handle and transport

Plastic tube tank –600ltr



Notes:
- This a small version of the tube tank and could be developed to give a storage of say 600 litres or so.
- A handpump developed for use with this tank is very low cost and very low maintenance.
- This version uses a tube of plastic sheet which is turned up and tied (0.87m flat tube is available on the market). Two layers of plastic offer extra protection against leakage. The 0.87m (flat) plastic tube gives a diameter of 0.55m. This is the internal diameter of the tank.
- The capacity for each metre of depth is 230litres. Digging inside the pit can be difficult, but is aided by using a long bar and a long handled hoe. Depths of 2 metres can be reached this way, and with the 1m of parapet wall this gives a capacity of 600litres.
- The sand in the bottom prevents damage of the liner should someone enter the tank and aids cleaning (the settled matter can be scraped from the sand.
- The tank will be monitored for the following: damage, durability, cleaning, repair, replacement.

APPENDIX III: SMALL JAR COSTS

Ferrocement jar costs

Item	Unit	Number required	Unit cost	Total cost	Total US$	Total £
Cement	kg	68.5	300	20,550	13.70	9.26
Sand	kg	245	20	4,900	3.27	2.21
Aggregate <50mm	kg	40	25	1,000	0.67	0.45
Bricks	no	100	42	4,200	2.80	1.89
Rubble	kg	75	0	0	0.00	0.00
Chicken mesh 0.5"	m	3.2	1,667	5,334.4	3.56	2.40
GI Pipe 1"	m	0.5	4,200	2,100	1.40	0.95
GI Elbow 1"	no	1	1,500	1,500	1.00	0.68
PVC Pipe 1.25"	m	0.5	1,667	833.5	0.56	0.38
Tap 0.5"	no	1	5,000	5,000	3.33	2.25
Reducer 1" – 0.5"	no	1	1,500	1,500	1.00	0.68
Basin	no	1	1,000	1,000	0.67	0.45
Labour (skilled)	days	2	5,000	10,000	6.67	4.50
Labour (unskilled)	days	4	3,000	12,000	8.00	5.41
	Material costs			47917.9	31.95	21.58
	Total cost (including labour)			69917.9	46.61	31.49
	Cost per litre stoarge			95.84	0.06	0.04
	Cost per litre storage (incl labour)			139.84	0.09	0.06

Notes

1. Mould cost not included - cost of mould is approximately 6000 Ush and may last for up to 10 or 15 jars depending on care taken during manufacture
2. Larger sizes of jar - say up to 1500 litres - can be achieved by experimenting with the mould size
3. Wall thickness is approximately 20mm but varies due to bag shape. Keeping the wall thickness of the f/c to the suggested thickness helps keep cement costs down.
4. Sawdust is obtained from local sawmills (sometimes at a small cost)
5. The volume of the jar is obtained by using a bucket of known volume and counting the appropriate number of buckets of sawdust
6. The jar can be made without the plinth, but water extraction is then difficult - dipping with a container can then be practised. This would significantly reduce the cost of the jar
7. Some transport costs included (i.e. for sand, aggregates and bricks)
8. Cost of bucket slab not included
9. Omitting the tap reduces cost but contamination is more likely to occur

Brick jar costs

Item	Unit	Number required	Unit cost	Total	Total US$	Total £
Cement	kg	92.5	300	27750	18.50	12.50
Sand	kg	390	20	7,800	5.20	3.51
Aggregate <50mm	kg	40	25	1000	0.67	0.45
Bricks	no	300	42	12,600	8.40	5.68
GI Pipe 1"	m	0.5	4,200	2,100	1.40	0.95
GI Elbow 1"	no	1	1,500	1,500	1.00	0.68
PVC Pipe 1.25"	m	0.5	1,667	833.5	0.56	0.38
Tap 0.5"	no	1	5,000	5,000	3.33	2.25
Reducer 1" – 0.5"	no	1	1,500	1,500	1.00	0.68
Basin	no	1	1,000	1,000	0.67	0.45
Labour (skilled)	days	2	5,000	10,000	6.67	4.50
Labour (unskilled)	days	4	3,000	12,000	8.00	5.41
	Material costs			61,083.5	40.72	27.52
	Total cost (incl labour)			83,083.5	55.39	37.43
	Cost per litre storage			81.44	0.05	0.04
	Cost per litre storage (incl labour)			110.78	0.07	0.05

Notes

1. Some transport costs included (i.e. for sand, aggregates and bricks)
2. Cost of bucket slab not included
3. No mould required
4. The tank size can be increased slightly by increasing diameter, but tests should be carried out to determine the strength of the jar.
5. Omitting the tap reduces cost but contamination is more likely to occur
6. Where the ground slopes suitably, the plinth height can be reduced, thus reducing cost

Plastic tube tank costs

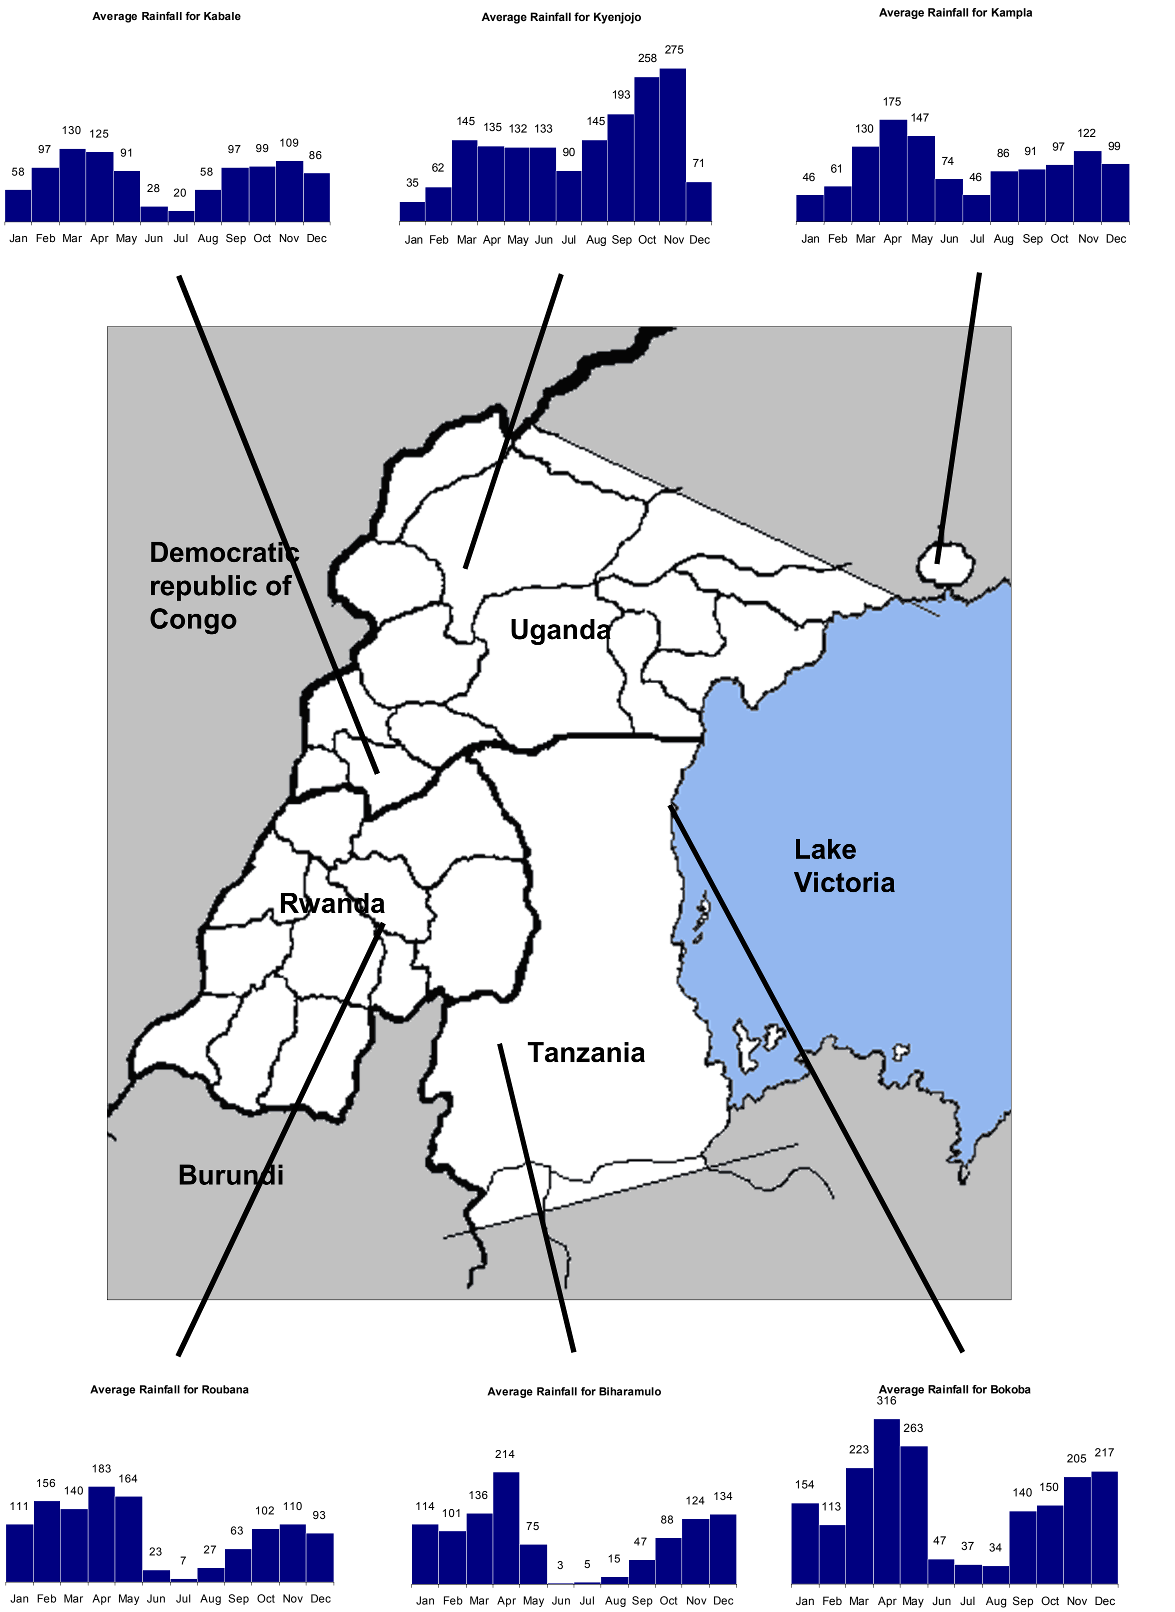
Item	Unit	Number required	Unit cost	Total	Total US$	Total £
Cement	kg	33	300	9,900	6.60	4.46
Sand	kg	136	20	2,720	1.81	1.23
Aggregate <50mm	kg	20	25	500	0.33	0.23
Bricks	no	115	42	4,830	3.22	2.18
Harold pump	no	1	15,000	15,000	10.00	6.76
PVC Pipe 1.25"	m	0.3	1,667	500.1	0.33	0.23
0.87 flat plastic tube	m	6	1,000	6,000	4.00	2.70
Basin	no	1	1,000	1,000	0.67	0.45
Labour (skilled)	days	1	5,000	5,000	3.33	2.25
Labour (unskilled)	days	2	3,000	6,000	4.00	2.70
	Material costs			40,450.1	26.97	18.22
	Total costs (incl. labour)			51,450.1	34.30	23.18
	Cost per litre storage			67.42	0.04	0.03
	Cost per litre storage (incl. labour)			85.75	0.06	0.04

Notes:

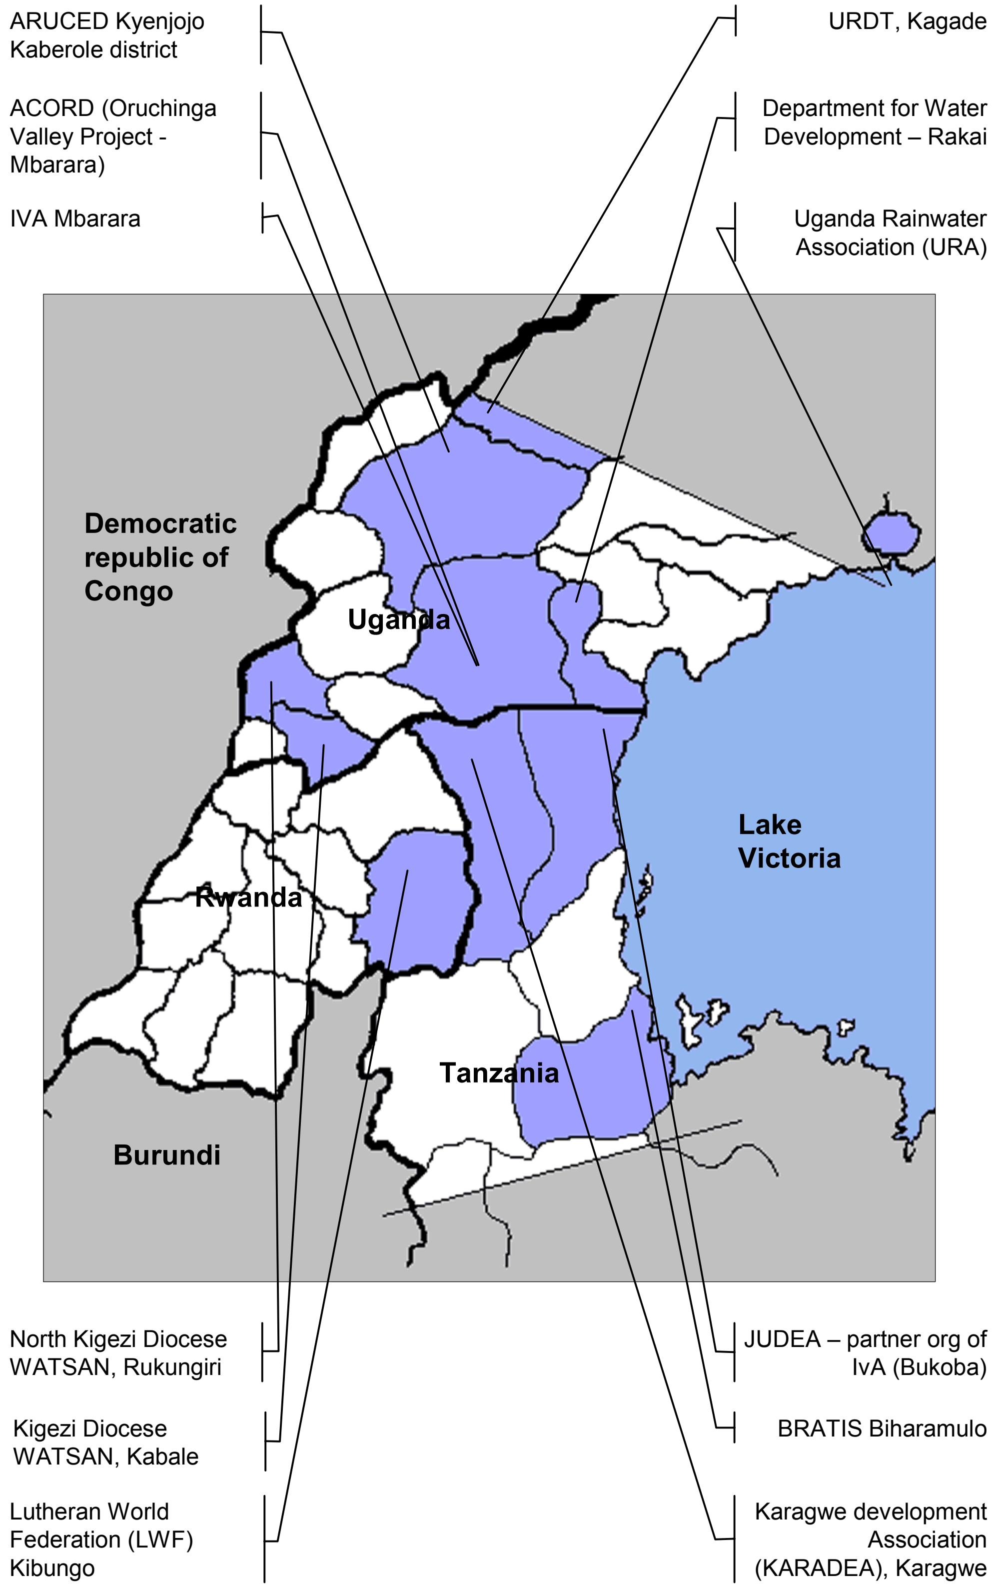
1. Diameter of Jar is 54cms
2. Diameter of polythene sheet is 55cms
3. The ring is cast at 54cms
4. Some transport costs included (i.e. for sand, aggregates and bricks)
5. Cost of bucket slab not included
6. The handpump can be omitted but water is then more prone to contamination and the lining is more likely to be damaged

APPENDIX IV: MAPS

1. Map of the Target Area showing average annual rainfall



2. Distribution of organisations



APPENDIX V – MINUTES OF SEMINAR HELD 19TH & 20TH JULY 2000 AT MBARARA

The two-day Seminar was held at the Pelikan Hotel, Mbarara, Uganda

Timetable for the seminar

DAY 1

9.00 a.m. - Opening address - Kimanzi Gilbert - DWD

9.05 a.m. - Self-introductions by participants

9.15 a.m. - Dr. Terry Thomas - Introduction to the Seminar and its objectives

9.45 a.m. - Mr. Swithen Nyakaana - the findings of the Feasibility Study - a brief overview

10.15 a.m. - Break for coffee

11.00 a.m. - Presentation - the experience in Rukungiri (North Kigezi Diocese) - followed by discussion

12.00 a.m. - Presentation - the experience in Karagwe (Karadea) - followed by discussion

1.00 p.m. - Break for lunch

2.00 p.m. - Presentation - the experience in Rakai (DWD) - followed by discussion

3.00 p.m. - Break for coffee

3.30 p.m. - Presentation - the experience in Rwanda (LWF) - followed by discussion

4.30 p.m. - End of Day 1 Activities

DAY 2

7.30 a.m. - Breakfast

8.30 a.m - Field visit 1 - **UNIFA** (Tarpaulin Tank)

10.00 a.m. - Field visit 2 - **Kyera Farm** - (Small jars, Partially below ground tank, Ferrocement tanks, Experimental Rammed Earth tanks, Grass roofs). *Tea will be served at Kyera Farm*

12.00 p.m. - Return to Mbarara

1.00 p.m. - Lunch at Pelikan Hotel

2.30 p.m. - Mr Dai Rees - technical issues related to small-scale RWH - followed by discussion

3.00 p.m. - Discussion - small-scale RWH Technology

3.30 p.m. - Break for coffee

4.00 p.m. - Time for reflection and comments

5.00 p.m. - End of Seminar

1. Mr Kimanzi was unable to attend the Seminar and the opening address was made by Dr Terry Thomas, who warmly welcomed all participants.

2. Dr. Terry Thomas, Director, DTU, University of Warwick, UK. Introduction to the seminar - background, aims and objectives.

Contents of the presentation:

- Types of Roofwater Harvesting and our focus today
- Small systems
- DTU Roofwater Harvesting Programme
- Key Questions

Dr Thomas discussed the following issues:

- Institutional vs Domestic RWH – and how the bias often been toward large institutional RWH by the funders
- ASAL vs Humid zones – Dr Thomas pointed out that the focus of past RWH programmes has tended to be in arid regions and for full coverage through RWH
- Total, partial, seasonal or casual. Dr Thomas outlined these 4 ‘styles’ of RWH and briefly discussed the relative merits of each.
- Water for people, cattle or gardens? During this study we are concerned mainly with water for people, possibly with a small surplus for animals or the garden.

- Our focus today. Dr Thomas pointed out that we are focusing on domestic, humid zone, partial or seasonal, for poorer people
- "The fifty thousand shilling system". Is this system achievable, and is it affordable and attractive to the poor of the region?

Dr Thomas then spoke about the law of diminishing returns and the relatively good return from a small scale system (e.g. a five day supply of water can give 70% of total water needs, wheras a 100 day supply may only give 95% coverage).

Dr Thomas spoke briefly about the DTU roofwater harvesting programme.

- Dr Thomas then presented some key questions to the participant, questions that he hoped would be answered during the course of the Seminar:
- How does RWH compare with other sources in terms of…….. cost and effort?, ...reliability?,.... water quality - (actual and perceived)?.... ease of installation?….. general image?….. permanence?
- How much can "most" people afford to spend on water supply?
- The practicalities of multi water sourcing?
- Who are best suppliers of domestic RWH systems - householders, fundis, self-help groups, industry, local ngo's, local government?
- What are major constraints to the use of RWH?

Mr. Swithen Nyakaana, DWD, Mbarara (and Social Scientist employed to carry out the Feasibility Study). An overview of the findings of the Feasibility Study to date.

Mr Nyakaana presented the findings of the feasibility study to the participants. He emphasised that there is a need for RWH in the region and that the technology is feasible, both technically and economically. Some of the factors for choice of RWH system include:

- Relief and topography
- Soil texture
- Existing water facilities (e.g. ponds, pans, valley tanks, wells, boreholes, etc.)
- Quality of water
- Demand
- The availability of hard catchment surfaces (usually in the form of corrugated iron (mabate) roofing (figures quoted were Uganda 60 – 80%, Tanzania 40 – 60%, Rwanda – no figures available)
- Maintenance costs are low
- Time saving

He pointed out that RWH is:

- practised locally and the skills required are readily available
- known to local people as a viable alternative water supply
- suited to the area in terms of climate
- suitable to individuals or community groups

The identified constraints were noted:

- Transport and communication are poor and expensive
- Some skills need improving
- There is insufficient choice of technology available
- Information is not readily available in the area – there is inadequate extension service

The Rev Eric Kamutera of North Kigezi Diosece (NKD, Rukungiri, Uganda) then shared the experiences of his organisation with the group.

Rukungiri is situated between 2000 and 3000 above sea level. It is a densely populated area with 200 people per km^2 and an average annual rainfall of 1500mm, falling between March and June and then between September and December. Recently the climate has been erratic and changeable. Rev Kamutera stated that RWH has great potential in the region and already 5000 homes, of the 100,000 or so homes, has DRWH. Water collection in the area is very difficult as the terrain is hilly and very muddy in the wet season. Most of the homes in the area have hard roofs. Since 1992, NKD have been promoting cement jars, ferrocement jars and ferrocement tanks in the region. They have worked closely with Water Aid (who funded the RWH programme) to promote the 250 litre jars, working closely with women's co-operative and women's groups. The aims of the water programme have been threefold:

- to provide wholesome water for drinking (the beneficiaries were advised to conserve the water for drinking purposes only)
- to reduce the burden of women and children
- to supplement existing sources

Some of the systems built have been communal, some for individual homes. There have been some management problems with the communal systems. The average family size is 6 – 8 people.

The constraints faced by the programme were noted as:

- limited funds
- limited storage capacity of the tanks
- problems with management of communal systems
- poor design or lack of choice (particularly covers, inlets and construction quality – some tanks failed due to poor construction)

Local initiative resulted in larger jars – up to 5000 litres) being constructed. These were reinforced with chicken wire and steel bars.

Rev Kamuteera recognises the limitation of their top down approach to RWH dissemination and recently the Uganda Rainwater Association (URWA) has been training women's groups in the area. NKD are convinced that RWH is a serious alternative for rural water supply in their area.

Mr Ssemanda Edward from Rakai District Department for Water Development (Uganda) presented the experiences of their work in RWH.

The rainwater programme in Rakai started in 1997 when a group of women from Kenya trained two groups form Rakai district in the skills of water jar construction and also in self expression and confidence building techniques. The two groups then built a tank for each of the group members using funds from a revolving credit scheme. The Twekembe group now builds tanks for profit as well as being involved in other profit making activities such as jam making and baking. They have trained a further 17 women's groups. The Katuntu group have trained groups from 3 other Districts and some are going to Zambia in September to train women there.

The water situation in Rakia District is difficult. It is a dry area (compared to neighbouring Districts) and the groundwater is highly mineralised. The main water sources in the area are ponds and swamps.

The appraoch taken by Rakai DWD was to 'give' only what was essential – i.e. cement on occasions, but to encourage people to rely on their own resources to supply other materials and labour. To date 300 jars (500 litre) and tanks (2500 litre) have been built in one county, with as much as 30% coverage in some areas. The cost of the jars is approximately 160,000 Ugandan Shillings (£72) and the tank 220,000 Ugandan Shillings (£100).

Please see the report titled 'Rakai Women's Groups Involved in Rainwater Harvesting Activities – Women Leading the Development Process in the New Millenium' (distributed during Seminar).

Next Mr Charles Rwabambari took advantage of some spare time to present the work of ACORD, based in the Oruchinga Valley, south of Mbarara.

The ACORD programme started in the Oruchinga Valley in 1987 with the objective of improving the standard of living of the people and improving household income. The programme identified water as one of the key problems in the area and has developed a programme based on hand augered wells and RWH (Rock catchment, tanks and dams).

However, donors were not keen to support RWH activities. After a visit to the 1993 IRCSA Conference in Nairobi, ACORD staff arranged a visit for a local women's group to the Laikipia region of Kenya. The women in this region had earlier received training in tank construction and were willing to train their Ugandan sisters. The experience is documented in a video titled 'Mvua ni Maji' – Rain is Water.

The implementation method used by ACORD is that for every domestic tank constructed by the group, ACORD provides funding for another tank to be built.

Problems faced by the organisation include:

- inflation
- drought

- no clear government policy on household water security
- poor communication
- dependency on imported materials
- low priority on rural water supply by the authorities

The opportunities include:

- economic improvement in recent years
- benefits of RWH easily seen
- skills are readily available in the region
- RWH provides a better quality of water
- simple O & M
- reduction of burden on women and children

Future work includes:

- continued support for community initiatives
- further improvements in household water security
- further networking with other organisations in RWH

Mr Oswald Kasaizi of KARADEA was next to share his experiences of RWH in the Karagwe District of NW Tanzania.

KARADEA was started in 1987 with the objective of solving community problems. Their location is the remote area of NW Tanzania and they serve an area 6700 km^2 where there is an annual average rainfall of 1000mm (bimodal). They started with 10 integrated projects, provision of water being one of these. The terrain is hilly and water is a serious problem. In 1990 their RWH programme got underway with the construction of 1400 litre jars. RWH was seen as being affordable and managable. A British VSO volunteer who was working with KARADEA at the time helped to start the programme. A 50% subsidy for tank construction was provided by VSO initially but later the tanks were sold at cost price. Meetings in the communities were arranged and women were targeted. Water committees were established with a 75% female balance. Initially things were slow and attendance at meetings was poor, but eventually word got around about the benefits of RWH and things took off. Fundis (male and female) from the villages were trained. Eventually 5 workshops were set up for semi-centralised manufacture (the finished jars [500kg] were transported to site from the workshop on donkey carts for up to 10kms). Selling jars was difficult in this low-income region due to the 100,000 TSh cost, and so a rotating fund was established to help promote the technology. People paid an initial 25,000 and the remainder was then repaid into the fund over a one year period.

Problems faced:

- transport
- very high cement costs (almost 3 times the price of cement in Dar es Salaam)
- competition with other organisations
- low income in the region
- lack of hard roofs in the region

Solutions

- rotating fund established
- subsidised sale of mabate sheets
- external funding sought from Government and NGO's

In 1996 / 97, after the return of the Rwandan refugees from the area, an international NGO copies the KARADEA example but jars were given to beneficiaries. KARADEA could no longer sell jars and so started producing larger ferrocement tanks (10 – 25m^3). These have also been successful.

To date it is estimated that about 600 individuals households have RWH jars. AT the KARADEA HQ water from their numerous tanks is sold for income generation! RWH is seen as being a very promising water supply option but pressure is needed on Government to promote RWH and to alter policies favourably.

The final organisational presentation was given by Caritas Mukankushi of the Lutheran World Federation (LWF), Kibungo, Rwanda.

Rwanda is a country of 8 million people, and 23,000 kms^2 (pop density of 350 / km^2). LWF works with refugees and also in the resettlement camps, where the returned refugees (returnees) are now living. Generally Rwanda is well endowed with springs, and so spring protection and gravity systems are common. But the area where LWF is based do not have these springs. Danida has funded the drilling of boreholes in the area. RWH is limited to the returnee settlements in the arid Kagera National Park. The technology used is a 1200 – 1800 litre ferrocement jar which is built onto a bamboo basket mould. The tank is for individual household supply, uses 200kg of cement, has a wooden cover and costs between US$220 and US$250. LWF realise that the cost is high.

Identified constraints

- High cost – the community cannot afford to purchase the tanks themselves
- Limited rainfall
- Limited skills
- Poor information dissemination

After field visits to both the premises of the Uganda national Farmers Association (UNIFA) and Kyera Farm Training Centre, there was a presentation by Mr Dai Rees of the DTU, titled 'Technical issues related to small-scale Domestic RWH'. The content of the presentation is outlined below:

- What is small-scale RWH?
- Why small-scale RWH?
- The benefits of small-scale RWH
- Reverse economies of scale
- Actual benefits to the user - a study in Kabarole District
- Some low-cost technologies for small-scale RWH - experiences at Kyera Farm

Firstly Mr Rees described what he sees as being small scale RWH

- Storage capacity of 500 - 1000 litres
- Provides several days storage for a typical household (but not inter-seasonal storage)
- Suitable for partial water supply
- Used in conjunction with other water sources e.g. distant spring or borehole
- Suitable for humid climates with evenly distributed rainfall
- It is low-cost and therefore affordable by poorer families

He then looked at why small-scale RWH is well suited to the region:

- Low-cost and therefore more affordable
- Suitable for local construction by artisans, women's groups, farmers groups, etc.
- Suitable for regions with evenly distributed rainfall pattern e.g. SW Uganda, Rwanda, NW Tanzania
- Adoption can be incremental – people buy more capacity as and when it can be afforded
- A significant supplement to existing sources - say providing 50 - 80% of total domestic water supply

He then looked at the sensitivity of annual coverage to roof area, daily demand and tank size, using rainfall figures for Mbarara to demonstrate the point and also using figures form a recent study carried out in Kabarole District (Uganda) where a number of small systems have been built by the DTU and ARUCED.

Mr Rees then went over the costs and designs of for the small RWH systems that had been seen at Kyera Farm earlier in the day (and are shown elsewhere in the Report document).

Finally Dr. Thomas led a discussion as to the future of the DTU's involvement in RWH in the region. He particularly tried to ascertain what the participants saw as being the most suitable dissemination strategy for the region for the proposed dissemination programme for which the DTU hope to secure funding. The discussion homed in around two differing strategies, namely a product based, market orientated approach or a more traditional developmental approach as exemplified by the Rakai experience. The participants were divided as to which may be the 'best' option and different organisations felt drawn to one or other (or both) of the strategies. It was generally agreed that it would be interesting to proceed with both approaches and to monitor the outcome.

APPENDEX VI - PARTNER ORGANISATIONS IN DRWH

North Kigezi Dioceses:

Organisation location: Rukungiri district in SW Uganda

Visited by Swithen Nyakaana May – July 2000

Population: Rukungiri district = 390,780

The organisations main activities:

The North Kigezi Diocese WATSAN is a water and sanitation organisation. It is funded through its religious background and aims to improve people's development. People apply for support from the church in various fields: Water and sanitation, primary health care, farming and tree planting. The organisation has majored in water supply improvement and advancement of H/H water technology. The organisation is funded by the church and has worked in partnership with Water Aid U.K.

Administrative structure:

The organisation is divided into two sections, the management and the extension team. The management is composed of the co-ordinator, spring supervisor and the hygiene and sanitation group leader, and these are supported by the Water Aid representative. The extension team is composed of the water-jar officer, senior fundi (mason/craftsperson), sanitation senior fundi, sanitation/hygiene educator, driver/mobiliser and the contractors (fundi's). There are 10 people in the team; 3 of these are women and they deal with the software within the programme. The target group is organised by the local councils, chiefs, religious leaders, opinion leaders, CBO's and NGO's.

Topography and physical features:

The area is hilly with some very steep hills (around 250) separated by narrow valleys. The valleys have seasonal rivers but few springs. The people live in these areas because the soils are very fertile; crops grow well though there is a problem of lack of markets. This is attributed to bad roads and steep terrain. The problems faced due to these features are shortage of water, bad roads, little income due to poor markets, a burden of carrying water loads on the steep terrain. The water that is available from seasonal rivers is often dirty. The soils are loamy/clay, stony and volcanic soils. The hill slopes have stones of varying sizes. The grounds are very stable, pits are unlikely to collapse, so unde ground tanks can be constructed. In the valleys, there are some sandy pits, the sand is mixture of clay and silt. The sand is not currently used for tank/jar construction.

Rainfall: 800-1000mm

The area experiences rainfall mainly in two phases March to May and Sept to Dec. There are some trace rains in late July and August.

Economic activities and major crops:

Rukungiri is mainly a subsistence farming area, the crops grown include, banana (grown for food and beer brewing) maize, rice, beans, millet and potatoes. Most of the crops are eaten by the H/H.

Major H/H expenditures:

The main expenses for H/H's include, school fees, health services, agricultural implements, paying for labour charges, building houses, water jars, clothes, drinks, food and dowry payments.

Purpose for intervention in RWH

The purpose of the organisation's intervention with RWH is to focus on areas with people in the Rift Valley & other hilly areas with either no springs or only unprotected springs. The organisation intends to promote RWH as a technology, because there is a lot of potential due to widespread hard roof coverage (70% - 85%) and sufficient rainfall (800-1000mm). RWH will reduce water shortage and amounts of water loads being carried by women & children from the valleys.

Achievements of the organisation

The organisation focused on training women groups in jar construction in the sub-counties of Bwambara, Kihiihi, Kambuga and Nyarushanje. The total number of group members trained has been forty but most of the group members have failed to use the skills due to lack of money. It takes a very long time for the group to collect money among themselves, due to low incomes. The women groups are constructing 800 l tr jars costing USh.120,000/-.

The organisations approach is basically training and demonstrations. The groups being assisted are those that have been in existence for some time. The group selects a site for the demonstration and the community takes responsibility for managing the facilities. The organisation has a sanitation component, so group member are required to ensure that latrines are available.

Agency's opinion about effectiveness:

- The organisation supports the promotion of small water tanks/jars. The beneficiaries have expressed the need for training in the construction of Ferro- cement tanks.
- The organisation lacks external support as Water Aid no longer work in the district.
- The organisation has learnt that technology development requires a strong economic base from the beneficiaries.
- The organisation has trained groups in jar construction but it feels there is need to make improvements in making jar covers also guttering is a problem.
- RWH is not only an alternative water source but can also be an income generating activity, especially to women groups…

  Example: Mrs. Mungereza was asked what she has benefited from her membership of a water group.

  "I call upon fellow women to join the groups, at first people thought it was time-wasting. But now, after constructing my 3000 ltr tank in addition to 350 ltr water jar. In the previous rain season, I sold water & got USh.80,000/-; I was about to sell all the water but I reserved some for my H/H. From the money, I have bought home utensils. My husband and has promised to support me in constructing another tank".
- The organisation, looks at the people as poor, so there is need for subsidies to these people so that they can get started.
- The organisation is seeking support from donors, because the water problem is still on.

Observation:

- The groups could benefit from being informed on ways of disseminating existing technologies, e.g. phased construction can help the beneficiaries rather than advocating big tanks, as they claim to being poor.
- The organisation has emphasised the promotion of above-ground tanks/jars and underground tanks have not been demonstrated, however the inclusion of the latter could have given the beneficiaries another possibility to choose from.

ACORD

Organisation Location: Orichinga valley, Mbarara district

Visited by Swithen Nyakaana in May–July 2000

Population: Mbarara District = 930,772

ACORD started in southern Sudan in the early 1950's in war torn areas by inter-agencies response to people's problems. The organisation was initiated by Oxfam to solve people's problems by relief and community rehabilitation by initiating income-generating activities. The other partners in funding include Britain, France, Europe, Canada & Belgium. ACORD has many branches in Africa and one of which is in Mbarara.

ACORD Mbarara operates in the southern part of Mbarara District bordering Tanzania. The project offices are in the Oruchinga Valley. The organisation operates in the three sub-counties of Kabingo, Ngarama and Kikagati.

Administrative structure:

ACORD Mbarara has two main sections, management and extension team and employs 20 staff. They work in different sections, i.e. management, field staff & support staff, and cover credit/micro-finance, agriculture, water & Sanitation, HIV (STD) and gender issues. The communities they work with are organised under the local council (L.C) system; other leaders include Chiefs, elders, religious leaders and community based organisations (CBO).

Topography and physical features:

The area is quite hilly with very few natural water sources. The hill slopes are covered with stones and rocky outcrops. The area experiences water shortage, poor communication, limited health facilities, lack of markets due to bad terrain and limited extension services.

Rainfall

890mm

Economic activities in the project area:

The basic economic activity is subsistence agriculture. Banana growing is the main H/H income earner. Other activities include keeping animals, growing beans, & groundnuts, brick making and stone sales Some people in the area salary earners.

Purpose of intervention and opportunities for RWH

The organisation started by assisting refugees & distributing seeds but this was gradually phased out. A self-reliance participatory methodology took root and people started requiring other services such as support for income-generating activities. The purpose for the organisation's intervention in RWH was to improve the quality and quantity of water for H/H and sanitation and hygiene.

The target group was the population with water stress in the three sub-counties of Kabingo, Ngarama & Kikagati. These are the areas where H/H experience water shortage most of the time because the area has limited natural water sources. A limited number of individuals have tried out their own water ponds. There has been an increase in the population as many people have been migrating to the areas but the water sources remain scarce, this is one of the reasons behind the organisations intervention.

The availability of hard roofs in the area is 90% the catchment area the average H/H is 54m2. People have started income generating activities. They are ranked rich = 17%, medium 65%, poor =15% and destitute = 3% so the money can be channelled to technology development

Impact:-

- Some women have started home gardens and zero grazing.
- H/H have built individual tanks
- The trained artisans have got employment
- RWH has been considered as a supplementary water source.
- H/H with tanks collect less water from more distant sources

Achievements of the organisation

ACORD supported the communities by training interested groups in demonstration tank construction, which includes providing transport for all materials. The capacity of the demonstration tanks are generally 6m3. A ferrocement design of about 4 m3 and a much cheaper, partly-underground, tarpaulin design have been developed and promoted. In the case of the former, a group of 9 women build and share tanks until there is one at each household. A few much larger community systems have been built in plateau areas. Where ACORD has trained, the skills are now available and people have initiated low cost tarpaulin tanks, and the people have a spirit of working together. The average H/H tank cost USh.400,000/- to USh.600,000/-, 48 tanks have been constructed after the demonstrations.

Specific problems of water collection and availability of water

Women and children mainly carry out water collection, though the children have been noted as the ones that collect the most water for H/H. During serious droughts men are hired to transport water from more distant permanent sources (springs, gravity fed systems).

The people expressed problems with accessing water, lack of finance, high charges for skilled labour. The cost of a 6 m3 tank is USh.150,000/-. There is a high transport charge for the sand: 7 tons of sand cost USh.20,000/- but with transport this becomes Ush.100,000/-

Agency's opinion of effectiveness

Training: Identified groups should be trained by use of demonstrations at the beginning of the project, and tours conducted to view new technologies. This is seen as a valuable method of awareness creation. It creates economic empowerment, reduces costs for the project, the multiplier effect is high and the skills remain within the community.

Subsidy: Quick project implementation and enhances group participation which creates a sense of ownership.

Private water provision (RWH): To benefit the poor the provision should be through group formation by selecting a feasible technology, then the poor can plan for the tank size according to their economic base.

Organisations Future plans: Continuity and sustainability:

To train artisans & pump mechanics, involve government structures (e.g. LC5s) & District extension staff, train groups in accountability and group dynamics and give the groups a chance to originate the choice of the technology. As a multiplier mechanism, locked up information can be disseminated via seminars and inter-agency forums to form a common front.

Observations

- For a project to succeed there is need to first initiate and sensitise the communities/target group to initiate income-generating activities, then invest in the technology development.
- Training, demonstration and subsidising costs makes the technology advocated far simpler and awareness takes root in a short time.
- The organisation has mainly one type of technology, this being the ferro-cement tank. The community may still miss a more favourable option, which could have a higher adoption rate.

The organisation has put a limit in terms of tank size which it can subsidise (i.e. 6m3). This may have been a problem to the target group by not giving them chance to choose the type and size of tanks to build.

Rakai District Water Development

Organisation Location: Rakai district

Visited by Swithen Nyakaana, May – July 2000

Population: Rakai District = 383,501

The organisations aims and activities:

The organisation deals basically with rural water development and is under local government control. The partners in funding are SIDA and Rakai District Administration.

Administrative structure:

The organisation is composed of water staff, health assistants, community development assistants, drivers and a secretary. As a means of dividing out the extension activities, the department employs a district water officer, county water inspectors, sub-county health assistants, and sub county community development assistant as well as drivers and secretaries.

Due to the nature of the work there are few women involved in the hardware section, though one women is in the field of community development. The communities are organised under the leadership of LCs, religious leaders, opinion leaders, cultural leaders, NGOs and CBOs.

Topography and physical features:

The area has gentle and steep hills (15°-25°) with no rivers and few swamps. The valleys have seasonal water bodies due to ground run off. These ponds provide water for both domestic and animal use. The main problems faced due to the physical features are poor road networks because of the hilly terrain and a lack of clean and soft water. A notable feature of the District is that its soils are highly mineralised. Any water in contact with soils is either salty or changes colour owing to this mineral contents: thus little groundwater can be used.

The soil texture varies depending on the area, i.e. silt in valleys, hilltops have murram with graded stones and sandy /clay in other places. Some areas have under-laying rocks at 3m deep. The ground and soils are stable which favours underground tank construction. The sand from the valleys is used for the mud rendering of house walls but is regarded as of poor quality.

Rainfall: 800-1000mm

The area experiences two rainy seasons, one in March-May and the second in August-December.

Economic activities in the project area:

Mainly subsistence farming with banana plantations (grown for both food and beer), coffee, potatoes (Irish and sweet), maize, beans, animals (hens, goats) and brick making.

Purpose for intervention in RWH

The purpose for the organisation's intervention in relation to RWH was to promote an alternative source of water for H/H's and reduce walking distance to collect water. It also aimed at tapping water before it touches the ground as this would prevent it becoming so highly mineralised. The target group for the organisation's intervention is H/Hs and women in particular.

The organisation basically deals with training. The women are required to form groups, and then apply to the Chief Administrative Officer; then the District Water Officer assesses what the group requires. Demonstration training for the group is conducted on site with selected group members. The philosophy in all the steps is participatory and the technology being promoted is on jars and Ferro–cement tank construction. The groups requested specific training skills for constructing bigger tanks of 3000-6000 ltr. Underground tanks have not been tried out though it is hoped that the cost may be much less. However, there is need to analyse the effect of cement on the highly mineralised soils.

Achievements of the organisation

The training in tanks of bigger capacity, using welded mesh as a mould has already been done. The welded mesh is provided by the organisation after which the training is left with the community. Most of the jars constructed by the women groups are of size 1500 ltr, they cost USh.250,000/-. The bigger ferro-cement tanks of 7000 ltr cost Ush.510,000/-. The communities note that the ferro-cement tanks are are cheaper per litre than jars.

Women groups have been empowered and they are constructing RWH facilities on their own. The three women groups in Rakai have constructed tanks on the H/H and have been given a chance to organise and plan for what they want, other than being guided by the support agency. Women groups have become more group oriented after seeing that group formation makes things easy.

Specific details:

Rolf Winberg a representative for SIDA's E Africa office in Nairobi responded to the people's call in relation to the mineralised water problem. Through the District Water Office, womens group representatives and some staff members travelled to Kenya to train in rainwater jar construction. After the training, the women formed three womens groups and started constructing water jars.

Agency's opinions for effectiveness observations

- Communities should be supported and guided to identify their needs, then they should be given a chance to organise themselves.
- There is need to integrated sector in development in order to achieve high adoption rate in the technology being advocated for.
- In development, there is no need to form parallel bodies when working in the same area. There is need for integration and support to each other.
- Dissemination of skills and training is the best tool to be handed over to communities if they are to work on their own with minimum external support.
- Women are the basic elements to faster change. So to every intervention there is need to involve the most affected persons, they know their problems better.
- Let the groups start from where they are with their limited resources. As their income base stabilises, they will demand more complex

facilities which will suit them at that particular time.

- Private water provision is more feasible when done at H/H level, this develops a sense of ownership

Observations

- Demonstrations make participants more involved and they can see their potential benefit; this leads to strong groups, and it encourages other new members. The people tend to demand more services, which leads to building capacity in the target group (planning and implementation).
- Empowerment starts with skill dissemination, which leads to self-reliance in both decision-making and a demand for more needs or support.
- Credit schemes were found more effective when beneficiaries raised the funds for the scheme themselves
- Subsidies to target groups activates group formation and a sense of ownership is developed. This further creates competition among the group members and the adoption rate is high.
- Provision of key components helps the group to access non-locally available materials commodities. The organisation's presence is felt.
- Construction in phases: communities should be encouraged to start where they are by building small tanks. The demand for others can be met by continuous construction of other small tanks with in the limits of their economic base.
- Sustainability: the basic strategy for this involves training, involving local leaders on ground and the beneficiaries, should use their own resources to multiply the technology.
- Technology development: for the technology to develop there is need for other income-generation activities by the potential adopters of it. RWH as a programme on its own is difficult to adopt or develop when the income base is very low. Technology development can be hindered by several factors, lack of extension services and/or lack of markets/income. There is need to work in an integrated way by involving other agencies that deal in those particular fields.
- Many people have abandoned tank construction due to fear that the sand is bad and the structures would crack. So, there is need to support the communities with transport facilitates so that cost of this critical raw material can be lowered.
- Most people are negative when looking at communal water structures, because such structures often end up in the possession of individuals.

  Case Study: "A communal water tank of 30m3 was constructed at the chiefs' house because it had the biggest catchment in the village. After one year the chief made a fence around his home and bought dogs, the people then abandoned the tank". This showed that the group lacked any laws to guide them in case one of them lacked trust from fellow members.

KARADEA (Karagwe Development Association).

Organisation Location: Kagera Region of NW Tanzania, bordering Uganda & Rwanda

Visited by Swithen Nyakaana, May – July 2000

Population: Not known

The organisations aims and activities

The association was initiated by both the community and the donors, A British volunteer Alice Morris strengthened the project with a grant from Britain. The grant at the start was used in conducting sensitisation workshops, and for training fundis in water jar construction. Sweden gave aid to the association with the intention of improving peoples living standards by providing clean water.

KARADEA's objectives include "the emancipation of women" and it contains 31 women groups. Its activities, as reflected by its organisational sections as listed below, include administering three loan funds, seminars for women and help to orphans RW jar construction has been undertaken for 13 years. Although for 2 years high cement costs and the temporary intervention of a new (refugee-support) NGO providing free jars interrupted this activity.

Administrative structure:

KARADEA has the following sections: Water, Health & Nutrition, Solar, Finance, Appropriate Technology, Education & Research, Women's Development, Afforestation and Youth Development. The water section is sub divided with technicians and a water contractor who work on a part-time basis. They have an annual general meeting with the board of directors, the executive secretary, and heads of department. There are more women than men on KARADEA's staff because the programme is intended to assist women in easing their problems.

Communities are organised under village leaders, opinion leaders, religious leaders chief and NGO's. The most active person in mobilisation for the development programmes is the Village Executive Officer.

Topography and physical features

Generally the whole region is quite hilly.

Rainfall = 1000 mm

The region receives two rains, one in February–May and the other in September-December.

Economic activities in the project area:

The main income generating activities is subsistence farming. Most of the products are consumed at H/H level; these are beans and maize. Ground nuts, bananas, tomatoes and coffee are the main cash crops.

Purpose for intervention in RWH

The organisation recognised that access to water was very limited and in 1987, with assistance from Sweden and Britain (under Alice Morris), training artisans in jar construction was initiated.

Achievements of the Organisation

They introduced plastic bags of 1000 ltr, after some time it was discovered that they were prone to damage by termites. The bags were finally rejected by the communities. After the training the jars were bought by the individual beneficiaries. There is still a demand for services from the project by the community. Beneficiaries then started applying for assistance, the organisation would make costs for them depending on the distance from the head officer or nearby workshop, the beneficiaries would prepare the platform (the seat for the jar). The organisation provides transport for the jar from the workshop and makes/provides gutters. People are allowed to pay in instalments: contracts are made specifying when to fulfil the payments.

The common technology is the sand/cement (mortar) jar of 1400 ltr costing TSh.5,000/-. Some people have started constructing ferro–cement tanks and underground stone masonry tanks.

The quality-control advantages of manufacturing jars in specialised workshops have been offset by the difficulty of then transporting them (fragile and heavy) across difficult terrain. At one stage donkey-cart transport was introduced into Karagwe solely for this task. As a means of reducing transport distances, five workshops branches have been established. These are managed by the beneficiaries some of whom are employed in the workshops. Branches make reports to the heads of departments and the executive secretary. Every department makes reports on the activities conducted.

The organisation promotes training for both staff and beneficiaries. Two approaches are used to train staff, an expert is called in to train specific sections or staff are taken to selected institutions.

Agency's opinions about effectiveness:

- Training: the beneficiaries, artisans and staff involved in new technologies are a means of creating more awareness.
- Demonstration: the organisation does not use H/H demonstrations, but shows models in public places or jars are taken to exhibitions/open shows.
- Establishment of branch workshops: to reduce contact distance for the beneficiaries and organisation.
- Formation of groups and water committees: as a means of empowering the community. Phased jar construction by individual H/Hs ownership, as a means to meet people's water needs, in

small bits, by building jars in sequences with time.

NB: Very few H/H can construct tanks large enough to meet the whole water needs of a H/H. The common and affordable tank size for a H/H, depending on funds, is 5.6m3 = (4 jars of 1400L). These can be built one after the other. Beneficiaries need assistance in obtaining materials that are not available locally. The organisation success is partly dependent on providing other inputs i.e. transport, skills and supervision).

Observations

- For a programme to succeed there is a need to integrate technology development with other income-generating activities. Very few technologies can be adopted when the income levels for the beneficiaries are very low. Improvements to extension services and markets could lead to technology development
- Many households have more than one water jar. It has been noted the beneficiaries do not feel the total cost when jars are bought at different times.
- Children collect more water in the H/H than the men or women. Both men and women control the funds in the H/H, yet it is the children that suffer from collecting water. Children have no say on the funds to be invested on RWH.
- Jars and tanks may take a long time to buy when the H/H has many children as income is directed to higher priorities i.e. school fees.
- Portable water jars may be a problem when they are carried to areas that are very hilly.
- Jars are not made by individual H/Hs due to concerns that:

  1. It can reduce the quality of the jar constructed
  2. The cost for transporting sand is very high.
  3. There is a need to subsidise the jars to the community and the people's income is very low.

BRATIS (Biharamulo Rural Appropriate Technology Innovation Society)

Organisation Location: NW Tanzania.

The organisation is located in Biharamulo district N W Tanzania. Five other districts, Ngara, Muleba, Geita, Kahama and Kibondo surrounds Biharamulo. The organisations area of operation is Busenga, Husahunga and Nyakanazi. The head quarters are in Katooke and the other office in Biharamulo town.

Visited by Swithen Nyakaana, May – July 2000

Population: not known

In the initiation of the organisation the target group was not involved, they only benefit from the organisation through awareness creation and training. The organisation started as a voluntary youth group under the Caritas Church organisation (Diocese of Rulenge). After 3 years it become independent and registered in 1995. Mr. Angelo Nzigiye and the youth group initiated the organisation. The partners in funding are comprised of the Tanzania team, the District Council, and subscription by members. 50% of the funds are generated by executing tasks in construction and carpentry workshop

The organisations aims and activities

The broad objective is to animate communities to participate fully in their own social and economic development and aims to establish an organisational infrastructure among disadvantaged people.

Administrative structure

The organisation has a board of six directors, management committees and co-ordinator departments of carpentry, agriculture, entrepreneurship and technology.

Educated women often go to the bigger towns in search for better pay, as gender issues are not viewed as important topic at present. The organisation employs people of low cadre and trains them on the job.

The organisation's activity co-ordination is done through reporting and meetings are intended for planning and ironing out differences. The executive meetings are conducted every Monday while the Board and General Assembly meet every year. Each department reports independently and the reports are then co-ordinated to formulate policy on how the organisation is run.

The communities where the organisation operates are organised by village leaders, religious leaders, opinion leaders, traditional leaders and NGO's

Topography and physical features.

The organisation's area of operation has undulating gentle hills covered with stones and boulders; there are valleys and swamps, which serve as water sources for the area. The soils are fertile with natural vegetation. Firewood is scarce in the area and there are water shortages in the dry periods. Swamp water is dirty, some of the sources are on hills and in the valleys. Soil varies depending on the location: in the valleys there are clay/sandy, on the hills there are the red laterite soils and red loamy soils. The area has large rocky outcrops and the soil stability varies with the location. Sand in the area is available and is used for building constructions.

Rainfall

Not known but likely to be over 1000 mm per year, with 1 long and 1 short rainy season..

Economic activities in the project area:

The major activities are agriculture and the main crops are maize, beans, like coffee, sweet potatoes, keeping goats and cows. Other sources of income are charcoal manufacture, brick making, salary earners, carpentry and tailoring.

Purpose for intervention in RWH

The purpose for intervention in RWH was that there was a limited number of water sources available. The low amount of 10L/ per person/day was seen as another valuable reason for RWH intervention.

The organisation's aim is to try out RWH technologies for the beneficiaries to appreciate, adopt and practice (multiply). The main problems are that few people have hard roofs, 50% of 40-50m2 and the technologies appear to be costly. The target groups for the intervention were the villagers and areas with acute water shortage. This would help women suffering from the drudgery of water collection. It is the institutions that have taken up the technology by contracting the organisation to put up large tanks of 43m3 and some institutional VIP latrines.

The entrepreneurship department conducts the economic assessment for the area and determines the beneficiaries' contribution. The organisations approach is in sensitising the community on RWH. Identifying and training the artisans on the selected affordable technologies (jar/tanks). However, the adoption rate is still very low as the target group claims the technologies are very expensive.

Agency's opinions about effectiveness:

- The organisation has no intention of ending its services because the problems in water are still on and the youth groups still need support, so the programme should continue trying to resolve the problem, lack of support and funding are limiting factors.
- The organisation aims at assisting H/H by constructing small jar/tanks of ferro-cement and under ground tanks. Due to low costs.
- As a means of multiplying the technology. The beneficiaries, should is to participate in training to become artisans, the organisation is to give technical advice.
- On information services, the organisation has set up training centres where the youth go to seek advice and new technologies. The organisation has formed a networking forum for local NGOs.
- The organisation supports the idea of public demonstration, but if the first structure fails the idea being demonstrated does not take root. Unfortunately most demonstration systems in public places lack ownership and therefore good maintenance.
- Training the users in system construction may not be economical, when the trainees do not use the skills attained. The better approach is the training of artisans, as skills and employment are created and the multiplier effect is noted when there is the availability of funds. This is further developed if the group's activities are

subsidised, this creates a higher chance hat the technology in question is adopted.

- Most beneficiaries have failed due to lack of key components for RWH. There is a need for the provision of key components & services to be brought nearer, giving a reduction in cost/litre. For example tools and equipment such as moulds could be hired.
- As a means of reducing cost/litre at the time of construction, water provision for the poor should be implemented though group formation and subsidy
- The organisation has started income generating activities, promotion of improved bananas, making tiles – as a means of uplifting H/H income.

Observations:

- According to the organisations approach, if the target group is to benefit and adopt the intended technologies there is need for group formation, subsidy provision and credit scheme association as a means of empowering the individual H/H to construct their own water structures.
- The organisation may have good intentions and approaches in reaching the target group, but with limited funds and support this is difficult. The intended objectives may take long to be realised. Like wise, if the target group has financial constraints, the message and ideas sound beneficial but implementation remains a problems.
- HESAWA (Health through sanitation and water) had different approach in the same area, its approach is more towards donation. (The beneficiaries are required to contribute local materials for a 20m3 structure). This has been a hindering force for BRATIS to succeed. The beneficiaries look at BRATIS's requirements as expensive in comparison to HESAWA.

  CASE STUDY: NGO's with very similar activities may complement each other or compete, to the extent of displacing each other from either the area of operation or the technology".

- According to the beneficiaries' claims, the best tank size to meet the H/H water needs, may be constructed in the phased approach (one jar after another) up to the capacity of (4 to 6 m3).
- The organisation has started on projects intending to raise people's income, (introduction of new banana species, making roofing tiles, carpentry. Many technologies fail due to low income in the target group. No new technology can develop before the target groups' brains are trained and changed towards the new approaches. (Specific training).
- The organisation intends to network with other NGO's but there has cropped up a problem of extra payment to the focal people that run day-to-day activities. This has led to the need for the formation of a secretariat for NGO's.

  NB: (In collaboration there is need to avoid too demanding partners).

JUDEA. (JUhudi DEvelopment Association)

Organisation Location: North west of Tanzania bordering Uganda.

Visited by Swithen Nyakaana, May – July 2000

Population: Not known

JUDEA is a rural development NGO in Bukoba, Tanzania, it focuses on poverty alleviation and improving the living conditions in the rural communities. The organisation was initiated by Mzee Ishengoma and registered under co-operative organisations involving individual partners. The organisation was started on the basis of the individual annual subscription of 5000 TZS, and an entry fee of 2000TZS as the basic funds for the organisation. The Belgians (IVA and VIC) have given support to the organisation. IVA supports agriculture and VIC support JUDEA in under taking drilling. The administrative structure for the organisation is the chairman, the executive committee and the general meeting.

Administrative structure

JUDEA is an organisation initiated and run by retired people, mainly professionals.

Topography and physical features/soils:

The area where the organisation operates has gentle undulating hills, valleys, swamps and rivers. The soils are mainly loamy lateritic and murram. The ground is stable and favours underground tanks.

Rainfall: 1900 mm per annum

Economic activities in the project area:

The economic activities in the area are mainly agriculture or subsistence farming. The main cash crop in the area is coffee. Other crops include beans, bananas & maize etc.

Purpose for intervention in RWH

JUDEA wants to promote RWH as a source of water supply and assist elderly people of Sawata & Sadiawazee Tanzania, by constructing H/H water jars tanks to reduce water stress. The target group for the organisation is the mostly the elderly H/H,s but women and children are a focus as well. The criteria used in choosing areas to benefit from the RWH programmes are those areas that have water stress, no alternative water sources, those with hard roofs and where the people are willing to form groups and contribute.

Agencies opinions about effectiveness

- As the organisation has not fully participated in RWH system building, many of their ideas are waiting to be turned to reality.
- The organisation intends to introduce and promote water jars of 500 ltr to 1000 ltr, and encourage underground tank technology using tanks of capacity 2000 to 7000 ltr.
- The organisation does not intend to end the programme, it wishes to continue but the organisation lacks founders and financial/technical support.
- The organisation has a limited number of staff, due to lack of funds. It intends to establish a training scheme and open up a workshop for water jars, and public demonstration on low cost technologies as a means of awareness creation.
- Though the organisation has not implemented RWH activities, suggestions on possible means on approach & dissemination of RWH technology were noted.
- Group formation, mobilisation and sensitisation for RWH and create a structure, which creates awareness and strengthens RWH as a technology.
- The communities need to be introduced to simple techniques, affordable and with in their financial reach.
- As a tool to promote RWH, there is need to form a collaborative NGO body and implementing agency in RWH to form a common front in promoting the technology.
- Government and community based organisations need to have documented policies regarding the approach & extension to support the dissemination of RWH technology.

Observations

- The organisation has a vision to support the elderly and the poor who have no capacity to contribute towards the services they require. The group would require a grant for the organisation to achieve its goal.
- The other population if mobilised and sensitised would take up the organisations idea because water is a problem to most H/Hs.
- HESAWA (HEalth through SAnitation and WAter) has been operating in the region, so the sensitisation required is not new, and the organisation needs to introduce the feasible technologies and train the target group on implementation.
- The composition of the organisation may cause a rejection by potential groups, as there may be a bias towards elderly people only. There is need to integrate other players in the organisation. The youth and women can play a good role in community mobilisation and sensitisation.
- There is need for both the organisation and target group to train or visit other areas implementing RWH so that the organisation can gain awareness of available technologies. Skilled labour and raw materials could be considered.

IVA + Uganda Nat Farmers Association, Mbarara District

Organisation Location: IVA has its office in Mbarara town, S Uganda.

Visited by Swithen Nyakaana, May – July 2000

Population: Mbarara district = 930,772

IVA is a Belgium farmers alliance service similar to UNFA. The organisation provides funding to support farmers in Mbarara. The organisation works through UNFA members, UNFA members contact the office for technical support /skills development.

The organisations aims and activities

IVA operates throughout the whole of Mbarara district. They use a bottom-up approach when executing the extension, IVA has its representative up to parish/cell level and deals with the grass root farmers.

Administrative structure:

The organisation has a project management team composed of two Europeans and two Africans. The support staff comprise of agricultural teams and a secretary. The target groups are organised through committees, groups and the leaders include LC chiefs, opinion leaders, religious leaders and NGO's.

Topography and physical features:

The organisation's area of operation varies considerably, it therefore deals with hilly areas, valleys without or limited natural water source, valleys with a flat basin, steep hills with rocky out crops like those in Rugaaga S county. The hillsides are used for both crop production and as grazing land. Water sources are few and far between in the hilly regions.

The soils are of a variety, black soils, sand loamy clay soils are found in the valleys, while stony, murram, soils found on the hillsides are very compact and difficult to dig, but may be suitable for underground tanks. IVA operates in one of the areas with the best sand pits (Nyeihanga). This sand is good in jar/tank construction.

Rainfall: 890mm

The rainfall in Mbarara district occurs in February-May and Sept-December with some light occasional rains in July.

Economic activities in the project area:

The income generating activities include banana plantations, coffee growing, animal keeping (cattle, goats, hens and rabbits) sand extraction, charcoal etc.

Purpose for intervention in RWH

The organisation conducting a needs assessment survey in the area which showed a water shortage. Many areas have no or limited natural sources of water. In the survey it was noted that most of the water sources are located in the valleys, with ponds and springs being used for both animal and human use. From this survey IVA felt that they could meet people's needs by introducing RWH systems.

Achievements of the Organisation

In the course of one year 10 groups have been formed and 8 ferro-cement tanks have been constructed. The organisation carries its activities out through UNFA members, at the parish level people are mobilised to form water groups, when groups are formed and contribution accepted two agreements are made one for the group and the other between the group and the organisation. Then group member selects local builders and a demonstration training session is conducted.

Agencies opinions about effectiveness

- IVA promotes training the beneficiary groups as a means to create skills in the target groups. This is done on public demonstration.
- Prior to technology development there is need to create income for the target group so, that the funds from their produce is again put into the new technology development.
- As an entry point there is need for group formation, this encourages the group to access financial support and funds are easily generated for an activity.
- The organisation encourages the idea of inter-agency collaboration, this increase information

flow and there is a gain from sharing the experience and/or technical assistance.

- The communities should not be limited on a particular tank size or technology, the people know their problem best and how to solve them e.g. the organisation demonstrates; on 3000 ltr tank costing USh.400,000/- but the communities now are constructing 5000 ltr tanks.

Observations

- As IVA deals with UNFA members and those that are not members do not have access to the organisations services.
- If UNFA fail to deliver then IVA will also be regarded as having failed.
- H/H with a regular (but low) income could improve themselves through a RWH programme. It has been noted that most of the H/H with rainwater tanks are those that who have benefited form UNFA programmes. Therefore technology development requires external financial support, this can be generated locally or through subsidising.

LWF (Lutheran World Federation) in Rwanda

Organisation Location: The organisation has its country office in Kigale.

Visited by Vince Whitehead, July 2000

Population: Not known, but population or Rwanda is currently 7.3 million and population densities are generally high

LWF is a worldwide religious organisation and deals with humanitarian assistance. It started in 1946 as a world service provider by the federation of Lutheran churches. The partners in funding include the Federation of Lutheran churches of Europe, North American and Australia. The organisation operates especially in areas of Rwanda to which former refugees and IDPs have recently returned, including in the Ndego II sector of Kibungo, Kigarama Departement and in Gitarama Departement. The population served is between 6000-7000 people but the number is increasing, as there are more people returning home.

Administrative structure

LWF consists of a director, a programme co-ordinator, and three project managers there are thirty-two staff in total. Nine out of the thirty-two staff are women.

Topography and physical features:

Much of this area of Rwanda is characterised by high hilly regions and isolated steep valleys. Many of the peaks are rock-strewn, with little vegetation. Lower down the slopes are a mixture of rocky outcrops and lateritic soils. Erosion from the rains regularly causes deep ruts in the unmetalled roads. The occasional hurricane has been strong enough to take the CI sheets off houses. The soils are very stable and favour underground tanks; in the area there are some rocky outcrops.

Rainfall: About 1000 mm

The area experiences rain from February-May and October-December. The Kibungo district was suffering a serious drought during the time of the visit.

Economic activities in the project area:

The main economic activities in the area are the selling of agricultural produce and animals (goats, hens).

Specific details

In Ndego II, people were walking 6 km twice day collect water; the round trip took about two hours on foot and one hour on a bicycle. The water sources in the area include lakes and shallow wells (the wells were protected by NCA, Norwegian Church Aid). Water collection is done by women and children. In drought seasons some people hire others for water collection. In the communes hard roof coverage is 100%, each with a catchment area of only 15-20 m2.

Purpose for intervention in RWH

In Rwanda as a whole, gravity piped water schemes are common. However they are not easily applicable in the specific target areas of LWF. Rainwater harvesting has not been developed much in Rwanda, but the potential of assisting returnees is high. All the roofs in the communes are new and made from corrugated iron, which is an ideal solid catchment area for RWH. Also because of the six month long drought season there is a desperate need to alleviate some of the problems faced with extreme water shortages. Many of the tanks currently built are very costly and have limited capacity, which seems insufficient to assist them through the dry season.

Achievements of the Organisation

Some of the work in building tanks has been built on experience of the returnees from Tanzania seeing the Umutara tanks. The tanks were made from a basket of reeds covered with cement mortar and placed on a stone foundation. The inside of the tank is rendered with waterproof cement. Communities are required to organise them selves via meetings and to provide sand and stones. LWF provides cement, guttering and skilled labour. The organisation has provided credit not specifically for RWH, but to micro-financing and agricultural schemes. There has been very little capacity building through training. One training session for masons was conducted with twelve men and one female being trained in house construction.

Agency's opinion about effectiveness

- The organisation provide materials as a gift to returnees at the beginning, this is now being scaled down and will probably be on a oan basis in future.
- The involvement of CBOs in spring protection, shallow well and gravity flow scheme development. Water committees are formed and representatives are selected. Representatives come together and build up larger bodies for all water system management.
- The communities in Mugesera district were shown video's on RWH by women's groups from Kenya and other realisation developmental communications.
- On the means for collaboration, high demands from the returnees have initiated collaboration from UNHCR/ECHO. This has been used as a methodology to all developmental programmes. The beneficiaries put forward a request for the services they require rather than donors giving them what the donors wish to give.
- The organisation suggests starting with water tanks of small capacities (1.5 or 2 m3) for H/Hs; the more prosperous H/Hs can construct 5m3 water tanks.
- The organisation intends to create local capacities to take over the responsibilities after five years. The idea is still on trial to see if CBO's can look after themselves.

Observations:

- The organisation has had little dealing with RWH technology in the past, but it has a strong need to initiate the advancement of RWH in its region of operation.
- Some tanks in the community for returnees that were observed in the National Parks cost around RFr.20,000 (about $50) - the high cost was because of the high cement content, transport cost and for a technicians services.
- The area where the organisation is operating is still faced with new returnees and their resettlement, so the technology to develop at the beginning may require a push from the implementing organisation. The returnees have very little to offer and have very little material possessions, they lack any real land security during early resettlement and their contribution may be hard to mobilise.
- Depending on the distance from the existing permanent water sources (lake, gravity flow scheme) the idea of RWH can still be promoted as a jar or tank as an asset for a particular H/H giving water 'on the step'.
- The organisation needs to sensitise communities & train artisans from their area of operation on the new, available & affordable technologies in the region. Tours visits, and demonstrations could be the basic tools in disseminating the information about RWH technology.

Kigezi Diocese: Kabale

Organisation Location: Kabale

Visited by Swithen Nyakaana, May – July 2000

Population: 417,218

Kigezi Diocese Water Project is a church initiated project and aims to ease people's water shortage problems. The partners in funding at present are Tear Fund, Irish Embassy, DFID and the beneficiary- communities. The role of the beneficiaries' community is supplying locally available materials.

Administrative structure

Water Project staff comprises a programme co-ordinator (water engineer), an assistant water engineer charged with construction and an accountant. The organisation has a health component. There are four female co-ordinators responsible for monitoring/ functionality. The construction section consists of masons who build water jars/tanks, spring protections, san plats, and other constructions. The technicians are involved with the plumbing, pipe laying and tap-stand fixing. Higher cadre officers do the supportive supervision. Within the communities are organised through the LCs, opinion leaders, religious leaders and NGOs.

Topography and physical features:

Kabale District is high, cool and very hilly. Population density is very high and for many years Bakiga have been emigrating to other parts of Uganda, There are no significant rivers; springs are located down in the valleys and near to Kabale town there is the picturesque Lake Bunyonyi. The soils are very fertile for crop production, the though the area suffers soil erosion. Cultivatable land is covered with many stones, which makes tillage difficult. The soil is composition of inteharaea(?), murram, sandy/silty soils, and sandy loamy. Many stony grounds are porous, the ground is stable and could favour the use of ground tanks. Sandpits are located in the valleys; the sand is used in building construction.

Economic activities in the project area:

Economic activities in the area are basically subsistence farming, with crops of sorghum, beans, Irish potatoes, sweet potatoes, & millet.

Rainfall: 1000-1200 mm.

The area experiences two rainy periods of March to May and September to December.

Specific details

Most H/H experience water shortage, as springs are usually quite distant. There are long dry spells and small containers are used for RWH. A jar of 350 ltr costs USh.90,000/-. The water shortage is overcome by collecting water from distant places: lakes and permanent springs. RWH is practised by few H/H. Women and children collecting water from springs may be queuing up to an hour during the peak times, walking time for the round trip may be 1.5 hours, which is over steep terrain. Missionaries introduced gravity flow schemes as a means of reduce the amount of time and walking for water. Though gravity flow water routes are determined by the terrain, people who live uphill quite a distance away from a source have their water problems not solved but reduced. Those that have tried out RWH have faced such difficulties as scarcity of money buying sand and transportation of materials to site, skilled labour.

Purpose for intervention in RWH

The purpose for the organisation's intervention is to minimise water-borne diseases, to reduce time spent in water collection and to introduce new low-cost technologies for H/H water supply. The target group is the rural community at both institutional and H/H level, but focussed on relieving the water burden of women and children.

Achievements of the Organisation

The organisations entry point is at the parish level. The mobilisation and sensitisation is done by software on how the contributions are shared. Benefitting H/Hs are required to provide only 'local materials' i.e. earth mortar, while the project provides skilled labour, cement, moulds and gutters. Beneficiaries pay only USh.7000/- (out of a total cost of USh.90,000/-) for a 350 ltr jar. An average H/H can make 350 ltr last for 6 days. The organisation requests a payment for training artisans.

As a means of sharing their experience the organisation collaborates with the District Water Office (Health), LCs, churches, EU, DFID, Irish Embassy, women groups, Tear Fund, Rotary clubs and the government. This has helped the organisation in sharing experiences on new technologies, identified resourceful people and avoided the double counting of RWH structures.

Agency's opinion about effectiveness.

- The communities in the area of operation are poor so there is need to identify low cost technologies within the reach of the low-income base. Even a USh.50,000/- jar seems too expensive for the communities.
- Subsiding should be looked as the only means of encouraging people to start RWH.

Observations:

- The project contribution is very high, though some H/H do not seem to have picked up the donations. With more sensitisation many H/H are now welcoming the RWH technology.
- The organisation has not trained many artisans in the area. For all the works done, the project staff provides the skilled labour. For one to be trained he is required to pay for the training. The community solely depends on the project's skilled labour.
- The organisation has promoted water jars only where people have been looking at small structures. There is need to introduce new technologies, i.e. underground tanks, which are potentially lower cost per litre.

Domestic Roofwater Harvesting
Research Programme

THE OPTIMUM SIZING OF GUTTERS FOR DOMESTIC ROOFWATER HARVESTING

by Gwilym T. Still and Terry Thomas

December 2002

Development Technology Unit

School of Engineering, University of Warwick

ABSTRACT

Guttering, in a roofwater harvesting system, has the purpose of intercepting the roof run-off and conveying it to a downpipe (which in turn carries it to a store). The two phases of 'interception' and 'conveyance' make different and sometimes conflicting demands upon a guttering design. Their respective failures (overshoot and overflow) occur under similar circumstances, namely intense rain, and for most analytic purposes it is appropriate to consider as total water loss just the higher of the overshoot loss and the overflow loss, rather than their sum. A good gutter design must satisfy many criteria including durability, cheapness and ease of fixing. In this paper on gutter sizing, the primary approach is to find that gutter size and shape that maximises the ratio of water benefit to system cost. The work was motivated by field observation of evidently over-sized gutters and the absence of any published 'informed' guidance on sizing. The study entailed theoretical analysis, laboratory experimentation and some field studies. The findings are that:

(i) 'U' or trapezoidal-section gutters give the best economy,

(ii) roof area is the primary determinant of gutter size and

(iii) a 'U'-shaped or trapezoidal section gutter of width only 70 mm will be sufficient for most house roofs in the tropics.

The optimum gutter location and fixing trajectory are also explored to produce recommendations.

CONTENTS

PREFACE

This Working Paper summarises research performed over a period of 5 years by Warwick University's Development Technology Unit. Some of it is mathematically analytical or entails computer simulations, however all the more complex maths has been removed to the Appendices of the Paper. Readers who only seek the findings, rather than the route by which they were reached, are recommended to read just the Introduction and the Conclusions.

Several people have been involved in the work besides the two named authors. Inputs have come from engineering students at Warwick University, from members of Palm Foundation (Nuwara Eliya, Sri Lanka) and Uganda Rural Development & Training (Kagadi) and (under the aegis of a research contract from DFID, UK Govt) from a Research Associate at Warwick and subcontractors in Sri Lanka (LRWHF) and Uganda (ACORD). The authors wish to acknowledge financial support from DFID, the European Union and the Nuffield Foundation.

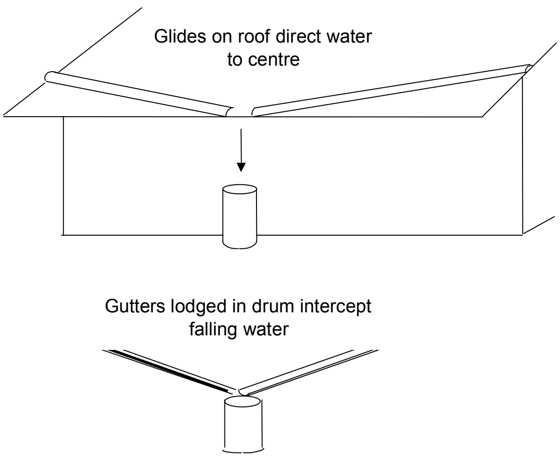
Gutter behaviour is very complex to analyse, yet RWH guttering design is not of such great economic importance that it justifies huge efforts to codify. The Paper exposes that complexity but then employs 'reasonable approximation' to reduce it to the point where simple design rules can be generated.

1 INTRODUCTION

Gutters are an almost essential but relatively cheap part of a roof-water harvesting (RWH) system. It *is* possible to collect roofwater without them by using instead glides or ground level troughs (Gould & Nissen-Petersen, 1999; Qiang & Fuxue, 1995) and some house geometries concentrate run-off from adjacent roofs into gulleys/valleys.

However the great majority of roof-water collection systems contain gutters to intercept run-off from the roof edge and convey it laterally to a downpipe leading to a tank

Figure 1.1: Alternatives to Roof-edge guttering



In temperate countries at latitudes above about 40^{o}, roof overhangs are often very small, so gutters are commonly installed to prevent rainwater running down the house walls and damaging them. In countries closer to the equator, the higher temperatures and higher sun angles make it attractive to project roofs 60cm or more beyond house walls to provide shading. Such large overhangs throw most roof run-off water clear of the walls, especially in single-storey buildings, and therefore guttering is not needed for wall protection. Any guttering that is installed must therefore be financially justified wholly by its contribution to water harvesting.

In addition to the prevalence of big roof overhangs, and sometimes of poorly aligned roof edges, the *humid* tropics are characterised by three features that impinge upon gutter design, namely:

- rainfall can be intense,
- the dry season is not long,
- household incomes are low.

Intense rainfall requires guttering of relatively high flow capacity: a design norm equivalent to rainfall intensities of say 1.5 to 2 mm per minute. The short dry season permits use of relatively small and cheap tanks: this in turn raises the fraction of RWH system cost attributable to guttering. Finally, low household incomes require low-cost RWH systems. These three factors result in the need to pay more attention to minimising guttering costs in the humid tropics than elsewhere.

Any observation of existing tropical RWH systems reveals many inadequacies in guttering (Gould & Nissen-Petersen, 1999), often resulting in the loss of over 50% of potential water yield. Gutter slopes may be inadequate or even negative; joints may leak; serious blockage by debris is common, as is twisting of gutter sections (resulting in spillage over their sides). In institutional systems, lack of clear management responsibility results in damaged or stolen guttering not being replaced, often leading to total failure of water delivery.

A 'failure' of a different kind is that both gutters and downpipes are often seriously oversized in domestic RWH systems. This may be due to the unrealistic choice of 100% as the design criterion for run-off capture. To intercept *all* run-off from the poorly aligned edge of a small house's roof may indeed require 100mm or even 150mm gutters, whereas to collect 96% of the run-off can be achieved with guttering of half the cost. Furthermore it is uncommon to find guttering economy given any attention when decisions are being made about tank location or tank height, so often gutters have to be designed for unnecessarily difficult conditions.

In some cultures it seems that aesthetics favour the selection of particularly conspicuous (large) gutters and pipes: in other cultures every attempt is made to hide them.

Finally guttering has a ‘health’ dimension, in that gutters can be a breeding ground for mosquitoes and in that gutters full of debris impart extra bacteria into the water they convey.

Ideally, guttering should be cheap to produce, efficient in capturing run-off water, easy to align and install, resistant to damage and (if not completely self-cleaning) simple to clean. The worldwide trend towards multi-storey housing increases the difficulty and even danger of installing and cleaning gutters, so that designs and attitudes adequate for RWH in rural homesteads in the past are unlikely to suffice for urban or rural housing in the future.

There has of course been some past research into guttering, but there is rather little one can refer to with respect to either the theory of its performance or to its performance in practice. Gutter manufacturers have undertaken tests of their own products and sponsored some research by others (for example into ‘downpipes for very large buildings). There are some standards (BS6367, 1983) and web pages. However very little of the published literature refers to conditions in poor tropical communities, to the specific context of roof-water collection or matches the information needs of promoters of RWH. The research reported in this Paper was therefore undertaken to extend existing guttering knowledge to better cover domestic tropical RWH, to fill gaps in that knowledge and to give certain aspects of gutter design a more scientific basis. Finally we have tried to translate our findings into ‘rules of thumb’ simple enough to be transmitted to RWH practitioners.

In the sections that follow we have concentrated on gutters proper, giving only brief attention to downpipes and avoiding any consideration of first-flush diverters or other devices sometimes incorporated into downpipes. Moreover our limited resources have led us to concentrate research upon gutter performance and sizing, rather than the equally important issues of gutter manufacture, design and durability.

The format of the paper is as follows. Sizing gutters for firstly water conveyance and then run-off interception are considered in isolation, giving some bounds on gutter size. Following this, modelling of gutter performance is conducted considering both these mechanisms acting together. Conclusions are given following analysis of the results.

2 SIZING A GUTTER TO CONVEY WATER

2.1 Capacity to convey water

Before examining the interaction of the conveyance and interception functions, we first fairly crudely examine conveyance on its own. We do this in order;

(a) to short-list configurations that are efficient at conveyance,

(b) to develop the conveyance model later to be used in combination with an interception model to produce an overall performance forecast and

(c) to be able to optimise gutters in situations where interception can be assumed to be near complete (e.g. where roofs are not corrugated and winds are generally gentle).

In this section we will consider sizing a gutter just to convey water from its entry into the gutter to the downpipe. The findings from the work are summarised in Appendix 1, which gives a more detailed explanation of the data used and analysis performed.

Sizing a gutter for conveyance involves modelling the flow within the gutter. The flow changes along the gutter, extra water coming in from the roof; so we are dealing with an example of spatially varying flow. There are difficulties with modelling this form of flow. Obtaining a full algebraic solution is not practical. So we developed instead a numerical model of this situation, and validated it via an experimental test rig. Further work yielded an asymptotic non-dimensional solution to the flow equation. [This was however only a second order solution, i.e. it was not exactly the solution of the original equation, but a very close approximation.] In this solution, the most significant term was equivalent to applying the long-established Manning formula:

$$Q = \frac{1}{n} a r_h^{2/3} \sqrt{S} \qquad \text{Equation 2.1}$$

Flow (Q) thus depends on the roughness of the gutter material (n), gutter cross-section area (a), hydraulic radius (r_h) and gutter slope (S). The roof area efficiently drainable by a gutter is proportional to Q.

However to this Manning term has to be applied a correction based on the aspect ratio of the gutter; namely the ratio of the gutter's length to its width. This correction gets smaller as the aspect ratio increases: i.e. as the gutter increases in length, the flow within it approximates more and more closely to that predicted by the Manning equation. As gutters in domestic applications nearly always have an aspect ratio higher than 100 (they are very narrow relative to their length), the correction to the Manning formula becomes sufficiently small that it can be neglected. The Manning formula alone may then be used to size gutters for water conveyance. Moreover, provided the roof area is not extremely squat (i.e. gutter length is not less than the slope-length of the roof perpendicular to the gutter), the gutter can be sized just according to the roof area, as is in section 4.7.

So we start by assuming all water falling on the roof also enters the gutter. If we now wish to minimise the system cost per litre captured, it can be shown (see Appendix 1) that a tropical gutter should be sized to match a rainfall intensity of around 2 mm/min of rainfall. (This intensity gives a gutter outlet flow of around 0.03 x A litres per second, where A is roof plan area.) As shown in Table 2.1, quite small gutters are adequate for rainwater conveyance from domestic roofs of representative areas.

Gutter trajectories where the slope varies along the gutter are also considered, leading to the conclusion that a gutter laid at a slope of α % at the outlet could be laid at $\alpha/2$ % for the first 2/3 of its length with no loss in conveyance capacity. This is covered in Section 2.3.

As we can achieve almost any flow capacity from a given gutter by making it steep enough, there is no meaning to 'optimum size' unless we first constrain the gutter slope. Moreover from just a conveyance point of view we would choose a deep gutter shape such as a square section or a deep-drawn 'U'. (Later we will find that for economy, interception requires a shallow shape.) Table 2.1 lists the roof areas that different sizes of square gutter could optimally drain at various given slopes.

As a further point of interest, it would appear that many downpipes are oversized: calculations given in A1.5. These suggest that pipes with bores around 40mm should give adequate capacity for the flowrates of interest.

Table 2.1: Optimum roof areas drainable by square gutters (considering only conveyance)

Square gutters	**Slope (%)**			
	0.5	1	2	4
Gutter width	**Optimum roof area gutter will serve (m^2)**			
33 mm	10	14	20	28
50 mm	29	42	60	85
75 mm	88	125	177	250
100 mm	190	269	380	538

Note that (sheet) material width is 3 times gutter width for this square section.

2.2 Gutter shape and conveyance

The effect of gutter shape on conveyance can be examined assuming the Manning formula for capacity is valid. Where it is, capacity is proportional to:

$$A_g^{5/3}\ p_g^{-2/3} \qquad \text{Equation 2.2}$$

Where A_g is gutter cross-sectional area and p_g is the length of the wetted perimeter of the cross-section.

Changing from square section (as in Table 2.1) to other common shapes (semi-circular, trapezoidal and vee) requires us to decide what is to be fixed. Two important strategies are: -

(i) holding the amount of material in the gutter constant – in effect we hold the gutter perimeter p_g constant. – so that gutter cost is kept approximately constant

(ii) holding constant the gutter width (its aperture and therefore its ability to intercept roof run-off).

Routine calculations then give us Table 2.2

Table 2.2: Roof areas drainable by gutters of different shapes (assuming square gutter is sized to drain 100 m^2)

Shape	square	semicircular	trapezoidal	vee (90°)
w / p_r	0.33	0.64	0.67	0.71
Strategy	**Roof area gutter drains (m^2)**			
(i) const p_r material	100	182	250	122
(ii) const *w* width	100	33	39	16

Thus on the criterion of flow capacity (and therefore roof area drainable) alone, for a given gutter *width* a square section is much superior to other shapes, while for a given gutter *cost* the square section is inferior. This switch reflects the low width-to-perimeter (w/p_r) ratio of the square shape. The trapezoidal shape is probably the best shape overall – the one used in these calculations has 'wings' set at 30° to the vertical and of the same size as the base.

2.3 Gutter trajectory (varying the gutter slope)

Hanging a gutter at a constant slope is easier than trying to follow a more complex trajectory. However this is not an efficient way of using a gutter of constant section: at rainfall intensities causing the lower (i.e. discharge) end of the gutter to overflow, the upper part of the gutter does not run full and is therefore 'oversized'. One option would be to steadily increase a gutter's *size* as one progressed from its top to its bottom end. This is not usually practical and a constant gutter section must be accepted. A second option would be to steadily increase the gutter's *slope* along its length. Here we explore the theoretical benefits of such a procedure to see if they might justify the extra complexity it introduces into gutter hanging.

At *constant slope*:

local slope is: $S(x) = S_o$, where x is distance from the top end and S_o is maximum slope,

local drop is

$y(x) = S_o\, x$ Equation 2.3

maximum drop is

$y_o = L\, S_o$ Equation 2.4

mean drop is

$y_m = L\, S_o /2$ Equation 2.5

However the most efficient profile for a gutter would be the one whereby (at the design rainfall intensity) the gutter was running just full at every point along its length. Manning's flow formula indicates that the local slope of such an 'ideal' gutter would need to be not constant but according to

$S(x) = S_o\ (x/L)^2$, where L is the gutter length.

At this *ideal slope*:-

local drop is

$y(x) = x^3\, S_o / 3\, L^2$ Equation 2.6

maximum drop is

$y_o = L\, S_o /3$ Equation 2.7

mean drop is

$y_m = L\, S_o /12$ Equation 2.8

Thus compared with constant slope, by using an ideal profile we have achieved a 6-fold reduction in the mean drop, giving thereby a probably substantial improvement in run-off interception. Alternatively we could have kept the same interception (same mean drop y_m) and have increased the maximum slope S_o by a factor of 6, thereby increasing gutter flow capacity by factor 2.45. A further option would be to commute this extra capacity into a smaller gutter size, thereby allowing use of a 29% smaller gutter (as $2.45^{-3/8} = 0.71$). These are significant benefits.

Hanging a gutter to such an ideal cubic trajectory is unlikely to become common practice. Gutters are not made to bend easily in a vertical plane. Moreover to avoid mosquito breeding we require all parts of a gutter to drain down after a storm has ended. So we avoid flat gutter sections and can contemplate changes in slope only at the joints between gutter sections. One simple compromise is the 'dual-slope' gutter whose upper end (length L_u) is laid at a low slope S_u and whose lower end (length L-L_u) is laid at full slope S_o. Using the Manning formula one can find by inspection that to minimise mean drop y_m the *best dual slope* arrangement is for

$L_u/L = 0.5$ and $S_u/S_o = 0.25$ giving a mean drop of $y_m = 0.22\ L\ S_0$

Comparing with the *uniform slope* gutter, this *best dual slope* represents, for constant mean drop, a flow capacity gain factor of 1.51 (which is significant) or a size reduction factor of 0.86 (not very significant).

In recommending dual slope to practitioners, we have to describe it in a simple and easily memorable form. It may be that

> *"Use a quarter slope for the upper half of the gutter length and full slope for the rest"*

is too complex, or requires too fine a level of slope measurement. For that reason we have also investigated a less efficient but more memorable dual-slope configuration, which uses "half slope" ($S_u = 0.5\ S_o$) and "full slope". A near-optimum and readily memorable form of this we may call *simple dual slope*

> *"Use a half slope for the first 2/3 of the gutter length and full slope for the rest"*

The numerical results of comparing *constant slope, ideal slope, best dual slope* and *simple dual-slope* gutters are given in Table 2.3. There we see that substituting *best dual-slope* or *simple dual slope* for constant-slope guttering is likely to yield significant improvement in run-off interception (via halving the mean gutter drop) and that for very long large gutters it may even be worth adopting a complex trajectory close to *ideal slope* to reduce gutter size.

Table 2.3: Comparison of gutter-slope options

Gutter slope		Max drop	Mean drop	Capacity* enhanced by
		y_o/S_oL	$y_m/2S_oL$	$(S_mL/y_o)^{0.5}$
Constant	$S=S_o$	1.00	1.00	1.00
Ideal	$S_o(x/L)^2$	0.33	0.17	2.45
Best Dual	$S=S_o/4$ & $S=S_o$	0.63	0.44	1.51
Simple Dual	$S=S_o/2$ & $S=S_o$	0.67	0.56	1.36

* Flow capacity subject to a fixed mean gutter drop y_m

2.4 Conclusions concerning conveyance alone

Because gutter length-to-width aspect ratio is so high, gutter flow can be calculated using the steady flow Manning's formula. This formula shows that for a given amount of material and given slope, square gutters convey less water than other common shapes. A trapezoidal shape is recommended.

Using such a shape, laid at a slope of 1% at its discharge end, a gutter width of 67mm (material width of 100 mm) should suffice to carry the water running off one side of a domestic roof. The gutter size giving best economy is one that overflows when rainfall intensity reaches about 2 mm/minute. A dual-slope (0.5% & 1.0%) trajectory will not compromise capacity but will approximately halve the mean drop along the gutter compared with a constant slope trajectory. its use is therefore recommended. Even bigger advantages would accrue if gutters could be laid to a $y = k x^3$ trajectory.

3 SIZING A GUTTER TO INTERCEPT RUN-OFF FROM A ROOF

We now move to consider the interception aspect of guttering, which in this section is treated in isolation, i.e. assuming that all water that is intercepted will be conveyed without spillage. In this case the only gutter dimension of interest is its 'aperture' *w*, namely the width of the opening at the top of the gutter.

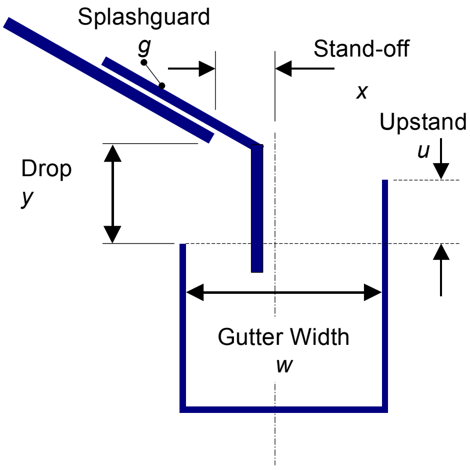
3.1 Characterising roof run-off

Water leaving a roof may collect at the edge and then fall in droplets, or it may leave in such a form as to give directed jets of water. This latter is particularly the case with corrugated roofs, where the corrugations act to concentrate the flow into channels, thereby increasing their flow velocity. By contrast, with tiled roofs the water is spread to such a fine layer that it rarely leaves the roof with a significant horizontal component to its velocity.

The performance of the gutter will vary from minute to minute, due to the ever-varying rainfall intensity. However the gutter designer needs an overall figure such as mean annual performance.

The interception performance of a gutter will depend primarily upon the dimensions labeled in Figure 3.1

Figure 3.1: Gutter Dimensions affecting Run-off Interception



These dimensions are, in declining order of influence,

i. Gutter aperture size (width *w*). The width of the opening at the top of the gutter will clearly affect its performance at collecting water leaving the roof. From the conveyance work in the previous section, we have in mind values around *w*=50 mm to *w*=100 mm; (2" to 4" gutters).

ii. Gutter drop *y*, measured from the discharge point on the roof to the top surface (level of water at overflow) of the gutter; spot values of 10mm and 100mm should cover the range of normal use.

iii. Gutter stand-off *x*, whose value is zero when the *centerline* of the gutter is directly below the edge of the roof.

iv. Gutter upstand *u* above its overflow surface. For symmetrical gutters this will be zero. For gutters with a raised outside edge this will be positive.

v. The presence or absence of a splash-guard on the roof edge directing water into the gutter: *g*=0 *or g*=1.

However besides the gutter dimensions many other factors affect interception performance, including:

i. Rainfall intensity.

ii. Wind strength.

iii. Backing – i.e. the presence or absence of a fascia board preventing wind passing across the gutter. Note that to be effective in controlling wind, such a board needs to be very close to the back of the gutter.

iv. Roof type – furrowed roofing gives a more strongly bunched and directed runoff than tile roofing.

v. Roof length *l* perpendicular to the gutter. For poor housing we might use *l*=2500 mm and *l*=3000mm, the latter being the length of a full GI sheet.

vi. Roof area draining into the gutter.

vii. Roof slope, which in the tropics typically lies in the band 15^o (S=0.26) to 30^o (S=0.5).

viii. Straightness of the roof edge (in plan) and the roof environment (e.g. overhanging trees).

It may be that a gutter sized to give sufficient flow capacity would not intercept sufficient water leaving the roof to make use of this capacity. Alternatively, sizing a gutter for interception alone would lead to an extremely wide, shallow gutter, which might lack the flow capacity to convey the water intercepted.

From observations by several fieldworkers, it would appear that except during the most intense rainfalls, water leaving the roof collects at the roof edge and then drips vertically, i.e. with negligible horizontal velocity. Such drips are strongly affected by wind around the gutter. Wind in turn is moderated by the presence of a fascia board. However it is intense rain that interests us most, because it generates such strong flows in the furrows of the roof that small jets are formed at the roof edge. These jets are more resistant to wind deviation but their velocity has a horizontal component that may carry them past the gutter's outside edge, resulting in loss through overshoot.

3.2 Gutter positioning in the absence of wind

Experimental work was conducted under laboratory conditions by two Warwick students, Boswell & Vispond, in 1997, simulating a range of rainfall intensities on corrugated roofs of varying length and slope. They found that the outward 'throw' of the run-off jets increases with roof slope, roof length and rainfall intensity, but that below certain levels of these parameters there was negligible throw.

For a representative roof (slope of 22^o), at rainfall intensities of 2 mm/min, the throw was found to be around 100mm at 100mm drop (slightly more for longer roofs). There is pulsation as the water leaves the roof, giving some variation in throw. The drop of 100mm was chosen, considering the previous work on conveyance, to be consistent with: a 1% gutter slope along a representative 10m roof edge.

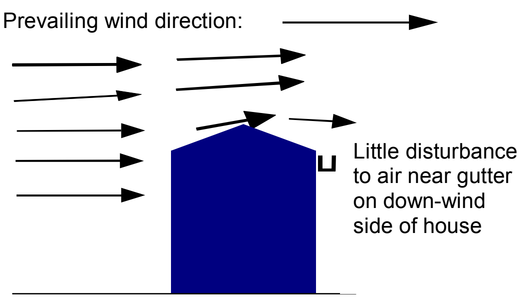
These results suggest that for likely gutter drops, to capture all the rainfall at intensities up to 2 mm/min requires a gutter stretching 100 mm outwards from the roof edge (requiring at least a *w* = 100 mm gutter aperture).

3.3 Effects of wind

Having obtained some data concerning the behaviour of water leaving the roof in calm conditions, it becomes necessary to consider the effects of wind. Wind is particularly important in the case of water dripping from the roof, as it will then be the only factor causing the water to deviate from a vertical path, and hence require a larger gutter.. However it is only wind perpendicular to the gutter that need concern us, since wind along the gutter can only generate a small end-loss.

One can argue that the wind is unlikely to be strong, and hence to have a significant effect on roof run-off, on the down-wind side of a house. Indeed wind below the roof edge on this lee side is probably an inwards-directed eddy rather than directed outwards. So we are primarily interested in wind influence on run-off on the *up*-wind side of a building. Here the effect of the wind is to reduce the outward throw, or in the case of 'dripping' run-off to impart a negative throw. This in turn requires the inside edge of the gutter to be set some distance *inside* the roof edge. Field observation suggests that provided the gutter inner edge is set about 20mm inside the roof edge, we need not worry unduly about wind effects.

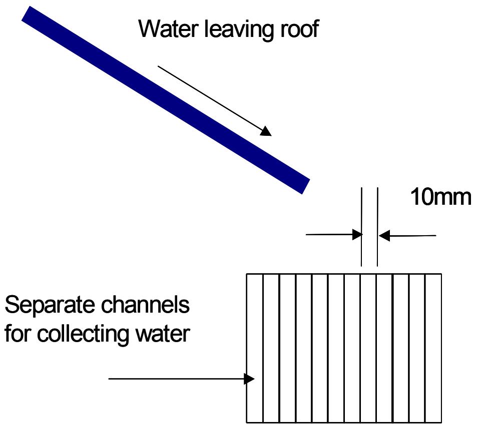
Figure 3.2: Wind flow past a building



3.4 Experimental evidence of gutter performance at intercepting run-off

Experimental work was conducted on GI roofing in Sri Lanka. Two roofs were used, one of 22^o slope and one of only 6^o slope. Both roofs were equipped with an experimental test rig that gave a distribution for the water leaving the roof to a resolution of 10mm:

Figure 3.3: Test rig for investigating roof run-off 'throw'



The distribution experiments were designed to allow the selection of an optimal gutter aperture, and give some indication of the trade-off, when increasing gutter slope, between increased flow capacity and reduced interception. To obtain an overall indication/measure of gutter performance, a number of rainfall events were sampled (more than 10).

Following collection of this data, it was observed that the rainfall leaving the 6^o roof fell within a narrow spread, and was not significantly affected by drop (y in Figure 3.1). This, suggesting the water did not acquire a significant velocity whilst on the roof, and that dispersal was caused by wind action.

An analysis similar to that described in the Section 3 on conveyance was performed, in which the gutter size was optimised to give the lowest possible system cost per unit of water collected. This is described briefly in 6A6.1.

This indicated that for a drop of 100mm, the economical gutter width w would be about 115mm, whereas for a drop of 10mm the size would be only *ca* 45mm. These figures apply to a 22^o roof angle and a 4 m long roof-slope. However the optima are not very sensitive to slope length. Both sets of results (6^o and 22^o slopes) indicated that water leaving the roof experienced a surface tension effect, causing it to curl back under the roof lip.

As the gutter itself will be at a slope, and hence the gutter drop y varies along its length, these values for respectively 100mm and 10mm drop may be taken as effectively maximum and minimum gutter sizes. Thus the optimum gutter width will fall within this range of 45mm to 105mm.

3.5 Summary of interception modelling

We have then performed two analyses, both assuming given values for roof-to-gutter drop. The first used rainfall simulations under laboratory conditions, and thereby showed the gutter aperture needed to intercept the same intensity of rainfall (2mm/min) as that already assumed for conveyance analysis. The second used data from fieldwork to optimise the aperture against a cost/unit water criterion.

Neither approach however generated an overall optimum gutter size, since neither determines the best slope of the gutter. Yet gutter slope generates the varying drop that causes the variation in performance along a gutter's length. We can however say, after placing an upper bound of 100mm on gutter drop y, that:

- the laboratory experiments place an upper bound of 120 mm on domestic gutter width,
- the fieldwork data places the optimum gutter width in the band 45 to 115 mm.

4 OPTIMISING SIZE & CONFIGURATION OF GUTTERS

4.1 Introduction to overall size optimisation

The previous sections have considered sizing gutters for interception or conveyance in isolation. This has been useful in giving some bounds to the size of gutter being considered, but cannot adequately simulate the interaction of the two in generating recommendations for gutter size and configuration.

Configuration is taken here to cover both the vertical trajectory of the gutter along the roof (the slope(s) it is hung at), and its horizontal position relative to the edge of the roof. To optimise guttering requires manipulation of these parameters in addition to gutter size. As mentioned before, changing the gutter slope will have opposite effects on the conveyance and interception performance. Both of these losses generally occur at the lower end of the gutter,[1] and so the smaller of the two will generally be subsumed in the larger when considering overall performance. Given the complexity of the interaction of these two phenomena, deriving a simple analytical model is not feasible.

So to obtain useful results, numerical simulation modelling was applied, which divided the gutter length into a series of small sections, and applied interception and conveyance criteria to determine the flow from one section to the next. Simulation was repeated over a full range of rainfall intensities, and, using information on actual tropical rainfall probabilities, the mean performance of the gutter was then calculated. Further details on the simulation are given in 6Appendix 6. Two simplifications are inherent in the model:

[1] The lower end of the gutter is the first place for interception losses to occur, and also for overspill from the gutter. With increasing rainfall intensity, overshoot will gradually occur further up the gutter, as will overflow. Overflow may also occur at the change in gradient if a dual-slope gutter has been used.

Firstly, the trajectory of the rainfall leaving the roof is assumed constant for a given rainfall intensity: pulsation effects are neglected. The losses from pulsation in one section would be opposed by gains in a separate section, so there is some justification for this.

Secondly, in the model each section as treated as having constant properties along its length. Maintaining a large number of section reduces inaccuracies arising from the use of such a numerical technique.

4.2 Gutter losses and overall losses

Gutters are part of a system that captures the rain falling on a roof and transfers it to a store. Not all the rainfall can be captured because of water-loss mechanisms. The four most important of these are:

i. Roof loss (due to splashing or absorption followed by evaporation): the latter is most prevalent during very light rainfall

ii. Gutter overshoot, due to inadequate gutter ‘aperture’, during intense rain or very strong winds: this is concentrated at the lower end of any gutter

iii. Gutter overflow during intense rain due to inadequate gutter capacity (itself a function of size, shape and slope): this normally takes place only at the lower end of each gutter

iv. Tank overflow occurring mainly when the rainfall in the say last 24-hours has been very high

These loss mechanisms interact, in that the same water cannot be lost more than once. Thus any process of calculating each loss independently and then adding them will seriously over-estimate the total loss. In the case of gutter losses (ii and iii), we should therefore calculate, for each rainfall intensity, both the overshoot fraction and an overflow fraction (assuming no overshoot), and then take the higher of the two to represent the loss due to the two mechanisms acting together. This is equivalent to the operation performed by the numerical model.

It is well established that it is uneconomic to provide a tank so large that there is never any tank overflow (loss mechanism). Indeed an economically optimum tank design is likely to give tank overflow in the range 10% to 30% of annual roof run-off. Because gutters are cheaper than tanks, when considered in isolation an 'economically optimum gutter' is likely to lose only 3% to 6% of annual run-off. A question to be answered in any analysis of optimum gutter-size is therefore: "what fraction of gutter losses may be discounted because they have already been 'counted' in tank overflow?"

A full analysis of the interaction between gutter-loss and tank overflow is very complex and also requires extensive meteorological data (concerning the correlation between intense rainfall and high daily rainfall). Ideally one would use ten years' of rainfall data sampled at 1 minute intervals. Unfortunately such data is almost unobtainable even for temperate climate sites let alone for tropical ones. We might however crudely test three propositions (approximations). In order to illustrate the discussions we will take the particular case where gutter loss is around 5% and tank overflow loss (assuming perfect gutters) would be 10%; thus apparent gutter and tank efficiencies are 0.95 and 0.9 respectively.

(Proposition A) Gutter loss is *uncorrelated* with tank overflow; so gutter optimisation can be performed without consideration of tank losses other than to multiply the calculated raw gutter loss by tank efficiency (here = 0.9) to estimate water actually lost to the consumer due to gutter losses. The total system loss would therefore be 14.5%, namely 4.5% attributed to gutters + 10% attributed to tank overflow.

(Proposition B) Gutter losses are *totally correlated* with tank overflows so that we may simply take the higher of the gutter's annual loss fraction and the tank's annual loss fraction as representing their combined effect. In our example total loss is 10% and the gutter loss, being the lower of the two, doesn't matter.

(Proposition C) Intense rain giving gutter losses *occurs on different days from* tank overflow, so that there is *negative correlation* between the two. Total losses are now simply the sum of gutter and tank losses –e.g. 5% + 10% = 15%.

Although the total losses are not much different under the three assumptions, the gutter-loss component changes considerably and it is on this component alone that we choose gutter size.

Under Proposition A, a reduction in gutter losses (by *z*% of annual rainfall) would cause a reduction of 0.9 x *z*% in overall losses, corresponding to an increase of 0.9 x *z*% in the percentage of rain captured. Under (B), gutter losses don't contribute to overall losses, and could be increased up to 10% without any loss in system performance: in this case the gutter is oversized. Under (C), any reduction in gutter losses will have an equal effect on system losses.

Gutter losses depend only on very recent rainfall – it takes on average about 10 seconds between a raindrop striking a roof and its water content reaching the discharge end of that roof's gutter. By contrast tank overflow is likely to take place during the wet season (because then the tank is usually already partly full) when at least 20 mm of rain has fallen within the last two days. During the dry season the condition changes to 'when at least 30 mm has recently fallen'. With the large tanks used in semi-arid zones, all tank overflow, like almost all rainfall, will be in the wet season. However with the smaller tanks appropriate to a humid zone, a fraction of both tank overflow and rainfall occurs in the drier season, when captured water is particularly scarce and valuable.

We therefore have a number of scenarios, given in Table 4.1:

Table 4.1: RWH Scenarios

Tank Size	Climate & Conditions	Comments
Large	Semi-arid, dry year	No overflow, so assumption (C) holds, and all gutter losses should be counted
Large	Semi-arid, wet year	Some overflow, hence assumption (A) or (B) holds, and around say 50% of gutter losses should be counted.
Small	Humid zone, wet season	Considerable overflow, so assumption (B) holds, and only an (unlikely) excess of gutter loss over tank loss should be counted.
Small	Humid zone, dryer season	Some overflow, so assumption (A) holds, and around say 90% of gutter losses should be counted.
Small	Humid zone, whole year	Mostly assumption (B) holds, but (A) is representative for some of the time, so count say 60% of losses.

For a semi-arid zone and a large tank, we worry most about 'drier than average' years so assumption (A) can be accepted and as a 'rule of thumb' 90% to 100% of gutter losses should be counted. For a humid-zone small-tank system we might count only 60% of gutter losses in realistically accounting for the impact of gutter overshoot or overflow, the other 40% being included within the usually larger tank losses.

4.3 Overspill/overshoot tradeoffs

As we have seen from Section 3, sizing for interception gives a larger optimum gutter size as the drop from the roof increases. Gutter performance would be improved if the mean drop along the gutter length could be reduced whilst maintaining the gutter's flow capacity. We therefore need to choose a trajectory that best trades off overshoot losses with overspill ones.

Other trade-offs include those involved with gutter shape. Some of these relate to the gutter performance in use, and others to manufacture. The optimum shape for interception is a flat plate, which will clearly have a useless conveyance performance. There is a difference in ease of manufacture as well. If the gutter is being made from sheet metal, each fold will require additional forming, while folding metal will be simpler than trying to produce a specified curvature.

4.4 Typical roof situation

Given the large number of possible roof configurations, an exhaustive search for optimum guttering in every case would be time-consuming. The approach taken was to consider some typical values and ranges, and see which variables or combinations of variables could be eliminated or simplified. Some parameters were fixed, namely:

Roof Material Corrugated GI roofing was chosen, for several reasons: It is a common roofing material in developing countries, and is becoming more widespread in its use. The corrugations act to concentrate the flow, increasing the velocity at which it leaves the roof. This then acts as a worst-case material; a predicted performance from corrugated guttering should be equalled or exceeded by other roof materials.

Roof Slope A slope of 22° was chosen as representative. Roof slope variation is dealt with further in Section 4.8.

4.5 Gutter shape

We may take gutter cost as being mainly dependent on the quantity of material used to produce it, which for sheet material is proportional to the perimeter p_g of the gutter cross-section. In the preceding sections it was observe that 'deep' shapes are desirable for water conveyance, wide (and therefore shallow) shapes are good for runoff interception. Here then is another conveyance *v* interception trade-off. Figure 4.1 shows the results of simulations for different gutter shapes placed at the dual slope (0.5% - 1.0%) already found to be optimum.

Figure 4.1: Overall performance of differently-shaped gutters

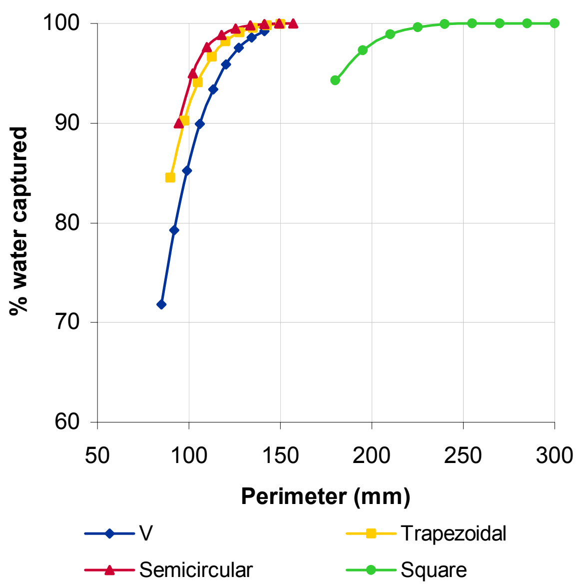


Figure 4.1 is illustrative of the situation for a range of gutter sizes. There is a distinct extra cost to using a square cross-section, because it has only a small aperture. There is however little difference between the remaining three gutter cross-sections, semi-circular, trapezoidal and vee: all have similar performance for equal material quantities. This is not surprising since both the aperture-to-perimeter ratios (w/p) of the three sections and their √area-to-perimeter ratios are similar as the following table shows.

Table 4.2: Properties of different gutter shapes

Cross-section	Ratio (√area)/p	Ratio *w/p*
Semicircular	0.40	0.64
Trapezoidal	0.41	0.67
Vee	0.35	0.71
Square	**0.33**	**0.33**

At this point the analysis simplifies, as from now on we may consider only one section, We reject the square section and choose as our norm for analysis the trapezoidal section (with wings set at 30° to the vertical). We know that substituting either semi-circular or vee shaped gutters would give very similar economic performance.

4.6 Gutter slope and trajectory

In the context just of conveyance, different gutter trajectories were discussed in Section 2.3. That discussion identified an 'ideal' but impractical trajectory of constantly-varying slope and a more practical 'simple dual-slope' trajectory that performed better than a fixed slope one. We can now examine the overall (interception plus conveyance) performance of a few promising trajectories. We have selected two candidates for the shape of the trajectory, namely uniform slope and simple dual slope., and we combine these with different mean slopes to give six rival configurations. These six, listed in Table 4.3, were tested in the overall model and their gutter efficiencies plotted against gutter width for a variety of roof lengths. (A rainfall intensity distribution representative of the humid tropics was used in combination with a trapezoidal gutter shape – see Appendix 6 – and the mean annual gutter losses were calculated.).

Table 4.3: Six gutter-slope configurations

Config No	Description	Slope of gutter (%)		
		First 2/3	Last 1/3	Mean
C1	low dual slope	0.25	0.50	0.33
C2	**medium dual slope**	**0.50**	**1.00**	**0.66**
C3	high dual slope	1.00	2.00	1.33
C4	low constant slope	0.50	0.50	0.50
C5	medium, constant slope	1.00	1.00	1.00
C6	high constant slope	2.00	2.00	2.00

The most efficient configuration (highest water capture for given roof and gutter material) was found to be C2, shown bold in the table above (Dual-slope: 0.5% & 1%). The two high slope configurations, C3 and C6 performed poorly. The remaining configurations, C1, C4 and C5, were a little inferior to C2. We therefore carry C2 forward as a recommended norm.

4.7 Roof area and shape

For a given roof area, increasing the gutter length will reduce the roof-slope length perpendicular to the gutter. The lower roof length will reduce the exit velocity of the water, but the longer gutter will develop a larger drop at its discharge end. So there are opposing effects acting on the interception performance. To test the proposition that roof area determines gutter performance independent of the shape of that area, several configurations were considered in which the aspect ratio of the roof area (gutter length / roof-slope length)was varied from 1 to 4:

Table 4.4: Various roofs used in modelling

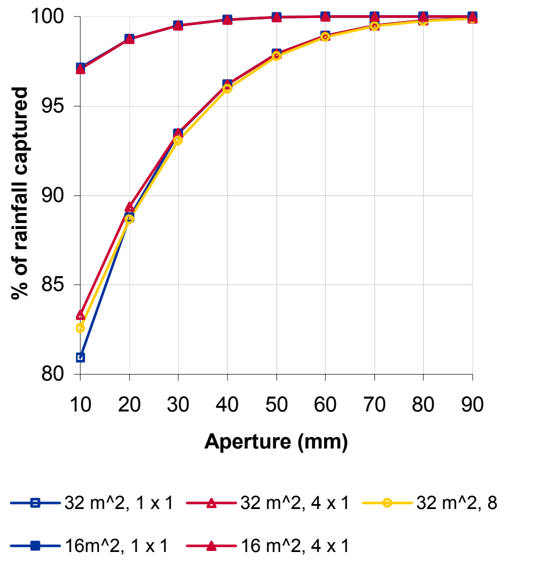
Roof-plan area* (m^2)	Gutter length (m)	Roof-slope length (m)	Aspect ratio
16	4.2	4.2	1
16	5.9	3.0	2
16	8.4	2.1	4
32	5.9	5.9	1
32	8.3	4.2	2
32	11.8	3.0	4

Note that roof plan area is smaller than roof length times depth, as the roof is not horizontal.

The performance of these configurations is shown in Figure 4.2.

As would be expected, for a given gutter size a higher fraction of yearly rainfall is captured on the smaller roof area. The more interesting feature of the efficiency plot however is the similarity in performance for the different roof shapes (aspect ratios from 1 to 4). This suggests that the effects of reduced mean drop and increased exit velocity (from using a low roof aspect ratio and hence a short gutter) largely cancel within our region of interest. Thus *we may size gutters according to the roof area*, rather than according to gutter length and roof-slope length considered separately

Figure 4.2: Gutter efficiency v roof size and shape



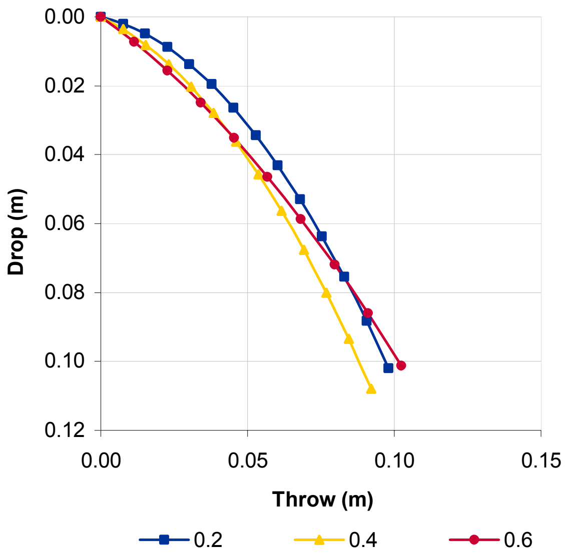
4.8 Roof slope

We might expect variation in the roof slope to alter the trajectory of the water leaving it. Analysis of the laboratory work conducted certainly shows that an increase in roof slope also increases the exit velocity of the water. Figure 4.3 shows jet trajectories leaving 4.2m-long roofs of 11°, 22° and 31° for rainfall intensities of 1 & 2 mm/min. In the region of interest (drops from 0 to 10cm), the throw from the 22 and 31° roofs are very similar. In addition to this, the throw from the 22° roof is larger initially, and there is then a cross-over point. For the lower rainfall intensity, the trajectory from the roof is greater for the lower slope.

The small variation with slope, and crossover within the area of interest indicate that gutter sizing is not very sensitive to variation in roof slope within the region of interest. For the normally-found roof slopes we may safely size gutters without taking actual slope into account.

The data from Sri Lanka and experimental work suggest that at untypically low roof slopes (less than 10°) the water leaving the roof has little velocity, so at this point there is some risk of gutter over-sizing.

Figure 4.3: Effect of roof slope on run-off trajectories



4.9 Reducing the number of variables

In Section 3.1, fourteen variables were listed as affecting 'interception', itself only one aspect of gutter performance. Such complexity is not acceptable in selecting an appropriate gutter size. However in the preceding sections we have considered many of these variables. For each we have identified a suitable 'good' value or we have shown that its influence on gutter performance is negligible. Thus we have reached the point of recommending:

i. a dual-slope gutter (with a slope in the region of 0.5% for 2/3 of its length, 1.0% for the remaining 1/3 of its length);

ii. a trapezoidal or semi-circular gutter shape;

iii. that the inside edge of the gutter be 20mm inside the roof edge;

iv. that roof *shape* can be ignored and only roof area considered;

v. that gutters correctly sized for a roof slope of 22° will also be good for common roof slopes from 15° to over 30°, thus we do not need to know roof slope;

vi. that within the humid tropics exact location and climate are not critical and we may assume a representative rainfall intensity distribution;

vii. that (common) corrugated iron roofs represent a worst case – gutters sized for CI will be adequate for other roofing types.

We are therefore now ready to explore optimum gutter size with only one variable left, namely roof area.

4.10 Economic gutter optimisation

We can define the optimum size (w=w_0) of a gutter as being the value that maximises the ratio of annual water captured Q to system cost and readily show (see Appendix 7) by standard calculus that this condition is met when:

$$S_{Q,w} = \frac{dQ/dw}{Q/w} = a \,.\, \lambda \qquad \text{Equation 4.1}$$

Where

$S_{Q,,w}$ is the sensitivity of annual gutter discharge (Q) to gutter size (w)

a is the sensitivity of gutter cost to gutter size (typically 0.6) and

λ is the fraction of total system cost caused by the gutter cost (typically 0.15 in small systems).

The sensitivity $S_{Q,,w}$ varies not only with gutter size but also with the site's rainfall intensity pattern, roof size, shape and type, gutter shape and location relative to the roof edge. However we can choose single representative values for all these variables except roof area. A_g. For each value of A_g, that leaves $S_{Q,,w}$ as only a function of gutter size w.

For very small gutters, the annual captured flow Q will be low but the sensitivity S high. As we make the gutter steadily larger, Q will rise and S will drop, until at $w = w_0$ the equation above is satisfied. In practice therefore we plot S against w and note where the locus crosses the value aλ. Under some circumstances, discussed in section 4.2, only a fraction μ of the gutter losses should be counted, since some gutter losses only serve to reduce tank overflow rather than reduce water capture. For small-tank systems in the humid tropics it was argued that we might adopt the value μ=0.6. Under these circumstances our criterion for optimum gutter size changes to:

$$S_{Q,,w} = a\lambda/\mu \qquad \text{Equation 4.2}$$

typically 0.15.

Table 4.5 shows the application of this formula to find the optimum gutter width for a roof area of 16 square meters. This is a typical area for one side (and therefore one gutter) of the roof of a small rural home.

Table 4.5: Gutter optimisation for trapezoidal gutter, humid tropics, roof area A_g=30 m^2 and $a\lambda/\mu$=0.15

Gutter width *(w)* mm	Gutter annual efficiency (%)	$S_{Q,,w}$
60	84.5	0.81
65	90.3	0.55
70	94.1	0.38
75	96.6	0.24
80	**98.2**	**0.15**
85	99.1	0.08
90	99.6	0.04
95	99.8	0.02

Note: Optimum size ($w = w_0$, when $S_{Q,,w} = a\lambda/\mu$) is shown in bold.

The process used in this table was then repeated for other roof areas to generate Table 4.5, which therefore constitutes the basic output of this Working Paper. From the figure we can also deduce that the sensitivity of ideal gutter width to roof area is around 0.35.

Moreover we may use the economic optimisation model to confirm some of the assumptions listed in Section 4.9.

In particular it was found that the variation of optimum gutter width across the three locations (climates) Lae, Kampala and Surabaya was only ±3% about the value obtained using a rainfall intensity distribution averaged over all three sites. So it seems reasonable to suggest that the results found may be generalised across the humid tropics.

5 CONCLUSIONS

Having examined by field observations, laboratory experiments and computer simulations the situation of gutter size and position for roofwater harvesting in humid tropics, the following gutter widths are recommended

Table 5.1: Recommended gutter widths for use in the humid tropics

Gutter width (mm)	Roof area in (m^2) served by 1 gutter
55	13
60	17
65	21
70	25
75	29
80	34
85	40
90	46
95	54
100	66

These figures are smaller than common guttering sizes used in the tropics and indicate there are opportunities for cost-savings. Thus even a quite large house, roof 10m x 6m, requires only a 75 mm (3”) gutter on each side.

Variations in roof slope between around 20^o and 30^o have negligible effect on gutter size requirements. When the roof slope drops to around 10^o there is a significant drop in the velocity of water leaving the roof and slightly smaller gutters might be used.

For realistic roof shapes, gutters may be sized simply on the basis of the roof plan area each serves rather than via separate consideration of gutter length and roof-slope length.

Trapezoidal, semicircular and Vee-shaped gutters give somewhat similar economic performance in intercepting and conveying roof run-off water. Choice between them can therefore be made on the basis of ease of manufacture or self-cleaning properties (Vee shapes become blocked rather frequently). Rectangular gutters however do not make efficient use of material.

Gutter mean slopes should be small, normally under 1% - and there is a small advantage in giving a gutter a dual slope such as 0.5% for the first 2/3 of its length, 1.0% for the final 1/3 to the outlet point. No part of a gutter should however be laid flat in an area subject to mosquitoes. In cases where roofs are not accurately aligned, higher slopes may be needed or the gutter direction should be decided only after the roof-edge slope has been measured.

APPENDICES

APPENDIX 1 CONVEYANCE ANALYSIS

Section A1.1 will examine the economics of sizing gutters for their capacity to convey the water entering them. This leads to the suggestion that gutters should be sized for rainfall intensities of around 2 mm/min.

In section A1.2, the theory and calculations for sizing gutters are covered. This is followed by brief details of experimental work conducted (section A1.4), and sizing tables for downpipes (section A1.5).

A1.1 Describing the flow distribution

A gutter that is 'too small' will, under very heavy rainfall, spill some of the water it is trying to carry. A gutter that is too big will cost too much.

The cost of spilling water may be just the value of the water not conveyed, or it may be higher (if overflow causes damage to the building) or lower (if the overflow would have been discarded anyway due to tank overflow or inadequate tank inflow capacity).

As mentioned earlier, in the context of rainwater harvesting in the humid tropics, most buildings will have a considerable roof overhang. In this case, the cost of letting water overflow is likely to be equal to or less than the value of the water not conveyed to a tank.

From the analysis that follows, it appears that it is generally economic to make gutters large - for example so large that only 1% of the roof runoff overflows the gutter system.

In any economically viable roofwater harvesting system, the amortised value of the water collected is greater than the capital cost of the system: in the ensuing analysis, however, we will assume a 'just-economic' RWH system in which the amortised value of the water *equals* the system cost. We will also assume:

(a) The value of water, per litre, is constant, so that a 1% increase in water harvested represents a 1% increase in user benefit.

(b) There is sufficient storage that increasing gutter output by 1% will increase water available for consumption by 1% too.

Clearly both these assumptions are debatable and could be altered: however that would introduce unwanted further complexity into the basic analysis below.

The cost of guttering can vary considerably from system to system, for example, in one $10m^3$ system the guttering was 12% of the system cost, whereas in a (600) system the figure was 30% (DTU Working paper 55). In this analysis a mid-range figure of 20% will be used. Therefore, under the assumptions just made, increasing gutter size in order to collect more water is always worthwhile, providing that the fractional increase in gutter cost does not exceed 5 times (100% / 20%) the fractional increase in water harvested. The analysis below refines this statement.

A1.2 Strategy for optimising gutter size for conveyance alone

A1.2.1 Formal modelling

At some representative sites, data can be obtained for the rainfall intensity i, giving a probability distribution $p_r(i)$. To find the gutter inflow Q_i we multiply the intensity by the roof area, a runoff coefficient C_r and an interception coefficient C_i. These may be treated as a constant, Ω, for a particular roof. Q_i is a flow rate, as is the gutter capacity Q_d. The conveyance coefficient (or 'efficiency'), C_c, is the fraction of Q_i that is conveyed by the gutter to the tank.

Knowing the gutter shape, and keeping other factors such as slope constant, increasing the gutter capacity Q_d by 1% will have a certain effect on the total cost of the system. From applying the Manning formula to the flow in gutters (the validity and specifics of this is discussed in section 3.3), the gutter size will require a 0.4% increase. This can then be adjusted to take account of the change in materials and manufacturing cost of the gutter, to give a say 0.36% increase in gutter cost. [2]

As previously mentioned, the cost of the gutter as a fraction of the system cost may be taken as 20%. This means that the 1% increase in gutter capacity will result in only a 0.072% increase in the system cost.

Increasing the gutter capacity by 1% will also increase the quantity of water captured by the system, as expressed as the capture coefficient C_c.

Within the context described, it is economically sound to continue mentally increasing the gutter size until the percentage increase in C_c falls to that of the increase in gutter cost, i.e. 0.072% for each 1% increase in gutter capacity. After this point, any further increase in gutter cost will further increase the quantity of water harvested, but will not give a superior performance measured by cost per litre of water captured.

For a particular rainfall intensity probability distribution $p_r(i)$, an exceedance function $P_r(i)$ may be defined, giving the fraction of time that the rainfall intensity exceeds any threshold i.

A given gutter arrangement will have a flow capacity Q_c at which it overflows. This can be expressed as a corresponding rainfall intensity I. It is also possible to calculate the fraction of water spilled by the gutter, $sp(I)$, and hence the gutter efficiency $\eta(I)$. These performances will be for an entire year of operation, not a single rainfall event. At this point we need to use the concept of sensitivity. For two variables A and B, $S_{A,B}$ is the sensitivity of A with respect to B. This may be thought of as the percentage change in A for a 1% change in B.

The conveyance coefficient (C_c) for a particular gutter is a complicated function of the gutter's flow capacity (Q_d), the rainfall intensity distribution $P_r(i)$, and Ω (the roof area multiplied by roof run-off coefficient). As the gutter inflow is proportional to the rainfall intensity (runoff and interception coefficients being known), the exceedance curves for gutter inflow Q_i and for rainfall intensity i are therefore simply related:

$$P_{Qi}(i\Omega) = P_r(i) \qquad \text{Equation A1.1}$$

From the theory included in Appendix 2, the sensitivity of conveyance coefficient to gutter capacity is given by:

$$S_{Cc,Qd} = \frac{I}{i_{mean}} \frac{P_r(I)}{\eta(I)} \qquad \text{Equation A1.2}$$

As the gutter efficiency tends towards 1, this simplifies to:

$$S_{Cc,Qd} = \frac{I}{i_{mean}} P_r(I) \qquad \text{Equation A1.3}$$

Where i_{mean} is the mean rainfall intensity.[3]

[2] The sensitivity of gutter depth D to gutter cost C_g is typically about 1.1 for gutters of fixed proportions cut from constant thickness sheet, although it would be as low as 0.6 if gutter thickness were kept proportional to its depth. In this analysis it is taken as 1.1, so the sensitivity of gutter cost C_g to gutter depth D is 1/1.1.

[3] In the calculations performed, the efficiency of the system has been included.

We are interested in the case where $S_{Cc,Qd} = 0.07$, so we require $\frac{I}{i_{mean}} \frac{P_r(I)}{\eta(I)} = 0.07$

For high rainfall intensities, the following formula may be used for the exceedance function:

$$P_r(i) = ae^{-bi} \qquad \text{Equation A1.1}$$

Our task now is to find what gutter size gives the required value to $S_{Cc,Qd}$. [4]

Data has been obtained for actual rainfall distributions for three locations in the humid tropics, namely Uganda (Kampala), New Guinea (Lae) and Indonesia (Surabaya), and is included in Appendix 3.

This leads to the suggestion that the gutter should be sized for rainfall intensities between 80 and 120mm/hour (1.3~2mm/min).[5]

A1.3 Theory of Flow in Gutters

Moving along the gutter towards the outlet at the downpipe junction, the amount of water flowing in the gutter increases, as more water is fed into it from the roof. This is an instance of what is termed spatially varying flow. In some cases, such as corrugated roofs, the water enters the gutter in discrete jets, one jet coming from each furrow. With other roofing materials the flow may approach a continuous sheet, although in most cases it will remain discrete.

Within the context of sizing the gutter, we will deal with the situation where the flow entering the gutter is known. It is relatively simple to calculate the quantity of water falling on the roof, taking account of roof dimensions and slope.

In this case, we wish to be able to choose gutter size, cross-section, slope and material (within limits set by the situation) to give a system that will convey all the water for a selected rainfall intensity from its entry to the gutter into the downpipe. The value of 2mm/min as a sensible maximum intensity is argued for in A1.2 and Appendix 3, and the design calculations have been performed assuming all water falling on the roof is intercepted. Although this will overestimate gutter size, there are arguments for the validity of making this assumption, including system degradation over time and probability of errors in configuring the gutter.

This system should be the cheapest possible, so quantities of materials should be reduced, as should complexity of manufacture. In some cases there may be considerable flexibility in gutter size possible, particularly if the gutter is being made locally by artisans. There will be other situations however where guttering is more readily available in standard sizes, from industrial manufacturers. The local situation will dictate which is more economically attractive-if an oversized extruded PVC gutter is cheaper than a smaller locally-made gutter, then clearly the former should be used.

A1.3.1 Parameters

The following factors will influence the flow in the gutter, and should therefore be considered when designing the guttering system:

---

[4] Interestingly, European standards for gutter capacities (where damage from overflow is the main concern, not rainwater harvesting) are set extremely high, corresponding to rainfall intensities I which are exceeded for less than 1 minute per year ($P_r(I) = 2\text{x}10^{-6}$)

[5] Logically the capacity Q_f of any tank inlet filters should be made to match the gutter capacity Q_d.

A1.3.1.1 Gutter material

This will affect the frictional force opposing the flow (quantified by the Manning roughness factor). The rougher the surface, the greater the resistance the water will experience, and hence the lower the gutter capacity.

This will be examined in greater depth later in section A1.3.2.1.

A1.3.1.2 Gutter cross-section

Different shapes and sizes of gutter will have different performances in otherwise identical situations. For example, a flat, wide gutter will have a greater resistance to flow when full than a semi-circular gutter of the same cross-sectional area.

There are likely to be local limitations on dimension (for example, standard sizes if mass-produced guttering is being bought/made from piping).

There are a series of common sizes of guttering used in industrialised countries. Obviously some of these shapes are more complex than can be reasonably treated by this paper, including the standard 'K' shape. It is hoped that the shapes considered will be best suited to the developing countries context. The most commonly used shapes are: semi-circular, rectangular, v-section and trapezoidal.

Standard sizes tend to be based upon gutter aperture: the width w of the top of the gutter. Common sizes range from 50 to 100mm.

A1.3.1.3 Roof dimensions

The edge-length, slope and roof-slope length (length of the roof perpendicular to the gutter) all influence the quantity of rainfall to be conveyed by the gutter. The edge-length clearly influences what gutter length will be required; the slope and roof-slope length will, (along with the rainfall intensity) fix the flow intensity leaving the roof.

A1.3.1.4 Maximum rainfall intensity to be accommodated

This has been discussed in section A1.2 and Appendix 3. Design and sizing recommendations produced are those to give a system that can convey all the water from a 2mm/min rainfall event, using coefficients for runoff and interception of 1.

A1.3.1.5 Gutter slope

Maximum permissible gutter drop will be influenced by both the throw from the roof (considered in section 1) and the gutter attachment methods to be used, both in terms of materials required, performance of fixings, and limits set by features such as fascia board dimensions. The maximum drop limits the mean slope of the gutter. For domestic roofwater harvesting, a slope of 4% is felt to be a reasonable maximum[6].

A1.3.1.6 Gutter outlet conditions

This will have some effect on the depth profile of the gutter flow. With a gutter unblocked at its lower end, the water flowing out is accelerating in the region of the outlet, hence reducing the depth of flow there for a given rainfall intensity.

An identical effect can be found when the flow from the gutter enters a downpipe that is not running full.

[6] Such a slope would give a drop of 100mm in 2.5m of guttering. Larger drops than this would cause difficulties in mounting the gutter (from limited fascia board depth etc), and would suffer from poor interception performance.

In both cases, this "draw-down" effect is beneficial, as it reduces the maximum depth of the water in the gutter for a given rainfall intensity. Hence a gutter experiencing this effect would have a greater capacity than one that was not.

However, experimental work suggests that this effect is not sufficiently significant to be worth considering in the design procedure.

In this case, it is sufficient to ensure that the outlet will not run full and increase the depth of flow within the gutter. The sizing of downpipes is covered briefly in section A1.5.

A1.3.2 The Manning Formula

The simplest theory to use within the context of flows in gutters is the Manning formula:

$$Q = A\frac{1}{n}R^{2/3}\sqrt{S}$$

Equation A. 1.4

Where Q= flow in channel (m^3/s)

A= cross-sectional area (m^2)

v= velocity of flow in channel (m/s)

n= Manning roughness coefficient

p_w= Wetted perimeter (m)

R= Hydraulic radius (m) ($R = \frac{A}{p_w}$)

S= Slope

There are some theoretical objections to the validity of applying this to the flow in gutters. The Manning formula is derived assuming a constant flow, and that the flow has reached an equilibrium. Neither of these is the case for the flow in gutters. The flow in gutters approaches the Manning solution as the gutter becomes longer, but does not reach the flow conditions described, hence the Manning formula will give an over-estimate of the performance of a set gutter.

A more appropriate area of fluid dynamics to apply to the flow in gutters is that of spatially varying flow. This was developed by Garcia (2000) and Still (2001) (in conjunction with Lucey). The details of the theory are unlikely to be of interest to all users, and so have not been included. Further information is available on the web at: http://www.eng.warwick.ac.uk/dtu/pubs/rn/rwh/ugp014_still.pdf

The spatially varying flow work allowed the generation of flow profiles-predicted depths of flow at varying points along the gutter. The approach taken to obtain these flow profiles for gutters was to use a non-dimensional asymptotic solution to the model developed. In essence this consisted of an initial solution which is equivalent to using the Manning formula, and corrective terms to account for the difference in the flow distribution. The corrective terms are based upon an aspect ratio, that is a ratio of gutter length to a cross-section dimension (width). As this increases, the deviation from the flow predicted by the Manning formula decreases. In the case of guttering, this aspect ratio is often of the order 100~1000, and so the corrections to the Manning formula become small enough to be neglected. In this case, analytic results can readily be obtained for different gutter cross-sections, slopes etc.

A1.3.2.1 Manning roughness coefficient

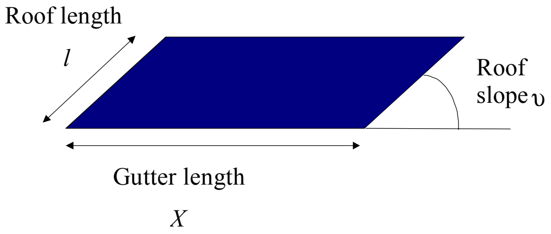
There are various possible values for this, according to the material being used in the gutter. For smooth PVC values of 0.009~0.011 are suggested. It is likely that in use some sediment will collect in the gutter, and that this will increase the frictional resistance to flow in the gutter.

One source suggests "for gutters with small slopes, where sediment may accumulate, increase [the Manning roughness coefficient] by 0.002." This would lead to a reduction in capacity of around 20%, which seems plausible. To take account of the effect of joints etc, a figure of 0.015 has been used in the sizing calculations.

A1.3.2.2 Using the Manning formula

Sizing calculations using the Manning formula are relatively simple (particularly compared to the spatially varying flow model).

Figure A. 1.1: Roof dimensions.



The assumption will be made that the gutter is being sized so that it is at the point of overflowing at the outlet end.

For this case, the flow within the gutter is expressed as a multiple of the rainfall intensity, *i* (mm/min), the gutter length, *X* (m), the roof length *l* (m), and the roof slope *θ*, as illustrated above in Figure A. 1.1. If the cross-sectional area and hydraulic radius are evaluated for the gutter running full, then the roof area at which the gutter will reach this stage can be calculated:

$$Roof\ area,\ A_{rg} = \frac{60\,000}{nl\cos\theta}\sqrt{S}R_H^{2/3}A$$
$$= \frac{60\,000}{nl\cos\theta}\sqrt{S}\,\frac{A^{5/3}}{\wp^{2/3}}$$

Some sensitivity analysis is possible from this:

$A_{rg} \propto \frac{1}{n}$: the roof area that can be covered by a gutter is inversely proportional to the manning roughness coefficient of the gutter material, so a 10% increase in the roughness value arising from gutter degradation over time, effects of joints etc will lead to a 10% decrease in the roof area the gutter can convey water from.

$A_{rg} \propto R_H^{2/3}A\,; R_H = \frac{A}{\wp}, R^{2/3}A = \frac{A^{5/3}}{\wp^{2/3}}$: generally, $A \propto Cross - section\ dimension^{\ 2}$, and $\wp \propto Cross\text{-}section\ dimension$, so

$\frac{A^{5/3}}{\wp^{2/3}} \propto \frac{(Dimension^2)^{5/3}}{Dimension^{2/3}} = Dimension^{8/3}$, so the roof area that can be covered is sensitive to a scaling in cross-section.

The hydraulic radius of cross-sections can be used as a measure of the efficiency of that shape for carrying water. The lower the hydraulic radius, the greater the wetted perimeter for a given cross-sectional area of water, and hence the poorer the performance for a given cross-sectional area and slope.

A1.4 Experimental evidence of gutter flow capacity

A test rig was to simulate water leaving a roof was constructed at Warwick University. This enabled measurement of the flow profile within the gutter for varying gutter cross-sections, slopes and simulated rainfall intensities. These profiles were compared with predicted profiles using the spatially varying flow theory and a numerical technique. A good match was found between the measured and the predicted profiles. This was taken as validation of the theory. Plots of the results may be seen on the website mentioned above.

A1.5 Downpipe Sizing

There are well-established procedures for estimating the maximum gravity-driven flow that will occur through a piping system - its so-called capacity Q_c. Unfortunately these procedures are too complex for general use in roofwater harvesting and need to be replaced by simpler ‘rules of thumb’ or design tables.

For a very long vertical pipe we can experimentally determine its capacity $Q_c = Q_m$. This will be the highest gravity flowrate we can get through a pipe of that size and is tabulated below. The term ‘very long’ indicates that secondary effects, like turbulence at entry or the presence of sharp bends, can be neglected and the flow obtainable only depends on the friction in the pipe itself. For any pipe, the *total head loss* h_L must equal the *actual drop* h_D (from the water surface at the top to the water surface at the bottom of the pipe run). For a vertical pipe this drop is the same as the pipe’s length L. For non-vertical pipes, h_L still equals h_D but $h_D = S \times L$ where S is the effective slope of the pipe. The capacity of a long sloping pipe is naturally less than for a vertical one. The table below shows the capacity of long smooth pipes of various internal diameters. Capacity is roughly proportional to the square root of the slope S. Thus at a slope of only 10% ($S = 0.1$) the capacity is only about 30% that Q_m of a vertical pipe.

Table A1.1: Ideal flow capacities of smooth downpipes running full

Internal Diameter	Vertical, S = drop/length =1.0			or Drop/length= 0.5			or Drop/length= 0.25		
	Capacity Q_m	Velocity	Equiv to h_v	Capacity Q_m	Velocity	Equiv to h_v	Capacity Q_m	Velocity	Equiv to h_v
mm	l/min	m/s	m	l/min	m/s	m	l/min	m/s	m
25	160	5.4	1.48	104	3.5	0.62	70	2.4	0.28
32	295	6.1	1.77	200	4.1	0.86	135	2.8	0.39
40	540	7.2	2.56	360	4.8	1.14	250	3.3	0.55
50	1000	8.5	3.60	680	5.8	1.66	450	3.8	0.73
63	1800	9.6	4.63	1250	6.9	2.23	840	4.5	1.00
75	2900	10.9	5.98	2000	7.5	2.85	1400	5.3	1.39

[In the table the water velocity in the pipe is expressed both as a speed (m/s) and as an equivalent head h_v. This head is the head thrown away if the kinetic energy in the pipe discharge is not recovered by suitable pipe tapering. It also equals the height through which the water would have to free fall to reach the velocity v.]

If a pipe is not ‘long’, the effect of the three factors discussed in Appendix 4 will no longer be negligible. All these factors reduce the pipe’s capacity.

For practical purposes we will be safe, even for quite short pipes, if we assume capacities of 50% of the tabulated figures.

In the analysis earlier, it was suggested that RWH systems be designed for a rainfall intensity of 2 mm/min (~120 mm/hour), which gives 200 litres/min for each 100 m^2 of roof area. Small domestic roofs are about 50 m^2 and therefore require a downpipe capacity of 100 litres/min. For this a 40 mm (internal diameter) downpipe would usually suffice and even a 32 or 25 mm pipe would often do. These are much smaller sizes than are commonly found in RWH systems. Even a large school building of 400 m^2 and an effective downpipe slope of only 0.25 does not need a pipe larger than 75 mm ID whereas 160 mm OD pipes are commonly used.

In some cases the downpipe may be replaced by a section of gutter running for the roof to the tank. In general, if this is made the same size as the gutter, and laid at a steeper slope, there should not be problems with overflow. Sudden changes in channel direction or constrictions should be avoided, as these will reduce the channel capacity, and may lead to overflow.

APPENDIX 2 RAINFALL INTENSITY FUNCTIONS

Records are available from which, for particular locations, rainfall intensity exceedence $P_r(i)$ or rainfall intensity probability density $p_r(i)$ can be derived. Rainfall intensity i is precipitation per unit time (e.g. mm per minute).

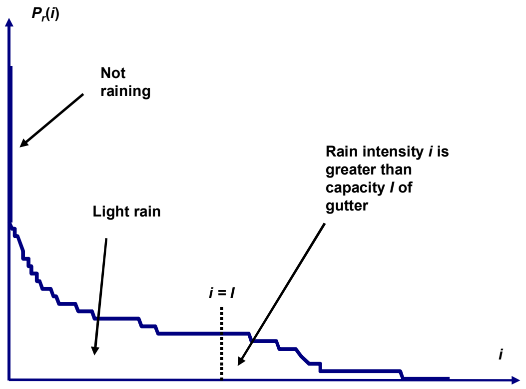
$P_r(i)$ and $p_r(i)$ are related by:

$$P_r(i) = \int_i^\infty p_r(i)di = 1 - \int_0^i p_r(i)di \text{ or } p_r(i) = -\frac{dP_r(i)}{di}.$$

We can note that:

1. The rainfall intensity is never infinite, so . $p_r(\infty)$ =0.
2. Hence the rainfall intensity can never exceed infinity $P_r(\infty) = 0$.
3. The rainfall intensity is never less than zero: "reverse raining" does not happen. $p_r(i) = 0$ for $i<0$

Figure A. 2.1: Rainfall intensity probability distribution



(There is some uncertainty about what happens at a rainfall intensity of i=0 since it only actually rains for about 1% of the time. Probability(i>0) is thus much less than Probability(i≥0) and therefore we might need to distinguish the former, $P_r(0^+)$=0.01 for example, from the latter $P_r(0^-)$=1.0. In practice this does not create a computational problem.)

The rainfall expected in unit time is $i_{mean} = \int_0^\infty i.p_r(i)di$

Substituting $p_r(i)di = -dP_r(i)$: $i_{mean} = -\int_0^\infty idP_r(i)$.

Integrating by parts gives $i_{mean} = -[i.P_r(i)]_0^\infty + \int_0^\infty P_r(i)di$

So $i_{mean} = \int_0^\infty P_r(i)di$, since $[i.P_r(i)]_0^\infty$ = 0. Equation A2.1

Thus i_{mean} is equal to the area under the whole $P_r(i)$ versus i curve.

If however, we restrict our interest to rainfall whose intensity exceeds a threshold intensity I then the quantity $e(I)$ expected in unit time will fall to:

$$e(I) = \int_I^\infty i.p_r(i)di = -\int_I^\infty idP_r(i)$$
$$= -[i.P_r(i)]_I^\infty + \int_I^\infty P_r(i)di = I.P_r(I) + \int_I^\infty P_r(i)di$$

Where $\int_I^\infty P_r(i)di$ is the area under just the tail of the $P_r(i)$ versus i curve

The *fraction* of the rain that falls at these high intensities ($i>I$) equals $e(I) / i_{mean}$.

A gutter designed for a maximum flowrate corresponding to rainfall intensity I will spill a fraction $sp(I)$ of the flow entering it. The mean spill flow, which is this spill fraction times the mean inflow, equals the integral, for all intensities greater than gutter capacity, of the difference between rain intensity and gutter capacity (expressed as equivalent intensity) weighted by the relevant probability of that intensity occurring, thus:

$$sp(I).i_{mean} = \int_I^\infty (i-I)\,p_r(i)di = -\int_I^\infty (i-I)dP_r(i)$$
$$= I\int_I^\infty dP_r(i) - \left[i.P_r(i)\right]_I^\infty + \int_I^\infty P_r(i)di$$

Therefore

$sp(I).i_{mean} = \int_I^\infty P_r(i)di$ Since the other 2 terms cancel out .

Note that the spill fraction $sp(I)$ is (much) less than the fraction ($e(I)/i_{mean}$) of rain falling faster than the gutter can carry, since even during intense rain the gutter captures some.

The gutter efficiency (fraction *not* spilled) is:

$$\eta_c(I) = 1 - sp(I) = 1 - \frac{\int_I^\infty P_r(i)di}{\int_0^\infty P_r(i)di} \qquad \text{Equation A2.2}$$

(Since $i_{mean} = \int_0^\infty P_r(i)di$)

$$\eta(I) = 1 - \frac{\textit{area under tail of distribution}}{\textit{area under whole distribution}}.$$

A2.1 Special case

In the region in the tail of the intensity exceedence curve (namely where $i>>i_{mean}$) we may often approximate $P_r(i)$ by

$$P_r(i) = ae^{-bi} \qquad \text{Equation A2.3}$$

This enables us to simplify Equation A2.2:

$$\eta(I) = 1 - \frac{\int_I^\infty ae^{-bi}di}{\int_0^\infty P_r(i)di},$$

and $\int_I^\infty ae^{-bi}di = \left[-\frac{a}{b}e^{-bi}\right]_I^\infty = \frac{1}{b}P_r(I)$

So $\eta(I) = 1 - \frac{P_r(I)}{b\int_0^\infty P_r(i)di}$ and hence the 'inefficiency' (fraction spilled) is

$$sp(I) = 1 - \eta(I) = P_r(I)/bi_{mean} \qquad \text{Equation A2.4}$$

This enables the sensitivity of efficiency $\eta(I)$ to gutter capacity (I) to be expressed as

$$S_{\eta(I),I} = \frac{\left(\frac{d\eta(I)}{dI}\right)}{\left(\frac{\eta(I)}{I}\right)} = \frac{-\left(\frac{d\,sp(I)}{dI}\right)}{\left(\frac{\eta(I)}{I}\right)} = \frac{\left(\frac{b\,P_r(I)}{b\,i_{mean}}\right)}{\left(\frac{\eta(I)}{I}\right)}$$

$$= \frac{I}{i_{mean}} \frac{P_r(I)}{\eta(I)}$$

As $\eta(I)$ approaches 1, we can say

$$S_{\eta(I),I} \approx \frac{I}{i_{mean}} P_r(I) \qquad \text{Equation A2.5}$$

Note that i_{mean} has the dimensions of rainfall intensity and b has the dimensions intensity^{-1}.

The sensitivity of *water harvested* to *gutter capacity* $S_{Qh,Qg}$ is equal to $S_{\eta(I),I}$

This quantity has been evaluated in Appendix 3 below (as a function of the rainfall intensity I that the gutters are just large enough to carry) for three locations in the humid tropics.

Setting $S_{Qh,Qg} = 0.03$, as suggested above for gutters alone, gives I values in the range 120 to 150 mm/hr.

Setting $S_{Qh,Qg} = 0.1$, as suggested above for gutters + filter, gives I in the lower range 80 to 90 mm/hr.

APPENDIX 3 CALCULATIONS FOR 3 LOCATIONS IN THE HUMID TROPICS

(At high rainfall intensities we use the approximation $P_r(i) = A\, e^{-bi}$)

Microwave telecommunications are interrupted by very heavy rainfall occurring along the path between transmitter and receiver. For this reason, detailed rainfall intensity data has been collected in many countries including some tropical ones. A telecomms engineer is primarily interested in the fraction of the time (in say minutes per average year) that rainfall is so intense that transmissions are affected. We can however use this same data to aid gutter design, provided we can convert it to express not the fraction of time but the fraction of total annual rainfall accounted for by very intense rain.

As we are primarily interested in *intense* rainfall, we can use a rainfall intensity model that is only valid at high intensities. Studies have shown that tropical rainfall derives from two main meteorological mechanisms and that the one that accounts for intense rain (say over 1 mm/minute) may be modelled by the probability density distribution

$$P_r(i) = A\, e^{-bi}$$

where i is rainfall intensity (e.g. in mm/min) and b is a constant (units of min/mm)

Moreover the annual rainfall R_a mm can also be expressed as a mean intensity

$$i_{mean} = R_a / (365 \times 24 \times 60)$$

Any particular gutter size, in the context of a particular roof and gutter drop, corresponds to a threshold I of rainfall intensity falling on that roof above which the gutter will overflow. At higher rainfall intensities $i>I$ the overflow fraction will be $(i-I)/i$.

By suitable algebraic manipulation of the quantities b, i_{mean} and I, we can estimate the fraction $sp(I)$ of annual rainfall that will spill and hence a conveyance efficiency. $\eta_c(I) = 1 - sp(I)$. Assuming for a moment that a constant fraction of water reaching the roof also reaches the gutter, annual water delivered by the gutter to the tank will be proportional to this conveyance efficiency η_c. Moreover we have shown earlier that the economically optimum size of gutter is that which gives a particular sensitivity of *water harvested* to *gutter size*. This criterion can be re-expressed as a particular value for the sensitivity of *conveyance efficiency* η_c to *design threshold rainfall intensity* I, namely to the measure $S_{\eta c,I.}$

We can also look directly at the values for spill fraction as a function of design intensity I to get an immediate feel for gutter sizing. For example we can decide that a conveyance efficiency $\eta_c = 0.95$ is appropriate and find the corresponding value for I.

If we extend this analysis to the *interception* of run-off by a gutter we must allow for important differences between 'overflow' and 'overshoot'. With conveyance a fraction $(i-I)/i$ of rainfall with intensity $i>I$ is spilled. With interception we assume ALL of the precipitation occurring at intensity $i>I$ is lost through overshoot. However for interception, unlike conveyance, the value of I corresponding to a particular gutter size varies along the gutter and cannot be defined for the gutter as a whole. One approach is to define I for midway along the gutter. If we define the fraction of annual rainfall intercepted as $\eta_i(I)$ we will find that $\eta_i(I)$ is often larger than $\eta_c(I)$. The corresponding sensitivity $S_{\eta i,I.}$ will also be different.

In the tables below we have listed values for these various measures (for representative values of I) for three tropical sites. There is some uncertainty about the notation used in the data source: $P_r(i)$ is assumed to be given in % rather than as a fraction. Otherwise the mean annual precipitation would be about 100 times higher than is likely for the locations given and one would have to assume that the probabilities given only applied to time when rain is actually falling. In the tables, I is defined as the rainfall intensity at which gutters are just full (or for interception analysis the rainfall intensity at which gutter overshoot commences).

To size a gutter we might use such conveyance criteria as

$$S_{\eta c,I} = 0.07$$

or $\eta c(I) = 0.95$

Applying all these criteria gives the range shown at the top of each page. For the three sites these criteria indicate one should size a gutter so that its flow capacity corresponds to about 1.7 mm per minute rainfall. Note that for no site would spill fraction exceed 2% if the gutter were sized for 2 mm/minute of rainfall.

The high intensity fraction for such a (I = 2 mm/min) gutter might however reach 8%. However analysis of overshoot (where loss from any small part of the gutter equals the high intensity fraction for that part) is more difficult to handle in this 'overall performance' way. So useful conveyance *v* interception comparisons cannot be made here.

APPENDIX 4 CAPACITY OF 'SHORT' PIPES

The capacity of a smooth vertical downpipe running full (neglecting entry, exit and "bend" losses) woud be:

Table A4.1: Flow capacity of downpipes

Pipe OD (mm)	25	32	40	50	63	75
Capacity at 90° (l/s)	2.5	5.0	9.0	16	30	48
Capacity at 45° (l/s)	2.1	4.2	7.5	13	25	37
Capacity at 35° (l/s)	1.7	3.4	6.2	11	21	32
Capacity at 15° (l/s)	1.2	2.4	4.4	8	14	23

(The angle quoted is that between a line drawn from downpipe entry to downpipe exit and the horizontal.)

However, extra head losses at pipe entry and at bends, and unrecovered velocity head at pipe exit will reduce these capacities.

'Head-loss' (*h*) is the difference in water level between the two ends of a pipe necessary to drive the specified flow along that pipe. The four main phenomena causing head-loss in a flow are:

Pipewall friction

Causing loss $h_1 \approx k_1 Q^2$ where k_1 is proportional to pipe length L and roughly proportional to $1/D^5$. D is pipe internal diameter).

Entry headloss

$h_2 = k_2 Q^2$ where k_2 is not greater than $.025/A^2$ in suitable (MKS) units. A is the pipe's internal cross-sectional area. For a rounded rather than sharp-edged entry, h_2 can be neglected.

Exit headloss

(Kinetic energy not recovered), $h_3 = .05/A^2$ or less. This maximum value (i.e. no recovery) however commonly applies.

Bends

Cause an extra headloss which depends upon their sharpness: it is common to replace the effect of a bend by an equivalent increase in pipe length and hence pipewall friction of $6D$, so $h_4 = k_4 Q^2$ where $k_4 = k_1 \times 6D/L$

Taken together, total headloss = $h_1+h_2+h_3+h_4 = (k_1+k_2+k_3+k_4)\,Q^2$

The table 5.1 above effectively only allows for h_1 and not for the other effects, and we should like to know roughly how much to reduce the capacities in that table to account for them. Unfortunately each system is different, but we can at least calculate the necessary (downwards) correction for a couple of representative cases.

Case (a) a 40mm downpipe has length 4m and drop 2m; there is also one bend.

4m of 40mm pipe has $k_1 = 49400$

1 bend is equivalent to an increase in length of 6 x .04 = .24m, $\therefore\ k_4 = 3000$

$A = .000\ 126\ \text{m}^2$ so assume a sharp entry so that $k_2 = 15900$

and a sharp exit will give $k_3 = 31700$

Thus using $k_1+k_2+k_3+k_4$ instead of k_1 in a formula of type $h_L = k\ Q^2$ requires us to multiply Q by factor $(49400/100000)^{0.5}$ = **0.70** (i.e. a 30% reduction)

Applying this factor to the tabulated flow (S = 0.5) of 360 l/min gives a flow of 250 l/min and a velocity of 3.4 m/s (equivalent to 0.56 m).

Case (b) a 63mm downpipe has length 2m and drop 0.5m; there are 2 bends

4 m of 63 mm pipe has $k_1 = 4444$

2 bends are equivalent to an extra 0.25 m of length, giving $k_4 = 278$

$k_2 = 2572$ and $k_3 = 5146$

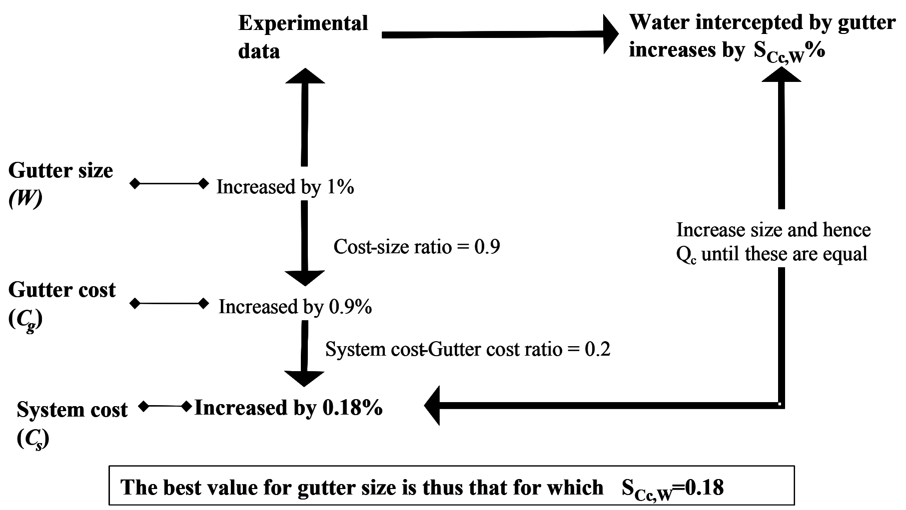
So correction factor for capacity is $(4444/12440)^{0.5}$ = **0.60** (i.e. a 40% reduction)

Applying this factor to the tabulated flow ($S = 0.25$) of 840 l/min gives a flow of 500 l/min and a velocity of 2.7 m/s (equivalent to 0.36 m)

APPENDIX 5 INTERCEPTION ANALYSIS

The basic approach used for Interception analysis is that set out in Appendix 7, namely to seek the gutter width *w* that gives the Interception-to-Width sensitivity corresponding to the maximising the system's benefit to cost ratio. This approach was applied to the interception performance of gutters with drops of respectively 10 mm and of 100 mm and a roof slope of 22^o. Unlike conveyance, interception shows a sharp rather than gentle cut-off when a critical rainfall intensity is reached. If the run-off flowrate is high enough to overshoot the gutter, then we assume that none of it is intercepted. (With conveyance the gutter capacity flow is conveyed and only any excess is over this is spilled).

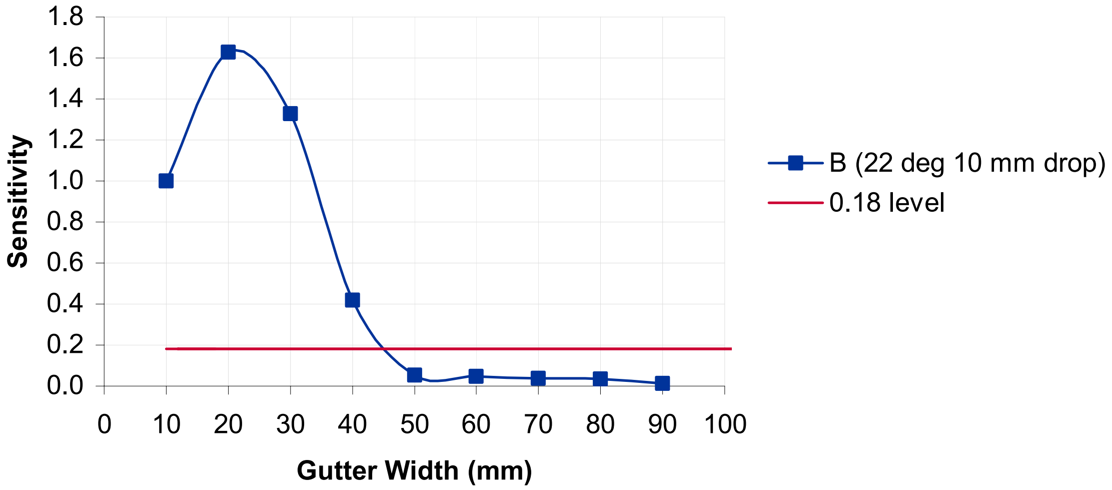
Figure A. 5.1



As can be seen, the gutter aperture is being increased until the sensitivity of water intercepted to gutter width equals that of system cost to gutter width. The diagram is slightly simpler than that used in the conveyance section, as the experimental data provides more direct information on the amount of water captured, without relying on further manipulation of rainfall data.

An example plot is given below:

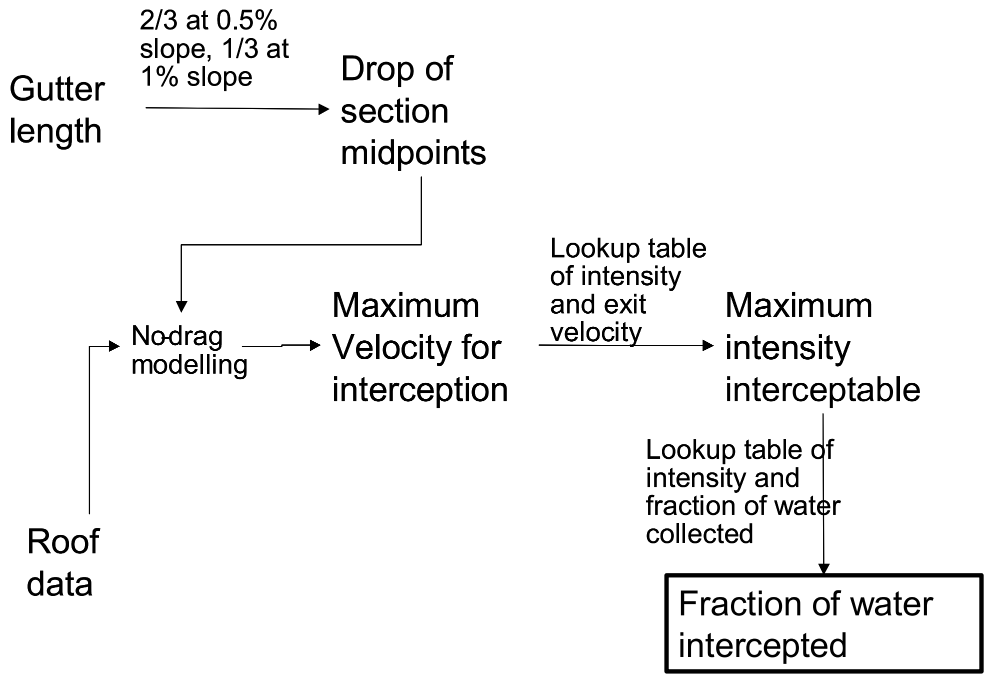
Figure A. 5.2: Sensitivity of water intercepted to gutter width (Sri Lanka data)



APPENDIX 6 COMBINED INTERCEPTION AND CONVEYANCE MODEL

A6.1 Explanation of interception data processing

As interception precedes conveyance, it was treated in isolation of the latter. Information from several sources was combined to model the interception performance of the gutter. This is summarised in the flow chart below:



The complexity in modelling interception performance arises from the slope of the gutter changing its performance along its length. To solve this problem several simplifications were required:

1. The gutter slope was specified at 0.5% for 2/3 of it's length, and 1% for the remaining 1/3.
2. The gutter is of a constant aperture along its length.
3. The jet leaving the roof was treated as following a single parabola with no spread. Although pulsation would exist, it was taken as causing benefits at some points and losses at others, and as such given no net effect.
4. The effects of wind were neglected on high rainfall intensities. To collect water from lower rainfall intensities the gutter inside lip was set 20mm inside the roof edge.

From experimentally-generated throw data, a simple calculation may be performed to predict the velocity of the water when leaving the roof edge in the absence of air resistance. By plotting this against drop, a regression may be performed to eliminate the effect of air resistance. A regression was then performed of exit velocities against rainfall intensity, and a lookup table produced of typical rainfall intensities and their respective roof exit velocities.

The gutter to be modelled was divided into a number of sections. For each section the drop at the midpoint was calculated. Given this drop and the throw (known from the gutter aperture and position relative to the roof edge), the exit velocity of water to just be caught by the gutter was calculated. The lookup table then gave the corresponding rainfall intensity at which this would occur.

The rainfall data from three locations used in the conveyance section was also processed here. For each site the exceedance probability at high rainfall intensities was plotted and a curve of the form $P(I) = Ae^{-bI}$ was fitted to the data. From this the amount of rainfall above intensity I per unit time was found, and thus the fraction of yearly rainfall falling below intensity I calculated. A second lookup table was produced giving rainfall intensity and fraction of rain falling below this intensity for each site. From this the performance of each section of the gutter was calculated, and these results aggregated to give an overall gutter performance.

A6.2 Interception and Conveyance Model

Following the production of the interception model, the discretisation approach was extended to model overall gutter performance. For a given configuration the capacity of each section of the gutter was determined. The gutter performance was modelled over a series of rainfall intensities, ranging from very high to moderate, for which latter condition the model predicted collection and conveyance of *all* water landing on the roof. For a given rainfall intensity, an algorithm determined how much (if any) run-off each section would intercept. The sum of this and water flowing from the previous section were compared to the capacity of the section. If the water entering the section were less than the capacity, all that water would be conveyed. If the water entering the section were greater than the capacity, the gutter would convey at a flow rate equal to its capacity, and the remaining water be spilled.

Using the probability data from tropical countries, it is possible to predict the quantity of rain falling in each small rainfall intensity band, and thus the overall efficiency of the gutter.

APPENDIX 7 OPTIMISATION OF SYSTEM PERFORMANCE

We wish to maximise the ratio of water captured (Q) to system cost (C) by optimising the gutter width (w): This optimum width we can denote as w_o.

$Q = f(w)$

The 'water captured' we can treat just as 'water intercepted' when we are exploring the economically optimum gutter size for run-off interception, subject to conditions such as pre-specified drop. Similarly we can treat it as 'water conveyed' (i.e. not spilled) when seeking the optimum size for conveyance. Normally however our interest is in optimising width for a system in which both interception and conveyance affect final water yield.

The system cost is the sum of tank cost (A) and gutter cost (assumed to be of form $B\,w^a$):

$C = A + Bw^a$

To maximise water captured: system cost, the following condition must be satisfied:

$$\frac{d\left(Q/C\right)}{dC} = 0 \qquad \text{giving} \qquad C\frac{dQ}{Dw} - Q\frac{dC}{dw} = 0$$

$$\therefore \frac{dQ}{dw} = \frac{Q}{C}\frac{dC}{dw} = \frac{Q}{C}aBw^{a-1} = a\left(\frac{Bw^a}{C}\right)\frac{Q}{w}$$

Rearranging this last equation yields

$$S_{Q,w} = \frac{dQ/dw}{Q/w} = a\lambda \qquad \text{Equation A. 7.1}$$

$\text{where}: \lambda = \dfrac{Bw^a}{C} = \text{fraction of total cost attributable to gutter}$ and $S_{Q,w}$ we call the 'sensitivity of water capture to gutter width'.

The economically optimum gutter width w_o is that which satisfies Equation A. 7.1.
